## Preface

Enzymes are the catalysts of life. They perform the majority of reactions in all living systems—all animals, plants, and microorganisms. Our lives are absolutely dependent on them. Even inhaling in oxygen and exhaling carbon dioxide are dependent on enzymes. Our plants take up minerals, water, and air, and combine them with carbon dioxide and ammonia to provide our fruits and vegetables, via enzymes.

The *Handbook of Food Enzymology* is a single source that can answer questions about what enzymes are, how they function catalytically, and how we depend on them and use them every minute of our life. This is not a book that can be read in a single day. Rather, it is a handbook to be used to find the answers to various questions: Who are we biologically and chemically? How do we function biologically? How do our foods, most of our clothing, and much of our shelter depend on enzymes? What are enzymes? What do they do? How can we manage them in the most effective way to live a long and healthy life with an abundance of food?

The *Handbook* is divided into two major parts. The first 26 chapters deal with general aspects of enzymology. There are two chapters ([1](#) and [2](#)) on the history of enzymology, which discuss protein structure and the kinetics of enzyme reactions and emphasize food production, and the trail of knowledge that led to this handbook. The next two chapters ([3](#) and [4](#)) deal with how enzymes are highly specific and highly efficient catalysts and the environmental factors that affect their activities. [Chapter 5](#) describes how to inactivate enzymes when their action is no longer desirable. [Chapters 6](#) and [7](#) deal with regulatory issues pertaining to using enzymes in our foods to change the taste, flavor, aroma, color, texture, and nutritional quality. [Chapter 8](#) deals with the evolution of enzymes under extreme conditions of pH, temperature, salinity, toxicity, and pressure, and how these enzymes with special extremophilic characteristics can be used effectively in foods. [Chapters 9](#) through 16 deal with how enzymes produce the components of our foods—the proteins, lipids, carbohydrates, and nucleic acids—as well as the enzymes that make it possible to synthesize our food components rapidly, efficiently, nutritiously, and in the quantity needed to feed 6 billion persons each day. The last 10 chapters ([17–26](#)) in Part I deal with management of enzymes postharvest and as tools for increasing the quality and consumability of our foods.

Part II describes specific prototypic enzymes of the six chemical types of reactions catalyzed by enzymes: oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases. The contributors of these 57 chapters have followed a common format in which they discuss what the enzyme(s), does, its importance to feed and food production, its chemical and biological properties, how to measure activity of the enzyme(s) and how to purify it from raw animal, plant, or microbial sources. Being catalysts, the enzymes are produced in rather small amounts (0.01 to 1% by weight of the total protein).

The contributors were carefully selected on the basis of their specific knowledge of the importance of enzymology to food production, food preservation, and food quality. We are very proud and fortunate to have attracted first-

rate, active scientists worldwide (20 countries are represented) as contributors to the *Handbook*. We hope the *Handbook* will be prominently displayed in all college and university libraries, especially those in which food production, nutrition, and food quality are important subjects, on the bookshelves of all food manufacturing companies, and in many faculty offices at major universities worldwide. When questions arise as to what enzymes are, what they do, and their importance in food supply and quality, we hope students, educators, and researchers will find the answers rapidly and satisfactorily in the *Handbook*.

We thank all the authors for joining us in this endeavor. Their contributions are excellent, up-to-date, and well written. Bringing together over 100 first-rate, active contributors to provide chapters in their selected area of food enzymology was our first objective. We wish to thank all the editors and authors who permitted use of copyrighted material, as well as those who typed the manuscripts. Marcel Dekker, Inc., and its staff were especially helpful as editors and contributors alike struggled to meet deadlines that extended over four years.

To the reader, may you find answers to all your questions on food enzymology in this handbook. If you don't, please ask any of us to help you find additional material and/or clarification.

# **Contents**

*Preface*

## **PART I. GENERAL ASPECTS**

### **INTRODUCTION**

**Protein Structure and Kinetics of Enzyme Reactions: A Historical Perspective**  
*John R. Whitaker*

**History of Enzymology with Emphasis on Food Production**  
*Poul Børge Poulsen and Klaus Buchholz*

**What Enzymes Do and Why They Are Highly Specific and Efficient Catalysts**  
*John R. Whitaker*

**Enzyme-Catalyzed Reactions: Experimental Factors that Affect Rates**  
*John R. Whitaker*

**Inactivation of Enzymes: From Experimental Design to Kinetic Modeling**  
*Ann Van Loey, Indrawati, Chantal Smout, and Marc Hendrickx*

### **REGULATORY ISSUES**

**Regulatory Issues of Enzymes Used in Foods from the Perspective of the E.U. Market**  
*Danielle P. Praaning*

**Regulatory Issues of Food Enzymes Used in the United States**  
*John R. Whitaker*

## **EXTREMOPHILIC ENZYMES**

**Properties of Extremophilic Enzymes and Their Importance in Food Science and Technology**  
*Magnús M. Kristjánsson and Bjarni Ásgeirsson*

### **THE FOOD CHAIN AND ENZYMES**

**Nitrogen Fixation and the Enzyme Nitrogenase**  
*William E. Newton*

**Enzymes in Amylose and Amylopectin Biosynthesis**  
*Bruce P. Wasserman and Ying Yu*

**Fatty Acid Biosynthesis and Triacylglycerol Assembly**  
*Allan Keith Stobart and Gareth Griffiths*

**Phospholipid Biosynthetic Enzymes in Plants**  
*Ralph E. Dewey and Anthony J. Kinney*

**Applications of Oxidoreductases in Foods**  
*Colja Laane, Yvonne Bruggeman, and Chris Winkel*

**Transgenic Plants for Production of Enzymes**  
*Anne S. Ponstein, Rob F. Beudeker, and Jan Pen*

**Enzymes in Protein Biosynthesis**  
*John R. Whitaker*

**Nucleic Acid Biosynthesis**  
*Dominic W. S. Wong*

### **ENZYMES AS TOOLS TO MODIFY FOOD COMPONENTS**

**Protein Modification to Optimize Functionality: Protein Hydrolysates**  
*Ton Kunst*

**Production and Modification of Acylglycerides**  
*Rob M. M. Diks*

### **ENZYMES IN FOODS POSTHARVEST**

**Significance of Indigenous Enzymes in Milk and Dairy Products**  
*Patrick F. Fox*

**Exogenous Enzymes in Dairy Technology**  
*Patrick F. Fox*

**Flavor Enhancement in Fruit Juices and Derived Beverages by Exogenous Glycosidases and Consequences of the Use of Enzyme Preparations**  
*Ziya Gümata*

## **IMMOBILIZED ENZYMES AND THEIR APPLICATIONS**

**Entrapment of Biocatalysts by Prepolymer Methods**  
*Takuo Kawamoto and Atsuo Tanaka*

**Genetic Immobilization of Enzymes on Yeast Cell Surface**  
*Mitsuyoshi Ueda, Toshiyuki Murai, and Atsuo Tanaka*

**Use of Immobilized Enzymes in the Food Industry**  
*Harold E. Swaisgood*

## **ENZYME UTILIZATION AND DEVELOPMENT**

**Enzymes and Food Analysis**  
*Philip O'Connell and George G. Guilbault*

**Recent Advances in Enzyme Development**  
*Dominic W. S. Wong*

## **PART II. SPECIFIC ENZYMES**

### **OXIDOREDUCTASES**

**Catalase**  
*Dominic W. S. Wong and John R. Whitaker*

**Horseradish Peroxidase**  
*Zhong Yi Yuan and Tai Jiao Jiang*

**Glutathione Peroxidase**  
*Jun-qiu Liu and Gui-min Luo*

**Glucose Oxidase**  
*A. J. Vroemen*

**Lactate Dehydrogenase**  
*Hayao Taguchi*

**Alcohol Dehydrogenase**  
*Sabato D'Auria*

**Alcohol Dehydrogenase**  
*Sandrine Dallet, Marie Trovaslet, and Marie Dominique Legoy*

**Amine Oxidase**  
*Akio Ito and Jichun Ma*

**Prolyl 4-Hydroxylase**  
*Robert B. Rucker, Ana Samimi, and Jerold A. Last*

### **Lysyl Hydroxylase**

*Ana Samimi, Jerold A. Last, Lucas C. Armstrong, and Robert B. Rucker*

### **Lysyl Oxidase**

*Robert B. Rucker, Alyson E. Mitchell, Eskouhie Tchaparian, and Jerold A. Last*

### **Superoxide Dismutase**

*Hirokazu Hara, Tetsuo Adachi, and Kazuyuki Hirano*

### **Polyphenol Oxidase**

*Edna C. Ramírez, John R. Whitaker, and Victoria M. Virador*

### **Laccase**

*William H. Flurkey*

### **Mammalian Sulphydryl Oxidase**

*Harold E. Swaisgood and Violeta G. Janolino*

### **Xanthine Oxidase**

*John R. Whitaker*

### **Lipoxygenase and Associated Enzymes**

*Harold W. Gardner*

### **Sorbitol Oxidase**

*Kohei Oda and Kazumi Hiraga*

## **TRANSFERASES**

### **Starch Phosphorylases**

*Ying Yu*

### **Amylosucrase**

*Volker Büttcher*

### **Dextranucrase**

*Klaus Buchholz and Pierre F. Monsan*

### **Levansucrase**

*Ki-Bang Song and Sang-Ki Rhee*

### **Cyclodextrin Glycosyltransferase**

*Lubbert Dijkhuizen and Bart A. van der Veen*

### **Limonoid Glucosyltransferase**

*Shin Hasegawa, Masayuki Kita, and Mitsuo Omura*

### **Transglutaminase**

*Chang-Rak Ha and Ichiro Iuchi*

## HYDROLASES

### Feruloyl Esterases

*Craig B. Faulds and Gary Williamson*

### Lipase

*Dominic W. S. Wong*

### Chlorophyllase

*Roger F. McFeeters*

### Phytase

*Onno Misset*

### $\alpha$ -Amylases

*Dominic W. S. Wong and George H. Robertson*

### $\beta$ -Amylases

*Dominic W. S. Wong and George H. Robertson*

### Glucoamylase

*Peter J. Reilly*

### Limit Dextrinase/Pullulanase

*E. Ann MacGregor*

### Limit Dextrinase

*James Hutchison Bryce*

### Methodologies for Assaying the Hydrolysis of Cellulose by Cellulases

*David Johnston*

### Cellulases in Food Processing

*Maija Tenkanen, Marja-Leena Niku-Paavola, Markus Linder, and Liisa Viikari*

### $\beta$ -Glucosidase

*Asim Esen*

### $\beta$ -D-Fructofuranoside Fructohydrolase

*Laura Cantarella, Francesco Alfani, and Maria Cantarella*

### $\beta$ -Galactosidase

*Raymond R. Mahoney*

### Pectic Polysaccharides

*H. A. Schols and Alphons G. J. Voragen*

### Pectic Enzymes

*Jacques A. E. Benen, Alphons G. J. Voragen, and Jaap Visser*

### Pectic Esterases

*Jacques A. E. Benen, Gert-Jan W. M. van Alebeek, Alphons G. J. Voragen, and Jaap Visser*

## Polygalacturonases

*Jacques A. E. Benen and Jaap Visser*

## Enzymes Releasing L-Arabinose and D-Galactose from the Side Chains of Pectin

*Ronald P. de Vries and Jaap Visser*

## Xylanolytic Enzymes

*Peter Biely*

## Enzymes with Activity Toward Xyloglucan

*Jean-Paul Vincken*

## Enzymes Degrading Rhamnogalacturonan and Xylogalacturonan

*Jean-Paul Vincken, Alphons G. J. Voragen, and Gerrit Beldman*

## Enzymic Hydrolysis of Cereal (1→3, 1→4)- $\beta$ -Glucans

*Maria Hrmova and Geoffrey Fincher*

## Enzymology of Endo-1,4- $\beta$ -Mannanases

*Henrik Stålbrand*

## Lysozyme

*Akio Kato*

## Ribonucleases

*Jaap J. Beintema and Wei Zhao*

## Proteolytic Enzymes

*John R. Whitaker*

## Thermolysin

*Kuniyo Inouye*

## LYASES

### Pectate and Pectin Lyases

*Jacques A. E. Benen and Jaap Visser*

### Alliinases

*Edna C. Ramírez*

### Cystine Lyases in Plants

*Edna C. Ramírez*

## ISOMERASES

### Xylose (Glucose) Isomerase

*Onno Misset*

# Protein Structure and Kinetics of Enzyme Reactions

## A Historical Perspective

**John R. Whitaker**

*University of California, Davis, Davis, California, U.S.A.*

### I. INTRODUCTION

This opening chapter focuses primarily on the history of applications of enzymes in food science and technology. The evolution of knowledge on proteins and food enzymology must also be understood from the fundamental aspects. Enzymes are proteins. Therefore, the history of food enzymology is a composite of advances in both understanding the chemistry of protein structure and environmental behavior, as well as the physicochemical properties (kinetics and thermodynamics) of enzyme behavior.

This chapter will first treat the history of food enzymology from the evolution of protein chemistry and then the physicochemical behavior of enzymes in relation to environmental conditions, including the effects of enzyme, substrate, cofactor and inhibitor concentrations, and the effects of pH and temperature.

### II. PROTEIN CHEMISTRY DEVELOPMENT

During the period 1820–1840 crude purifications of proteins began to be made by heat coagulation and precipitation with organic solvents and high concentrations of salts, such as ammonium sulfate.

#### A. Amino Acid Composition

Glycine and leucine were the first amino acids to be isolated (from hydrolyzed gelatin and wool, respec-

tively) (1). This was during the time when the word “protein” was coined to describe these compounds that have the compositional formula of carbon, hydrogen, oxygen, and nitrogen (~ 16%), with small amounts of sulfur and phosphorus. Methionine was discovered in 1922 by Mueller (1) and in 1935 threonine, the last amino acid, was discovered by Rose. It was very difficult to determine the amino acid composition in the earlier days. With the discovery in 1952 by Moore and Stein (2) that the amino acids of protein hydrolysates could be separated and identified readily within 24 h by ion exchange chromatography, the amino acid composition of many proteins became readily available. Today, the complete amino acid composition of a protein is done by automated analysis in 2–24 h using nano- or picogram amounts of hydrolyzed protein, at a cost of \$25–35 per total analysis.

#### B. Primary Structures of Proteins

Real proof of the importance of the peptide bond in proteins was when this bond joining individual amino acids into a longer polymer was discovered in 1903 by Emil Fischer, who synthesized the first peptides (3). Fischer synthesized many peptides during his scientific career. Höfmeister also reported the peptide bond in 1903 (4). Sanger developed the methodology for determining the amino acid sequences of proteins in 1955 (5) using insulin (a polypeptide of 5737 daltons). Edman developed a chemical method of sequencing

proteins in 1949 (6); the automated Edman degradation method, invented in 1967 by Edman and Begg (7), is used routinely now for sequencing picogram quantities of protein within 24 h. The methods are so sensitive these days that one must wear plastic gloves in all operations. A typical cost per amino acid residue is about \$20–25. The time required for sequencing depends on the size of the protein, since most proteins must be hydrolyzed to 25–50 amino acid residue fragments by two or more highly selective proteases in order to produce overlapping protein fragments. Each of the peptides must then be purified before sequencing.

The fastest, most economical, and most precise method of determining the sequences of proteins, since the 1980s, is by determining the nucleotide sequence of the gene for a protein. Extremely low amounts of DNA or sRNA are needed since PCR (protein chain reaction) catalyzed by S-polymerase can be used to make many copies of the gene. However, it is important to remember that the amino acid sequence determination via gene sequence does not include posttranslational modifications, including proteolysis, that are required to produce the active mature protein. The relationship between the primary sequence of proteins and gene nucleotide sequence was first postulated in the 1950s—the “one gene—one protein” hypothesis.

### C. Secondary Structures of Proteins

The  $\alpha$ -helix secondary element of proteins was first postulated in 1950 by Linus Pauling (8) and was found in myoglobin by Kendrew et al. (9) by x-ray crystallography in 1960. The determination of  $\beta$  strands in the primary structures of proteins, subsequently resulting in  $\beta$  sheet formation by folding of the polypeptide chain back on itself, was reported in 1951 by Pauling and Corey (10). The  $\beta$  and  $\gamma$  turns, loops, and bulges were clearly established in proteins by 1987, based on Milner-White and Poet's reported observation of reproducible x-ray crystallographic conformation in previously described loops (random folding) of a number of proteins (11). The key roles of glycine and proline in forming  $\gamma$  and  $\beta$  turns are now well established, with subclasses of each of these turns. Therefore, the key secondary components of proteins are  $\alpha$ -helices (a few other types of helices also occur in some proteins),  $\beta$  strands, and  $\beta$  and  $\gamma$  turns and loops. Supersecondary folding patterns (motifs), involving a minimum of three secondary structures, are well known (12, 13).

### D. Tertiary Structures of Proteins

Tertiary structures of proteins, along with secondary structures, were determined by x-ray crystallography of myoglobin by Kendrew et al. in 1960 (9). Even though hemoglobin was crystallized in 1848, and the law of x-ray diffraction was established by Bragg in the 1920s, computer capabilities for quantitatively analyzing the complex x-ray patterns of proteins were not available until the late 1950s.

The primary sequence of amino acids, while determining the folding pattern of proteins, is not responsible for the folding. The aqueous system is. To be more precise, the H-bonded clusters (6–8 water molecules) forces the proteins to fold with predominately hydrophobic amino acid residues inside and predominately hydrophilic amino acid residues on the outside, along with 20–40% (on average) bound water of hydration around the protein. Folding of proteins is an entropy-driven process. The entropic energy from the hydrogen-bonded clusters of water molecules is used to force the protein to fold so as to occupy its smallest possible surface area, generally a sphere. Proteins, and life, have evolved in an aqueous environment. No other solvent could have caused the evolution of biological functions as we know them.

Aqueous protein solutions contain three types of water—structural (constitutional) water ( $\sim 0.003$  g water/g protein), interfacial water ( $\sim 0.3$ – $0.5$  g water/g protein on the surface of the protein, and free water (14). The structural water molecules are bound tightly and are not removed by lyophilization or drying of the protein or by displacement of water by acetonitrile (15). In the serine superfamily of enzymes, 20 structural water molecules are found in identical locations in all (16). The surface of native proteins contains, on the average, 20–40% by weight of bound water molecules. The first monolayer (vicinal) of water molecules binds primarily to the charged and neutral side chains of the surface amino acid residues by hydrogen bonds. Water molecules surround surface hydrophobic side chains as a cage but do not interact with them. The second and subsequent layers (multilayers) of water molecules bind less tightly by dipole interaction with the monolayer water. Bound water and free water can be distinguished readily by nuclear magnetic resonance (NMR).

### E. Quaternary Structure

The importance of subunits in some proteins was recognized in 1970 by Klotz et al. (17), when it was

discovered that a 0.4 M sodium chloride solution caused hemoglobin to change from 68,000 daltons to 34,000 daltons. Later, it was shown that the tetrameric protein was cleaved to give two identical subunits containing two polypeptide chains,  $\alpha$  and  $\beta$ , and that higher concentrations of salts caused further dissociation to subunits ( $\alpha$  and  $\beta$ ) of 17,000 daltons. Perutz et al. (18) determined the x-ray crystallography pattern of hemoglobin in 1960. A number of other proteins and enzymes have subunits (17). Subunits of proteins were found to be devoid of biological activity; in time, a molecule of a protein was defined as the smallest unit that has biological activity.

## F. Macromolecular Structure

By the late 1960s, it was recognized that the skeletal muscles of animals are composed of several different proteins, myosin, actin, tropomyosin, and troponin (three types) that, when associated correctly, had contractile properties in the presence of the cofactor ATP. Later, it was shown that pyruvate dehydrogenase, the electron transport system, and other systems performing complex functions require association of several different proteins to perform the overall biological function (19, 20).

## G. Folding of Proteins from the Primary Structure

By the 1960s, physical chemists such as Harold Scheraga at Cornell University, Phillip Handler at North Carolina State University, Ronald Baldwin at Stanford University, and others began to ask how protein folding occurs and how fast it occurs. Dr. Scheraga, using the hypothesis that every atom of the protein had to find its proper location by a random process, and using high-speed computers, predicted that it would take  $\sim 10^{50}$  years for a 100-amino acid residue polypeptide to fold properly. About the same time, Hantgan et al. (21) and others (22, 23) began to unfold proteins by heat, urea, pH changes, etc., to remove the unfolding agent and measure the rate of regain of activity. Lu and Whitaker (24) and others found that denatured proteins could regain most of their activities in  $\sim 6$ –10 min at 35°C. Not too long after, sufficient data accumulated to show clearly that the primary sequence of amino acids contained the information needed to permit the protein to fold into the native structures, includ-

ing quaternary and macromolecular structures. But it is appropriate to mention that many proteins are posttranslationally modified in  $\sim 135$  ways (collectively among proteins) and that posttranslational modification plays a very important, sometimes essential role in the folding and stabilizing of a protein in its biologically functional form.

Detailed analyses of the data from x-ray diffraction of protein crystal structures became available in the 1960s owing to advances in computers. NMR was developed sufficiently by the 1980s to be used for determining the tertiary structures of proteins. Modern x-ray diffraction and new methods of intense beam magnification, using a synchrotron, permit the tertiary structures to be determined at 1.2 Å, sufficient to identify primary amino acid sequence, the secondary structure, the tertiary structure, and in some cases the quaternary structure. In some cases crystallographic structures of proteins are now being determined at a faster pace than the biological function of the proteins.

The most complex protein in which the tertiary structure has been determined recently is that of yeast RNA polymerase II (25).

## H. Protein Crystallization

Hemoglobin was the first protein to be crystallized, by accident, in 1848. Almost anyone can crystallize hemoglobin from blood, but recognizing that it is a protein is more difficult. Ovalbumin from chicken egg white was crystallized in the 1880s. But it was the crystallization of urease in 1926 by J.B. Sumner that finally proved that enzymes are proteins (26). Again, serendipity (being at the right place at the right time and recognizing it) played an essential role in this discovery. As the story goes, Professor Sumner of Cornell University made a water/alcohol extract of jack beans on a Friday, removed the solids, and placed the extract on the window sill of the laboratory and went home. On Monday, a solid had formed that, when the liquid/solid was swirled, refracted light—a biofringence. Recognizing this as unusual, he determined under the microscope that crystals were present. He showed that the crystals were protein with urease activity, so he suggested that enzymes are proteins. Despite the earlier “finding” by Willstätter in 1926 that highly purified peroxidase was not a protein (27), Sumner has been proven correct that all enzymes known to date are proteins. Willstätter made the mistake that many scientists make at one time or another; the ability to measure the peroxidase activity was much

more sensitive than the ability to measure the protein concentration.

Protein crystallization is a science these days permitting most proteins, including even glycoproteins and lipoproteins, to be readily crystallized as demonstrated, for example, by the crystallization of yeast S-RNA polymerase II (25).

## I. Active Sites of Proteins

Active sites of proteins are the locations where the biological function of a protein resides in the native protein. Study of active sites of proteins became a major field of study for enzymologists and protein chemists beginning in the 1960s. But as early as 1902, Brown (28) and Henri (29) independently proposed that enzymes must bind the substrate prior to conversion to product. Fischer in 1894 (30) proposed that the active site must fit the substrate as stereospecifically as a key fits a lock (lock-and-key analogy) in order to be bound properly and be converted to product. Koshland in 1965 (31) introduced the “induced fit” hypothesis to explain how apparently dissimilar molecules could sometimes serve as substrates for the same enzyme.

Initially, study of active sites of enzymes was approached by use of chemical modification of the side chain groups of amino acid residues of the native protein, using loss of biological activity as the measure. Also, the unfolding and refolding of proteins such as myoglobin and ribonuclease, especially around cofactors, hematin, etc., gave much information on active sites. Much was learned about essential amino acids in the active site. For example, in lysozyme chemical modification established that Glu35, Asn37, Asn44, Asp52, Asp59, Try62, Try63, Asp101, and Arg114 are a part of the active site (32). Asp52 and Glu35 are the key catalytic general acid/general base residues ( $-COOH$  and  $-COO^-$  are the catalytic groups). X-ray crystallography was key to determining that His69, Glu72, and His196 (chelates the essential cofactor Zn(II)), Arg71, Arg145, Tyr198, Tyr248, and Phe279 are in the active site of carboxypeptidase A (33). Zn(II) is responsible for catalysis. The other amino acid residues are key to binding the substrate properly in the active site.

The best current method of determining the essentiality of amino acid residues in the active site is the use of recombinant biotechnology to replace one amino acid at a time, thereby determining its effect on activity, is much more certain than the two methods above. Absence of binding and/or activity based on a single

amino acid replacement is about as close to the truth as one might get of the role of that amino acid.

## III. DISCOVERY OF ENZYMES AND DEVELOPMENT OF ENZYME KINETICS

### A. Discovery of Enzymes

There is some overlap between this section and that of [Chapter 2](#). This is justified based on the need to present a complete picture in the book.

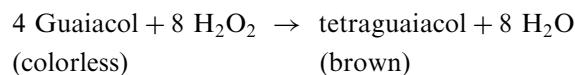

1. Catalase appears to be the first enzyme discovered. This occurred in 1812. In reality, the discovery was that something in blood caused the evolution of bubbles, shown to be  $O_2$ , when hydrogen peroxide was added. The reaction observed was

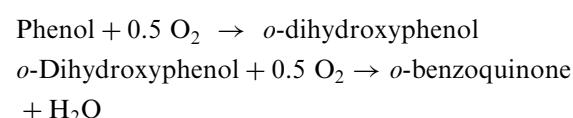

2. Diastase was discovered in wheat flour by Payen and Persoz in 1833 (34), when they reported that the enzyme caused the solubilization of starch. In addition, they found the enzyme to be thermolabile and precipitated by alcohol. They named the substance “diastase” because it separated, by solubilization, the starch from the bran. They further used “ase” in the name to designate it as an enzyme. The reaction observed was

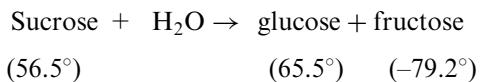

3. Peroxidase in plants was reported by Schöenbein in 1855 (35, 36). Schöenbein used gum guaiac which changes in color from light tan to blue when  $H_2O_2$  was added to an extract containing peroxidase. Several other compounds can be used to assay easily for peroxidase as shown by the equation:

4. Polyphenol oxidase was discovered by Schöenbein in plant extracts in 1856 (36). It was named polyphenol oxidase because of its ability to oxidize phenols, cause browning of plant extracts and bruised plant tissues. The enzyme can use a number of mono- and polyphenols plus  $O_2$  as substrates as shown by:

5. Invertase was discovered in 1860 by Berthelot in yeast (37). The enzyme catalyzes the hydrolysis of sucrose to glucose and fructose:

where the numbers in parentheses are optical rotation.

During this period of enzymology, polarimeters were developed that could manually or continuously follow the changes in optical rotation during the conversion of sucrose to glucose and fructose by the change in optical rotation from  $56.5^\circ$  to  $-23.7^\circ$  based on the difference in optical rotation of the sucrose (the substrate) to the products (glucose and fructose). This ability eventually led to discovery and quantitation of the effect of pH, temperature, and substrate concentration on the kinetics of enzyme reactions.

The discovery of enzymes continues even today. In the last listing in 1992 of well-studied enzymes there were 3196 enzymes listed (38). The types of enzymes so far discovered based on the chemical reactions catalyzed are oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases. Many of the individual enzymes have isozymes (same reaction catalyzed but they differ in primary structure of the protein). The nucleotide sequence of the genes that code for the biosynthesis of the enzyme can be modified by researchers to give multiple forms of enzymes via one or more amino acid changes of the primary sequence. Posttranslational modification of the protein can also lead to multiple forms.

## B. Enzyme Specificity

In the period 1894 to the 1930s Emil Fischer, a German chemist, and his associates developed and refined the concept of enzyme specificity and of the close stereospecificity between an enzyme and its substrate(s) (30). Based on their careful studies of enzyme action on numerous compounds his group synthesized, Fischer enunciated the now famous “lock-and-key” analogy of enzyme–substrate interaction. Other compounds, called competitive inhibitors, bind into the active site in competition with the substrate but they are not converted to products because they lack the overall keylike fit to the active site.

In 1959, Koshland emphasized the importance of the “induced fit” concept of enzyme specificity (31). His detailed research showed that compounds that do not have identical shapes can be substrates for the same enzyme and that this is possible because of

accommodation (flexibility) of the active site of the enzyme in binding the substrate. Further research has shown that the induced fit concept is an important factor in the specificity of numerous enzymes and perhaps less important in more rigid active sites of some enzymes, such as urease, which converts only urea to products.

## C. Quantitation of Rates

The importance of quantitation of rates was introduced briefly in Section III.A above. This section will expand on the topic.

### 1. Effect of Temperature on Velocity

In 1889, after a large amount of research on invertase using a polarimeter to study the effect of temperature on velocity of reaction, Arrhenius developed the empirical equation:

$$d\ln k/dT = Ae^{-E_a/RT}$$

which is still in use by most biologists today (39). Physical chemists derived *de novo* an equation (Gibbs equation; 40) that gives a slightly different numerical value from that of Arrhenius. The difference is given by

$$E_a = \Delta H^\neq + RT$$

At  $25^\circ\text{C}$   $E_a$  is 0.6 kcal/mol larger than  $\Delta H^\neq$  given by Gibbs' equation because a slight temperature effect on  $E_a$  is removed by using  $\Delta H^\neq$ . For most purposes the two methods of calculation agree within experimental error.

### 2. Effect of Substrate Concentration on Velocity

Studies of effect of substrate concentration on velocity of enzyme-catalyzed reactions advanced primarily owing to the availability of the polarimeter, permitting the effect of substrate (sucrose) concentration on the velocity of the invertase-catalyzed reaction to be studied in great detail. The results showed a “saturation-type” curve (Fig. 1). At very low substrate concentrations, the velocity increased in direct proportion to the increase in substrate concentration. At higher concentrations, the relationship was curvilinear and at high concentrations, the rate reached a maximum (and even decreased in some cases) owing to substrate inhibition.

In 1903 Brown (28) and Henri (29) independently proposed that the “saturation curve” for the relation-

ship between velocity and substrate concentration  $[A]_0$  could be explained by the equation

where  $E \cdot A$  is an obligatory intermediate; i.e.,  $E$  and  $A$  must form a noncovalent complex before conversion of substrate to products can occur. This concept is now universally accepted.

In 1913, Michaelis and Menten (41) showed that the enzyme–substrate saturation curve can be expressed mathematically by the equation of a right hyperbola

$$v_o = V_{\max}[A]_0/(K_m + [A]_0)$$

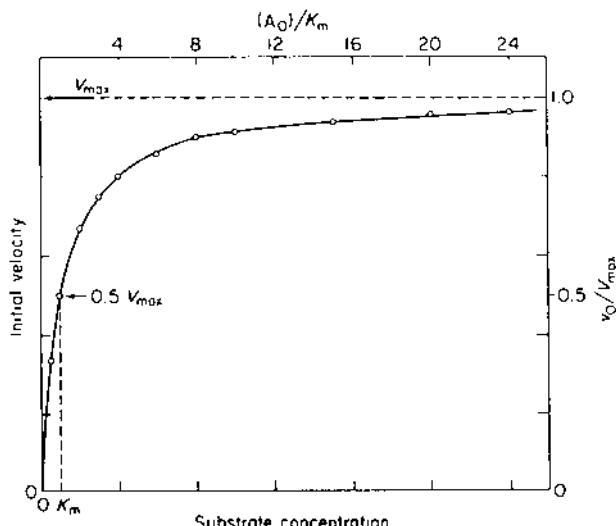

where  $v_o$  is the observed initial velocity,  $V_{\max}$  is the maximum velocity when the enzyme is fully saturated with substrate, and  $K_m$  is  $[A]$  at which  $v_o = 0.5 V_{\max}$ .

In 1918, Langmuir (42) showed independently that the same-shape curve is found for adsorption of gases onto metal surfaces, soluble solutes onto charcoal, etc. The Langmuir equation is:

$$\text{Fraction of surface covered} = n_s x / (n_e + n_s x)$$

where  $n_s$  is number of molecules striking  $1 \text{ cm}^2$  of surface per second,  $x$  is the quantity of molecules that binds on the surface, and  $n_e$  is the number of molecules leaving the surface per second.

In 1934, Lineweaver and Burk (43) showed that a reciprocal plot of  $v_o$  versus  $[A]_0$  (i.e.  $1/v_o$  vs.  $1/[A]_0$ ) converts the Michaelis-Menten equation to a form in which  $V_{\max}$  and  $K_m$  can be determined in an unambig-

**Figure 1** Variation of initial velocity with substrate concentration for an enzyme-catalyzed reaction according to the Michaelis-Menten equation. (From Ref. 41.)

uous manner (Fig. 2). There are two other methods that give linear plots—the Augustinsson method (44), and the Eadie-Hofstee method (45); however, the Lineweaver-Burk method continues to be the most widely used method.

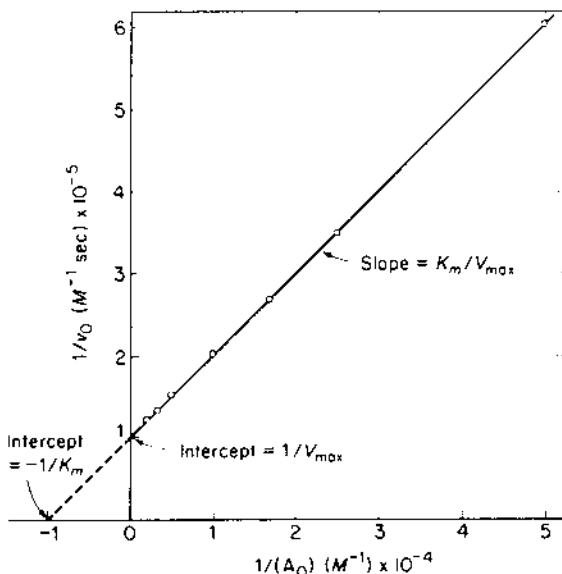

### 3. Effect of pH on Enzyme-Catalyzed Reactions

In 1909, Sörensen published a classic paper on the effect of pH on invertase activity (46). Not only did he show that the activity of enzymes is affected by the pH of the reaction, he was able to differentiate the effect on reaction rates and on stability of the enzyme.

Detailed studies of pH effects on rates of enzyme-catalyzed reactions were largely ignored until the 1960s when Bender, Whitaker, and others gave much attention to the interpretation of the results from a mechanistic standpoint. See Whitaker (47) for more details of the studies.

### 4. Further Refinements of Kinetics

During 1957–1963, there were substantial advancements in better understanding of the effect of concentrations of one, two, or multiple substrates on enzyme-catalyzed reactions. These advancements were made by

**Figure 2** Plot of reciprocal of initial velocity versus reciprocal of initial substrate concentration by the Lineweaver-Burk method. (From Ref. 43.)

Alberty (48), Wong and Haines (49), Cleland (50), and Segel (51). Cleland's descriptive nomenclature (50), ordered BiBi sequential mechanism, random BiBi sequential mechanism, and Ping Pong BiBi mechanism terms and methodology are used most frequently. See Whitaker (47) for a detailed discussion and use of these methodologies.

## 5. Concept of Initial Velocity

The concept of initial velocity,  $v_o$ , arose in the 1960s and is universally used by those interested in detailed studies of enzymes.  $v_o$  is determined as near time zero of the reaction as possible. No more than 5% of the original  $[A]_o$  should be converted to product in determining  $v_o$ . The method requires that the velocity be determined on a continuous time basis, generally by continuous recording of the data.

There are several reasons for using  $v_o$ . It largely eliminates problems caused by change in degree of saturation of the enzyme with substrate during the reaction time. It eliminates influence of the back reaction ( $P + E \rightleftharpoons E + A$ ). It eliminates effect of product inhibition of the enzyme. It eliminates effect due to instability of the enzyme, since the reaction is normally done within  $\sim 5$  min. Since it is based on a continuous recording, not on a one-point assay, the substrate concentration ( $[A]_o$ ) at time zero can be used.

## 6. Sigmoidal Kinetics

Experimentally, not all enzyme-catalyzed reactions follow Michaelis-Menten kinetics. In 1965, Monod et al. (52) published the first paper conclusively showing that some enzyme-catalyzed reactions do not follow the Michaelis-Menten equation. The kinetics are said to be *sigmoidal* or *allosteric* in nature. The form of the equation developed to express the results is:

$$v_o = V_{\max}[S]_o^n / (K_m + [S]_o^n)$$

Sigmoidal kinetics are sometimes found when more than one substrate molecule binds to the enzyme molecule. Generally, sigmoidal kinetics may be shown in enzymes that have quaternary structure. If binding of substrate into the active site of the first subunit affects, positively or negatively, the binding of substrate into the active site of the second subunit, sigmoidal behavior will be seen. Enzymes in metabolic pathways often show sigmoidal behavior (53).

## IV. ANALYTICAL TOOLS IN ADVANCEMENT OF ENZYMOLOGY

Advancement of enzymology, as with all chemical and biological sciences, has been influenced very much by the development of tools and methodology. Perhaps one of the first tools was the microscope, which permitted Pasteur to discover the asymmetry of molecules leading to discovery of isomeric differences among L-, D-, and DL-tartaric acid crystals in wine. A specific enzyme can use only one of the forms as a substrate. Another was the development of polarimetry which permitted detailed studies on the effect of pH, temperature, and substrate concentration effects on invertase particularly and other enzymes in general. These studies led to Sörensen's contribution to understanding the effect of pH on enzyme activity (46), to Arrhenius' study of temperature effect on rates of invertase-catalyzed reactions (the Arrhenius equation [39], and data on the velocity–substrate concentration relationships leading to the Henri (29) and Brown (28) hypothesis on essentiality of the EA complex, the Michaelis-Menten equation (41), and the Lineweaver-Burk reciprocal plot (43).

Kinetic analyses are used to determine how much enzyme is present in tissues. But their primary use is to determine the mechanism of action of enzymes via a detailed study of the kinetic effect of substrate concentration, enzyme concentration, pH, temperature, and inhibitors on the  $v_o$  of the reaction. Early investigations in this area were by Koshland and Neet (54) and by Vallee and Riordan (55). Many articles, books, and treatises of this subject have appeared over the past 30 years.

### A. Tools for Purification of Enzymes

Not much was done on the purification of proteins until the 1920s when Willstätter purified horseradish peroxidase to the point that no protein could be detected by the method used, but the peroxidase activity could be determined, leading to the conclusion that horseradish peroxidase could not be a protein (27). But Sumner (26) crystallized jackbean urease and showed it to be a protein. In 1930 Haldane (56) and others expressed the view that except for urease, next to nothing was known about the chemical nature of proteins.

In the 1930s, several enzymes, including pepsin, trypsin, chymotrypsin, and carboxypeptidase A, were crystallized by Northrop, Kunitz, Herriott, and Anson (57, 58) at the Rockefeller Institute. All were found to be proteins. The ultracentrifuge (59) and free boundary

electrophoresis (60) were developed and used to determine the molecular weight and purity of enzymes.

From 1930 to 1955, use of differential solubility of proteins at different pH's, as well as differential temperature stability, were used to purify proteins. Large amounts of protein were needed. In the late 1940s and early 1950s Moore and Stein (2) developed ion exchange chromatographic methods for separating the amino acids from hydrolysates of proteins, including enzymes.

But it was the period beginning in 1956 and extending to the 1980s that chromatographic methods based on cellulose ion exchangers for separation by charge (61), size (62, 63), surface hydrophobicity (64), affinity chromatography (65), and chromatofocusing chromatography (66) really made it possible to purify proteins routinely. Along with the advances in chromatography were advances in determining the purity of proteins, including molecular weight and subunit structure by polyacrylamide gel electrophoresis (67) and SDS-polyacrylamide gel electrophoresis (68). Further advances in procedures permit microgram amounts of enzymes to be purified and sequenced by the Edman degradation method within 24–72 h.

Fred Sanger and colleagues (5) worked out methodology for determining the amino acid sequence of insulin in 1955 (5737 daltons; 53 amino acid hormone). By 1958, ribonuclease (13,683 daltons; 121 amino acids) was sequenced by Moore and Stein (69) and Hirs et al. (70, 71). As noted above, small proteins up to ~ 50,000 daltons can be automatically sequenced within 24 to 48 h by the Edman degradation method.

The three-dimensional structure of an enzyme, ribonuclease, was determined by Kartha et al. in 1967 by use of x-ray crystallography (72). Major advances in x-ray crystallography have been made so that it used routinely to determine the tertiary and quaternary structures of proteins, even though the biological function of the protein is not known. In 2000, the complete tertiary structure of yeast S-polymerase II was determined (25); it consists of 10 different subunits.

In 1969, the first and only complete chemical laboratory synthesis of an enzyme, ribonuclease, was done (73, 74).

In the 1980s and 1990s three-dimensional structural analyses of enzymes in solution were elevated to high levels by NMR spectroscopy. This is the only technique that can determine the three-dimensional structure of proteins in solution. Fortunately, the three-dimensional structures of enzymes determined by x-ray crystallography and NMR spectroscopy are essentially identical.

The latest tools to be used in enzymology involve identification of presumed primary amino acid structure of enzymes by sequencing the genes that encode enzymes, by the replication of enzymes by the polymerase chain reaction, and the mutagenesis of enzymes by replacement of one or more nucleotide bases or by combinational methods. As noted earlier, significant posttranslational modification of the enzyme can occur after translation of the amino acid sequence.

### I. INTRODUCTION

The scientific development in biocatalysis goes back to the beginning of the 19th century. The first enzymatic actions, notably starch hydrolysis by Diastase, was acknowledged as a catalytic effect by Berzelius in 1835 and utilized industrially following the findings and developments of Payen and Persoz on diastase and its application in the brewing industries about 10 years later. Continuous scientific investigations, with emphasis on alcoholic fermentation, can be traced to the 1850s with investigations of Berthelot and Béchamp, the school of Pasteur, and the controversy with the chemical school of Liebig and his influence.

The first company based on applied biocatalysis also dates back to the 19th century, when in 1874, Christian Hansen started a company in Copenhagen named Christian Hansen's Laboratory which exists to this day, producing an enzyme preparation, rennet (chymosin), for cheese making.

After this early period, research in the subsequent decades brought about significant progress with the important findings of E. Fischer in 1894 on enzyme specificity, and E. Buchner in 1897 on the pure chemical nature of alcohol formation, and the key steps by Sumner and Northrup in crystallizing enzymes in 1926 and 1930, respectively. These represented turning points in identifying the nature of the catalytic agent. A con-

tinuous technical development can be traced to the beginning of the 20th century, where Röhm and the foundation of the Röhm and Haas company in 1907 may be seen as a major technical and economic breakthrough.

### II. THE EARLY PERIOD TO 1880

Applied biocatalysis has its roots in ancient China and Japan in the manufacture of food and alcoholic drinks. Without knowing, mankind utilized microbial amylases and proteases, in particular for the production of soy-derived foods. In Europe also, applied biocatalysis has a long history. Cheese making has always involved the use of enzymes. As far back as about 400 B.C., Homer's *Iliad* mentions the use of kid stomach for making cheese. It was discovered that milk, which was stored in a bag made of a stomach of a recently slaughtered calf, lamb, or kid was converted into a semisolid substance. Upon pressing of this substance a drier material was obtained (namely cheese) which showed preferred properties over milk, could be easily transported, and gained a flavor after some time. These ancient applications may best be described as an art and not as a technology, a scientifically based technique. The context of biotechnology has been described in a profound analysis by Bud (1).

## A. Findings and Empirical Results

Stahl explored in his book *Zymotechnika Fundamentalis* (1697) the nature of fermentation as an important industrial process, where zymotechnique should be the scientific basis (2). About a hundred years later the liquefaction of meat by gastric juice, as an enzymatic activity, yet not recognized as such, was noted by Spallanzani in 1783 (3). The enzymatic hydrolysis of tannin was described by Scheele in 1786 (4: p. 30). In 1814 Kirchhoff observed that a glutinous component of wheat was capable of converting starch to sugar and dextrin, and Vogel showed in 1817 that an infusion of oats would produce a fermentable sugar from milk (5: p. 5).

Some vital factor, *le principe vital*, was considered an important principle in the chemical processes associated with the synthesis of materials isolated from living matter.

All simple bodies in nature are subject to the action of two powers, of which one, that of attraction, tends to unite the molecules of bodies one with another, while the other, produced by caloric, forces them apart.... A certain number of these simple bodies in nature are subject to a third force, to that caused by the vital factor, which changes, modifies and surpasses the two others, and whose limits are not yet understood (6).

In one of the books on technology in the period preceding Berzelius and Payen, Poppe (7) discussed mysterious ideas concerning fermentation:

Fermentation is seen as a—at a time and under circumstances spontaneous—occurring mighty movement in a liquid of different compounds..., which is due to the fact that several compounds act in harmony with each other, others in opposition to each other, so that the first attract, the latter reject each other.... The sugar and a...gum extract material act by antagonist forces on each other so heavily, that they decompose and thus cause the formation of alcohol (*Weingeist*) (7: p. 229).

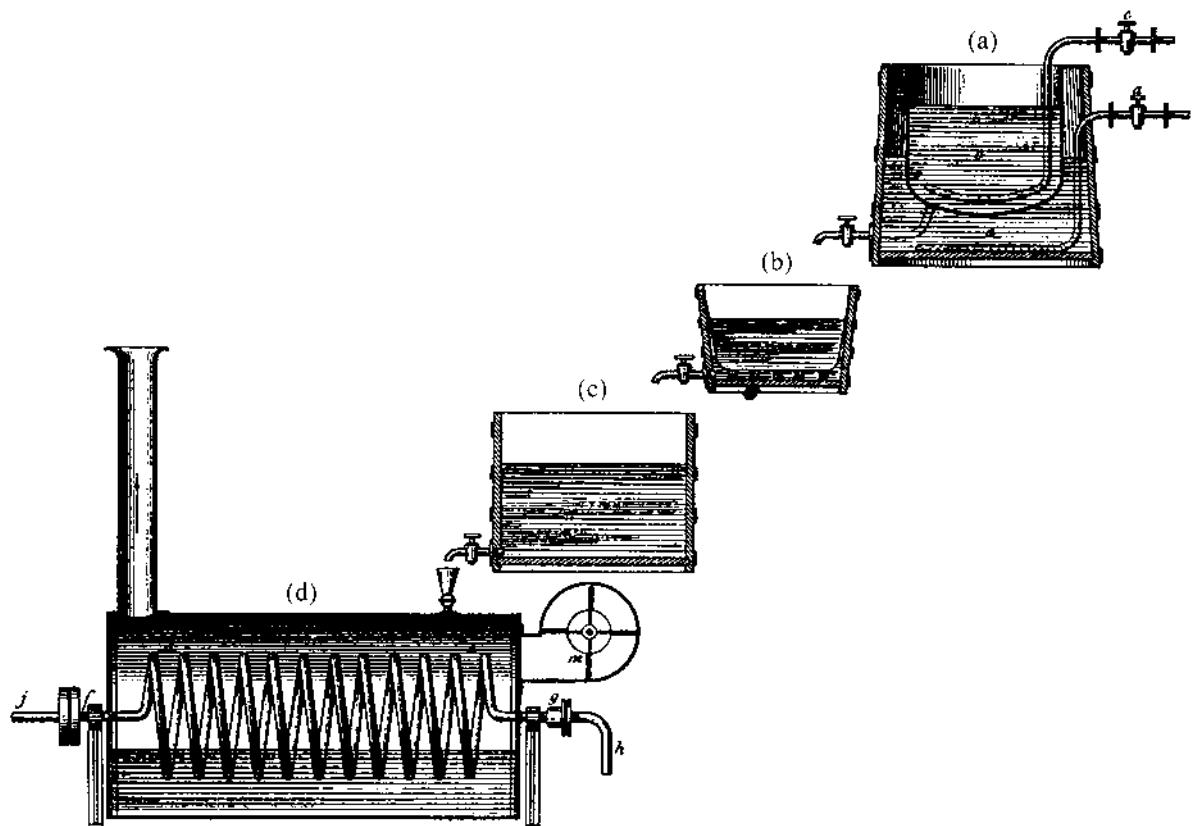

Gay-Lussac had postulated a *generatio spontanea*, the hypothesis that a continuing, rather mysterious chain should be the cause of spontaneous generation (of organisms) (summary in Ref. 8). Pasteur showed that this assumption was without any empirical basis.

Remarkably, a most significant change in the theoretical background, a change in paradigm, took place

in textbooks on chemical technology within a few years. Poppe's *Technology* (7) was prescientific insofar as it did not show any chemical formula, working on a strictly descriptive level. In contrast, Knappe's *Chemical Technology* (9) gave chemical formulae, thus for sugar (not yet fully correct) based on the atomic composition of the molecules. Most clearly Payen's textbook (10, Vol. 1: p. 1) reflected the theoretical background of chemistry based on atomic and molecular composition and constitution, differentiating theoretical, applied, and technical chemistry.

The book by Knapp (9: pp. 300–303), about a decade after Poppe's (7) view of fermentation, develops a rather distinct picture of the action of ferments (mainly referring to diastase and the work by Payen and Persoz), and these views are expressed more precisely by Payen (10: pp. 399–403). Fermentation is seen as a contact (catalytic) process of a degradation (*Spaltungs-*) or addition process (with water). It can be performed by two substances or bodies: a nitrogen-containing organic (nonorganized) substance, such as protein material undergoing degradation; or an organized body, a lower-class plant or an “infusorium,” such as with alcoholic fermentation. Probably the type of effect is the same insofar as the ferment of the second class produces a body of the first class, possibly a big number of singular ferments. In 1878 Kühne named the latter class of substances “enzymes”.

A breakthrough occurred with the observations of Dubrunfaut and subsequently Payen and Persoz. Dubrunfaut discovered the transformation of starch into sugar and some kind of gum by means of water and germinated barley, as well as the application of this finding for technical and economic purposes (11). Payen and Persoz in 1833 (12) prepared the acting principle in isolated form, which they named diastase, with the following characteristics: it is a white, amorphous solid insoluble in alcohol and soluble in water. For the production of diastase they macerated germinating barley in cold water, then pressed and filtered it. The filtrate was heated to 70°C, filtered again, then precipitated with alcohol. The precipitate was collected on a filter and subsequently, by repeated redissolving and precipitating with alcohol, separated from the accompanying residual nitrogenous substances (12). The dextrin production was performed in a reaction vessel as shown in Figure 1 (10). The vessel inserted in a water bath could be heated to 75°C, the optimal temperature for the formation of dextrin by diastase. The reaction progress was controlled by the iodine test and stopped by heating to 100°C. The product solution was subsequently filtered, collected in a reservoir, and

**Figure 1** Process for dextrin production with reaction vessel (a), filter (b), reservoir (c), concentration unit (d). (From Ref. 10.)

concentrated by heating with steam. The product rapidly found industrial application.

Payen and Persoz (12) identified numerous topics for further research, such as the existence of diastase in plants, its molecular weight and elementary composition, and the reaction products from different substrates. Diastase was the dominating object of research on enzymes throughout the century with  $\sim 10\text{--}20\%$  of publications dealing with this topic owing to its economic importance. Nevertheless the overall research activities remained very weak in this field, as compared to chemistry (see below).

A few further activities were discovered in subsequent years. Pectase was found in plants, both in soluble and nonsoluble form. It was able to break down pectose into pectinic acid, and was attributed to have some similarity to diastase. Neither material could be crystallized (10: p. 30). Claude Bernard was the first to show lipolytic activity in pancreas in 1856 (4: p. 25). Dobell (13) found that an extract from pancreas hydrolyzed both fat and starch; he gave a procedure for extraction and stabilization and named this preparation *pancréatine*.

Further enzymatic conversions (ferment actions) observed in that early period summarized in Frankland's list of soluble ferments (14) and by Sumner and Somers (3) are summarized in Table 1.

Alcoholic fermentation was a dominating topic of the time in the field called physiological chemistry which attracted a good deal of interest and activity of leading scientists (5). Trying to identify the active principle, Béthelot (15) showed, according to his own interpretation, that a peculiar nitrogen-containing substance, formed by yeast and precipitable by alcohol (he used casein) and comparable to diastase, could transform sugar into alcohol. He stated that this substance was different from yeast and that there was no production of yeast cells (8, 15). Thus, he claimed to have observed the transformation of sugar into alcohol without the participation of any activity of living organisms. He was convinced that the formation of alcohol from sugar was a genuine chemical process. However, his experiments were not performed under sterile conditions, and obviously unknown in part, anaerobic bacteria (in tests where oxygen was excluded) must have produced scarce amounts of alco-

**Table 1** Ferments (Enzyme Activities) Known Up to 1880

Enzyme	Ferment source	Catalyzed reaction	Author
Protease	gastric juice	meat liquefaction	Spallanzani, 1783 <sup>a</sup>
Cyanogen	plant roots	substrate: guaiacum	Planche, 1810 <sup>a</sup>
Glutin compound	wheat	starch hydrolysis	Kirchhoff, 1814 <sup>a</sup>
Emulsin	bitter almonds	amygdalin hydrolysis	Robiquet and Boutron, 1830 <sup>a</sup> ; Chalard, Liebig and Wöhler, 1837 <sup>a</sup>
Diastatic activity	ptyalin	starch hydrolysis	Leuchs, 1831 <sup>a</sup>
Amylase	malt	starch hydrolysis	Payen and Persoz (1833) (12)
Sinigrinase			Faure, 1835 <sup>a</sup>
Pepsin		protein hydrolysis	Schwann, 1836 <sup>a</sup>
Trypsin		protein hydrolysis	Corvisart, 1856 <sup>a</sup>
Saccharase	yeast	sucrose hydrolysis	Berthelot, 1860 <sup>a</sup>
Pectase	plants	pectin hydrolysis	Payen (1874) (10)
Pancreas		lipolytic activity	Bernard, 1856 <sup>b</sup>
Pancreas extract		fat and starch hydrolysis	Dobell (1869) (13)
Pancreatic ferment	pancreas	fat hydrolysis	Frankland (1885) (14)

hol, carbon dioxide, but also hydrogen and acetic and butyric acid (16). It was 40 years later when Buchner succeeded in demonstrating cell-free alcohol formation unequivocally (see below).

Pasteur presented a series of experimental results showing unequivocally that alcoholic fermentation proceeded only in the presence of living organisms. And he showed that in all cases where fermentation could be observed under precisely controlled conditions, it was microorganisms (of different kinds, also present in the air) that must be present to initiate fermentation. So he presented strong evidence against the assumption of a *generatio spontanea* postulated by Gay-Lussac. He definitely changed, about two decades later, the disciplinary context of fermentation away from chemistry, redefining the subject to a new autonomous discipline—microbiology (1).

The overall research activity on soluble ferments, meaning enzymatic reactions, was scarce in this period. Thus, in the German *Annalen der Pharmacie* in the period from 1833 to 1850, four articles were published on ferments and fermentation, three of them on diastase. The key paper was essentially a translation from Payen and Persoz (12, 17). In the German *Journal für Praktische Chemie* in the period from 1850 to 1860 no paper dealt with soluble ferments (enzymatic activities; eight papers were published on fermentation [*Gährung*], meaning microbial activity). In the *Bulletin de la Société Chimique de Paris*, one of the most important of the time for fermentation research,

there was about one article per year in the 1860s dealing with soluble ferments, meaning enzyme activity, and three or four dealing with fermentation. It was only in the 1880s that research and publication activities increased significantly.

## B. Technology

Work on technological issues was more important and even dominating over that on basic aspects from the beginning of the 19th century, especially for brewing, wine, bread, and acetic acid production. These topics made up important parts of the chemical technology of the time (7, 9, 10, 18). Knapp (9) considered scientific and practical industrial interests as equally important.

Diastase application was a major issue from the 1830s onward. “The diastase presents the best means for production of dextrin and dextrin syrup. These products not only become cheaper, but also more pure and tasty.” This latter argument was used in favor of the application in food and beverage production. Thus, it was recommended for the manufacture of bread, pastries, chocolate, and soups; furthermore, it was recommended for cider and fruit wine, but especially beer production, where a specific advantage was that the formation of haze at low temperature could be prevented (12, 17). Also, a sugar could be isolated after extended action of diastase on starch. A mass balance gave, in two experiments where the sugar was subsequently fermented by yeast and the amount of carbon

dioxide measured, sugar equivalents of 86.91 and 77.64 parts, with respect to 100 parts of starch. By means of crystallization the authors obtained a “completely pure sugar (which) is white, without smell....” It was less sweet than cane sugar. As a chemical formula they presented  $C_{12}H_{28}O_{14}$  (12).

The manufacture of dextrin was established: “Fouchard’s dextrin syrup is produced by the factory of Mr. Fouchard at Neuilly as a commercial product” (12). It remained so for decades, and was mentioned in most of the major books and series on technology and chemical technology (9:144–150, 10:125–131, 19, 20a). The treatment of starch by acids or diastase yielded a gummy syrup. Notably, French products seemed to have been produced enzymatically, as was obvious by their smell of malt (recognized by Knapp [9]). Payen (10) gave a short calculation showing that the application of malt is more economical than the use of sulfuric acid.

A further application of enzymes was the use of lab products to produce cheese (9:39, 40). Berzelius was cited with details stating that one part of lab ferment preparation coagulated 1800 parts of milk, and that only 0.06 parts of the lab ferment is lost.

The first company based on applied biocatalysis dates to the 19th century. In 1874, Christian Hansen started a company in Copenhagen. His company, named Christian Hansen’s Laboratory to this day, was the first in the industrial market with a standardized enzyme preparation, rennet, for cheese making. Rennet, a mixture of chymosin (earlier called rennin) and pepsin, was and still is obtained by salt extraction of the fourth stomach of suckling calves.

### III. THE PERIOD FROM 1890 TO 1940

#### A. Growing Interest

A pronounced increase in published papers on soluble ferments indicated the growing interest, and several key findings initiated the enzymology of the 20th century. Thus, the numbers of articles on soluble ferments summarized in the abstract service *Chemisches Zentralblatt* rose from ~15 per year in the mid-1880s to 35 in 1895 and to 94 in 1910.

From about 1894, Emil Fischer investigated in a series of experiments the action of different enzymes using several glycosides and oligosaccharides of known structure; the results revealed specificity as one the key characteristics of enzymes. Fischer derived therefrom his theory on specificity with the famous picture of a lock and key (21:836–844). A second aspect referred to

the protein nature of enzymes. In 1894 Fischer (21:829–835) stated that among the compounds that serve the living cell the proteins are the most important. He was convinced that enzymes were proteins. However, Willstätter, in 1927, denied that enzymes were proteins (22).

A few years after Fischer’s investigations, Eduard Buchner published a series of papers (23, 24) which signaled a breakthrough in fermentation and enzymology. The experiments began in 1893 (24c). In his first paper on alcoholic fermentation without yeast cells (23) he stated, in a remarkably short and precise manner, that “a separation of the (alcoholic) fermentation from the living yeast cells was not successful up to now”; in the following year (24) he described a process that solved that task. He gave the experimental details for the preparation of a cell-free press juice from yeast cells with disruption, filtration under high pressure, and further filtration. He then described the formation of carbon dioxide from carbohydrates (sucrose, glucose, fructose, and maltose). No fermentation was observed with lactose or mannitol. No microscopic organisms were present. Chloroform, an antiseptic inhibiting microbial growth, did not inhibit the “fermentation” (the enzymatic reaction). At elevated temperature protein was precipitated and the activity decreased and was finally destroyed. From these results, Buchner derived essential new insights into the nature of alcoholic fermentation. So the concept of enzyme action as a general principle in biochemical reactions was initiated by Berthelot (16) in the 1850s as to priority. The experimental verification, however, was Buchner’s work, and he earned the credit for it.

Many more details make up the demarcation of a breakthrough against an established paradigm which taught that processes in living organisms, where alcoholic fermentation was the most important example, were not of pure chemical nature but required a *vis vitalis*. The chemical paradigm, which reduced all reactions in physiological (or bio-) chemistry to chemistry without further hidden forces, began to play the dominant role.

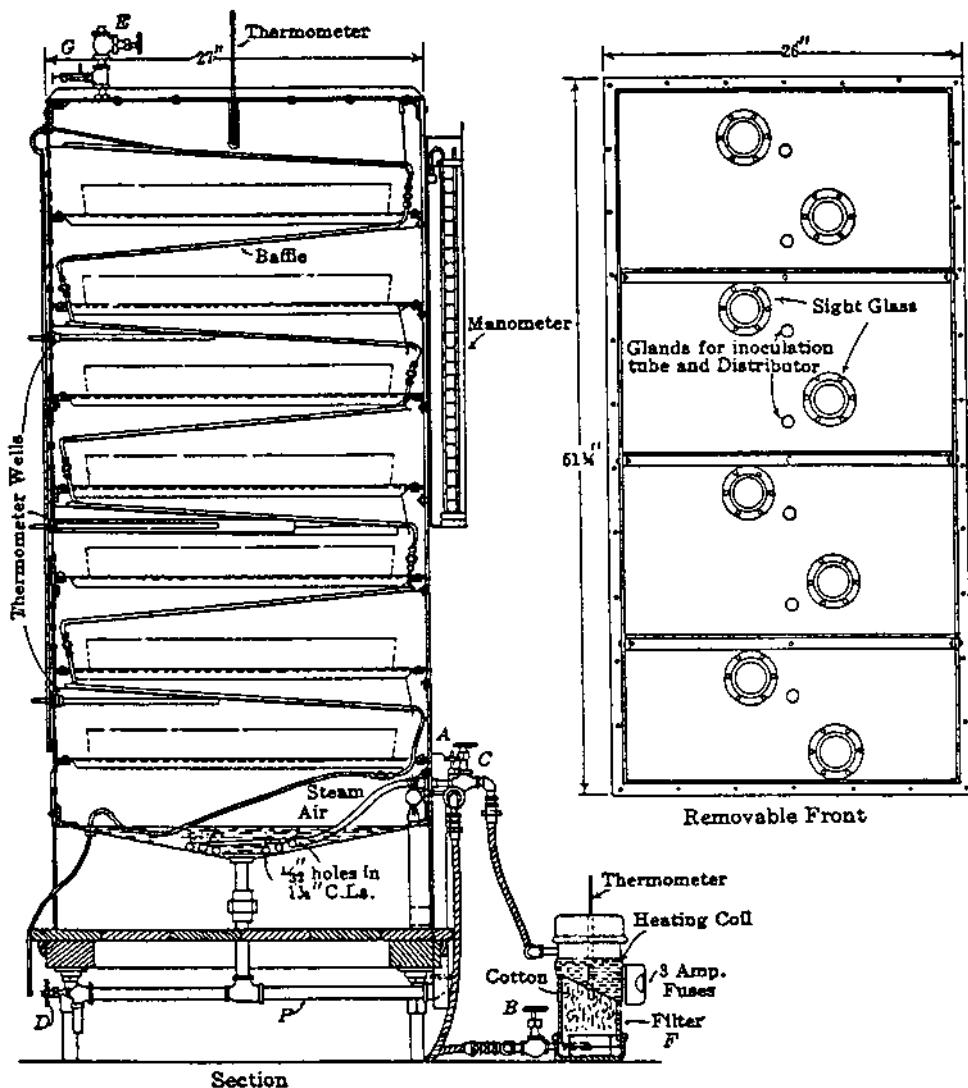

Further findings relevant for establishment of the chemical nature of enzymatic catalysis and technical application followed within a rather short time. Croft-Hill performed the first enzymatic synthesis, that of isomaltose, in 1898, by allowing a yeast extract ( $\alpha$ -glycosidase) to act on 40% glucose solutions (3). In 1900, Kastle and Loevenhart found that the hydrolysis of fat and other esters by lipases was a reversible reaction and that enzymatic synthesis could occur in a dilute mixture of alcohol and acid (25). This principle

was utilized for the synthesis of numerous glycosides by Fischer and coworkers in 1902 and by Bourquelot and coworkers in 1913 (26).

After a long period of ~ 100 years, with mysterious hypotheses and several technical applications, where one (diastase) was even economically important, research on enzymes obtained a chemically scientific status. The activity in research increased significantly owing to the new direction, and technical development also got a new scientific basis on which to proceed in a rational way. The definitive establishment of the chemical paradigm was the crystallization of urease by Sumner in 1926, and further enzymes (trypsin etc.) by Northrup and Kunitz in 1930/31. In every known case the pure enzyme turned out to be a protein (25).

## B. Technical Development

With the exception of Christian Hansen's rennet, the industrial development of enzymes was very slow initially. Takamine began isolating bacterial amylases in the 1890s in what later became known as Miles Laboratories (today a part of Genencor). In 1894 he obtained a patent for the production of a diastatic enzyme preparation from molds, which he called Takadiastase. The production was performed in a surface culture with wheat bran as a substrate and inoculation by spores of *Aspergillus oryzae* (Fig. 2) (4:401). Additional early applications and patents on enzyme application in the food industry have been collected by Neidleman (27) ([Table 2](#)).

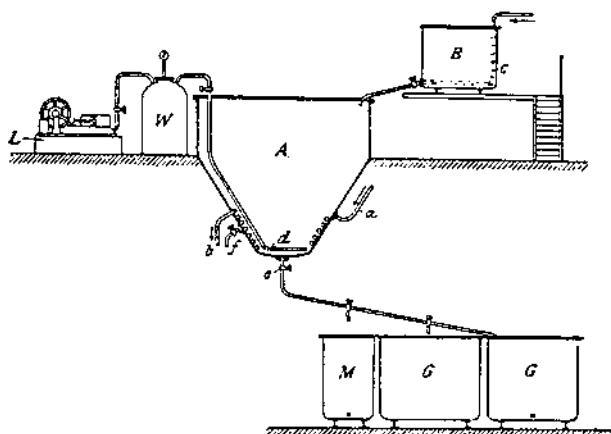

**Figure 2** Surface culture with *Aspergillus* in a cabinet incubator. (From Ref. 4.)

**Table 2** Selected Early Enzyme Patents

Inventor	Year	Enzyme	Title
J. Takamine	1894	Amylases	Process for making diastatic enzyme

Source: Ref. 27.

At the beginning of the 20th century the production of plant lipase was performed by mechanical disruption of the seed of ricinus by procedures of Nicloux and Hoyer. These seeds had to be stored for several days with some acid added, which then developed a much higher activity owing to the activation of lipase. These were then utilized for the production of fatty acids from oils and fats. A production vessel is shown in Figure 3. The vessel *A* can be heated by steam and mixed by compressed air from the compressor *L* and the storage vessel *W*. The procedure was as follows: oil or fat was mixed with 35% water, the temperature held at 20–25°C, the ferment (enzyme 4–8%) added to the liquid mass, along with manganese sulfate for activation of the enzyme. Mixing was performed for 15 min, then intermittantly. Eighty percent conversion was obtained after 24 h, 90% after 2 days. The

**Figure 3** Reactor for fatty acid production. Details of reaction vessel *A*; water reservoir *B*; tube for steam *c*, entrance of steam *a*, exit of steam *b*, compressor *L*, storage vessel for steam *W*, tube for air *d*, valves at positions *e* and *f*, *M* storage vessel for medium layer, *G* storage vessels for glycerol. (From Ref. 20b.)

enzyme was inactivated by heating to 80–85°C. Glycerol was taken from the lower valve e, fatty acid from that in the higher position f. Details for manufacture of 10 tons/week were given. It was pointed out that the reaction is reversible and that an enzymatic synthesis of fat from glycerol and fatty acid was described by Welter in 1911 (20b).

In 1895, Boidin discovered a new process for the manufacture of alcohol called the *amyloprocess*. It comprised cooking of the cereals, inoculation with a mold which formed saccharifying enzymes, and subsequent fermentation with yeast. Together with Effront, working on enzymes for alcohol production since 1900, Boidin founded the Société Rapidase (today a part of DSM-Gist-brocades) in 1920 (28:6). For chill-proofing of beer, proteolytic enzymes (produced by Wallerstein, later Bayer Travenol) have been used successfully since 1911 in the United States (4:337). So urgent was the demand throughout the brewing industry in the United States for a practical solution to this problem of sedimentation that in 1909 and again in 1910 the then U.S. Brewmaster's Association offered two cash awards (27). Lintner, as early as 1890, observed that wheat diastase was important in dough making. This effect was extensively studied, the addition of malt extract came into practice, and American bakers in 1922 used 30 million pounds of malt extract valued at \$2.5 million (4:422). The production of pectinases began around 1930 for use in the fruit industry (Schweizerische Ferment, now part of Novozymes).

The use of enzymes for the manufacture of leather played a major role for the industrial-scale production of enzymes. Wood was the first in 1898, to show that the bating action of the unpleasant dungs used at that time was caused by the enzymes (pepsin, trypsin, lipase) they contained. In the context of Wood's investigations the first commercial bate, called Erodin, was prepared from cultures of *Bacillus erodiens*, based on a German patent granted to Popp and Becker in 1896. The bacterial cultures were adsorbed on wood meal and mixed with ammonium chloride (4: 491). In 1907, Röhm patented the application of a mixture of pancreatic extract and ammonium salts as a bating agent (4:488). With this perspective he founded his company in 1907, which successfully entered the market. In 1913 the company had 22 chemists, 30 other employees, and 48 workers (29:101). A systematic approach toward the interrelation of scientific development and engineering aspects, which played a major role in this development, has been published by Buchholz (30).

#### IV. DEVELOPMENTS SINCE 1940

Even the development of citric acid by fermentation, (Pfizer) and penicillin (Beecham, Glaxo, Merck, Pfizer, Squibb, Bristol-Myers) in the 1940s did not really trigger a scale-up of industrial applications of enzymes. We must go forward to around 1955 before the development of enzyme production was gaining speed by growing sales of bacterial amylase and protease. It began in a very modest fashion. As an illustration, the turnover of the enzyme division of Novo Industri (now Novozymes), the leading enzyme manufacturer, did not exceed \$1 million (U.S.) annually until 1965. However, with the appearance of the detergent proteases, the use of enzymes increased. Everybody wanted Biotex, the protease-containing detergent. At the same time, an acid/enzyme process to produce dextrose using glucoamylase was used increasingly in starch processing. By 1969, within only 4 years, Novo's enzyme turnover exceeded \$50 million (U.S.) annually; in 1997 Novozyme's enzyme division had a turnover of ~ \$650 million (U.S.). The present global market is estimated to be around \$1.6 billion (U.S.) (31).

One question, which is as old as industrial enzyme, is: Can enzymes be reused? Some of the first attempts to reuse enzymes were described by Nelson at the beginning of the 20th century. But the enzymes adsorbed to charcoal were very unstable. In the 1950s, Manecke was the first really to succeed in making relatively stable systems; however, he could not convince industry of the importance of further development of his systems (30). It became the group of chemists working with Katchalski-Katzir in Israel who really opened the eyes of industry to the world of immobilized enzymes. Among Katchalski-Katzir's coworkers were Klaus Mosbach, Daniel Thomas, and Malcolm Lilly. The first immobilized enzyme products to be scaled up to pilot plant and industrial application (in 1969) were immobilized amino acid acylases (i.e., I. Chibata and colleagues at Tanabe Seiyaku Co. in Japan [32]) and penicillin G acylase (M. D. Lilly/University College, London, Beecham Pharmaceuticals, England, and G. Schmidt-Kastner, Bayer, Germany) (33, 34:7).

The largest immobilized enzyme product still today in volume is immobilized glucose isomerase. The first commercial enzymatic production of high-fructose corn syrups (HFCS) was in Japan in 1969 (Takasaki and coworkers), utilizing heat treated *Streptomyces* cells containing glucose isomerase in a batch reactor. In the United States, Clinton Division of Standard

Brands (now ADM) was the first company using “Takasaki immobilized glucose isomerase” to make industrial quantities of HFCS around 1971 (33). The skyrocketing sucrose prices, during 1973–75, where the price of sucrose increased from 5–7¢/lb to ~ 30¢/lb speeded the interest for HFCS. Thereby, immobilized glucose isomerase increased dramatically in price. Companies like Novozymes, and later Gist-brocades developed more stable enzyme products, which were easier and cheaper to use. Resources were spent on optimizing fermentation for glucose isomerase production, immobilization processes, and the application processes for the immobilized glucose isomerases. As a result, productivities of the commercial immobilized glucose isomerase products increased from ~ 500 kg HFCS/kg immobilized enzyme product (1975) to ~ 15,000–20,000 kg/kg (1997).

Other immobilized enzyme product successes (where annual production of immobilized enzymes has surpassed 1 ton/year) comprise: aminoacylase (Amano), hydantoinase (Smith Beecham), lactase (Valio), lipase (Novozymes), penicillin G acylase (Gist-brocades, Smith Beecham, Röhm), and penicillin V acylase (Novozymes/Gist-brocades) (33).

Numerous efforts and papers, as well as standardized procedures for the characterization of immobilized biocatalysts, have been published in recent decades. The scientific and technical progress may be questioned in the majority of the papers (35). A remarkable issue, however, might be the application of biocatalysts for synthesis of a broad range of products, most importantly in the sectors of food, food ingredients, and pharmaceuticals, and recently in glycobiology for making oligosaccharides and glycosides, and in organic chemistry, including nonaqueous systems and the hydrolysis and modification of fats and products derived therefrom, for surfactants (34:141–190).

Recombinant techniques have been established during the last two decades for much improved yields of enzymes by fermentation, modification of stability, and even selectivity and specificity (36). These techniques have pushed the application, and tend to considerably extend the scope of potential applications, of enzymes in diverse fields including food technology.

## What Enzymes Do and Why They Are Highly Specific and Efficient Catalysts

John R. Whitaker

*University of California, Davis, Davis, California, U.S.A.*

### I. INTRODUCTION

Enzymes are the key to all life. Therefore, it is not surprising that all organisms contain hundreds of different enzymes. It is common to find isoenzymes, which are multiple protein forms of an enzyme within the same organ, with qualitatively the same enzymatic activity. Therefore, each isoenzyme is encoded by a different gene. With so many different organisms in the world, all with hundreds of different enzymes, how is it possible to systematize enzymes and enzyme nomenclature? This was a problem that the biochemical and chemical community faced in 1955.

As indicated in [Chapter 1](#), the first enzyme recognized, based only on its activity, was catalase, in 1812. It converts hydrogen peroxide to water and oxygen; the oxygen bubbles out of the solution. As described in [Chapter 1](#), several other enzymes were discovered over the years. By 1955, more than 600 enzymes were known and partially characterized. The naming of enzymes was largely left to the discoverer. Some enzymes, such as catalase, diastase (now amylase), polyphenol oxidase, peroxidase, etc., used “-ase” to indicate that the compound was an enzyme. However, naming of other enzymes, such as trypsin, chymotrypsin, ficin, and papain, did not use “-ase”. Warburg and Christian in 1935 discovered an enzyme that, when partially purified, was yellow because of the cofactor riboflavin. They named it the “yellow enzyme.” Soon after, Warburg discovered a different

yellow enzyme so he named it the “new yellow enzyme.” When a crude preparation of enzymes that synthesized proteins was first discovered it was named “the pH 5 extract” because maximum enzyme activity occurred at that pH.

An International Commission on Enzymes was established in 1955 by the International Union of Biochemistry with the charge “to consider the classification and nomenclature of enzymes and coenzymes, their units of activity and standard methods of assays, together with the symbols used in the description of enzyme kinetics.” The Commission on Enzymes contained one or more members from each of the countries that were publishing significant research on enzymes. The first Report of the Commission on Enzymes in 1961 contained 712 enzymes. Subsequent updates have been issued. The most recent report in 1992 contained 3196 enzymes (1). In order for the enzyme to appear in the list, the researcher must isolate the enzyme and characterize it with respect to substrate(s) specificity, product(s) formed, nature of the overall reaction, and protein properties, and clearly demonstrate that it is unique.

### II. THE THREE-TIER CLASSIFICATION OF ENZYMES

The 1955 Commission on Enzymes recommended that each enzyme have three designations. These are: a

systematic name, a trivial name, and an Enzyme Commission (EC) number.

The systematic name consists of the name(s) of the substrate(s). In the case of two or more substrates (or reactants), the names of the substrates are separated by a colon. The second part of the systematic name, ending in -ase, is based on one of the six types of chemical reactions catalyzed (see below). When the overall reaction involves two different chemical reactions, such as oxidative demethylation, the second type of reaction is listed in parenthesis following the name of the first type of reaction—for example, “sarcosine:oxygen oxidoreductase (demethylating).”

The trivial name is one that is generally recognized and is in common usage such as trypsin, chymotrypsin,  $\alpha$ -amylase, cellulase, peroxidase, or catalase.

The number system derives directly from the classification scheme. Each enzyme number contains four digits, separated by periods, and preceded by EC. The numbers are permanent. Newly discovered enzymes are placed at the end of a list under appropriate headings. When the classification of an enzyme is changed, the original number remains in the listing, but the user is directed to the new listing, including the new number of the enzyme. For example, the listing of the proteases has been changed recently. A new arrangement of the carbohydrases will be published soon.

#### A. Rules for Naming of Enzymes

## 1. Classification into Six Groups Based on Type of Chemical Reaction Catalyzed

As noted above, the Enzyme Commission classified the enzymes into groups based on the type of chemical reaction catalyzed. Together with the name(s) of the substrate(s), this provides the basis for systematically naming individual enzymes.

There are six chemical types of reactions catalyzed by enzymes. These are (with the general group name of the enzymes in parentheses): (a) oxidoreduction (oxidoreductase), (b) group transfer (transferase), (c) hydrolysis (hydrolase), (d) formation of double bonds without hydrolysis (lyase), (e) isomerization (isomerase), (f) ligation (ligases).

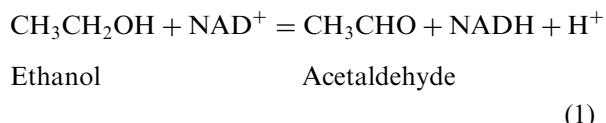

The first digit in the EC number system is based on the type of chemical reaction catalyzed, with (a)–(f) above being listed as EC 1–6.

## 2. The Overall Reaction as Basis of Nomenclature

The overall reaction catalyzed, based on the formal chemical equation [for example, Eq. (1)] is the basis

for the nomenclature. The mechanism of the reaction is not indicated. Therefore, an enzyme cannot be named systematically until the substrate(s), product(s), and the chemical nature of the reaction catalyzed are known.

The overall reaction catalyzed by a specific enzyme is shown in Eq. (1):

According to the Enzyme Commission, the systematic name of the enzyme is ethanol:NAD<sup>+</sup> oxidoreductase (more commonly called alcohol:NAD<sup>+</sup> oxidoreductase). The substrate (ethanol) that donates the hydrogens (becomes oxidized) is listed first, followed by the substrate (NAD<sup>+</sup>) that accepts the hydrogens (becomes reduced). According to the number system, alcohol:NAD<sup>+</sup> oxidoreductase is EC 1.1.1.1. The first digit designates it as an oxidoreductase. The second digit indicates that the donor of the hydrogens is an alcohol ( $R_2CH-OH$ ). The third digit indicates that NAD<sup>+</sup> (or NADP<sup>+</sup>) is the specific acceptor of the hydrogen(s), and the fourth digit indicates that the alcohol is ethanol. The trivial name of alcohol:NAD<sup>+</sup> oxidoreductase is alcohol dehydrogenase. In a publication the systematic name would be given at the first mention of the enzyme, along with the trivial name and EC number; i.e., alcohol:NAD<sup>+</sup> oxidoreductase (alcohol dehydrogenase; EC 1.1.1.1). Thereafter in the publication, the trivial name, alcohol dehydrogenase, would be used. [Table 1](#) contains the general listing of enzymes through the second digit as recommended by the Enzyme Commission.

### **B. Six Groups of Enzymes**

The six groups of enzymes, based on the chemical reaction catalyzed, are described in more detail in this section.

## 1. Oxidoreductases

Oxidoreductases are enzymes that oxidize or reduce substrates by transfer of hydrogen or electrons or by addition of oxygen. The systematic name is formed as “donor:acceptor oxidoreductase.” One example for alcohol dehydrogenase (EC 1.1.1.1) is shown in Eq. (1) above, in which the donor substrate is ethanol which contributes two hydrogens to NAD<sup>+</sup>, the acceptor substrate (and cofactor) with the formation of acetal-

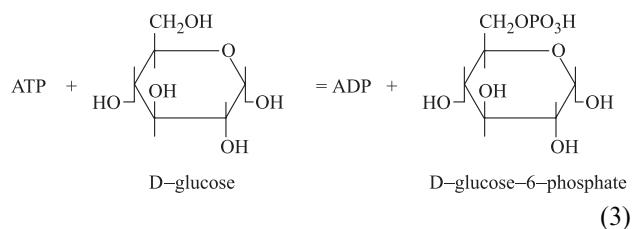

dehyde and NADH<sub>2</sub>; NADH<sub>2</sub> then loses a proton (H<sup>+</sup>) based on the pH of the reaction. Another example is the catalase reaction in which one H<sub>2</sub>O<sub>2</sub> molecule serves as the donor substrate and the second H<sub>2</sub>O<sub>2</sub> molecule serves as the acceptor substrate to form O<sub>2</sub> and H<sub>2</sub>O [Eq. (2)]. The systematic name is “hydrogen peroxide:hydrogen peroxide oxidoreductase” (EC 1.11.1.6).

Whitaker (2) has suggested dividing the oxidoreductases into eight subgroups based on mechanistic considerations. But the International Commission on Enzymes considers only the overall reaction in naming enzymes.

## 2. Transferases

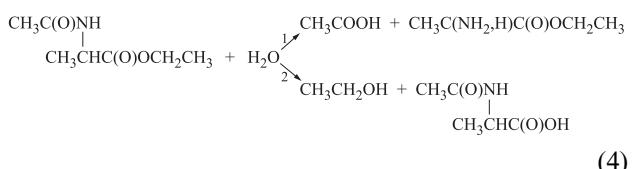

Transferases are enzymes that remove groups (not including H, which belongs in group 1, the oxidoreductases) from substrate(s) and transfers the group to acceptor substrates (not including water). The systematic name is formed as “donor:acceptor group-transferred-transferase.” The types of groups transferred are given by the second digit in EC 2. of Table 1. A specific example of a transferase is shown in Eq. (3).

The systematic name of the enzyme that catalyzes the reaction in Eq. (3) is “ATP:D-glucose 6-phosphotransferase” (EC 2.7.1.2). The trivial name is glucokinase. The position to which the group (phosphate) is transferred to the glucose is given in the systematic name when more than one possibility exists, such as D-glucose-1-phosphate.

## 3. Hydrolases

Hydrolases are enzymes in which water (H<sub>2</sub>O) is the second substrate. Water participates in the breakage of covalent bonds; for example, peptide bonds in proteins, glycosidic bonds in carbohydrates, ester bonds in lipids, and phosphodiester bonds (and others) in nucleic acids. The systematic name is formed as “substrate hydrolase.” The elements (H and OH) appear in the products of the reaction as shown in Eq. (4)

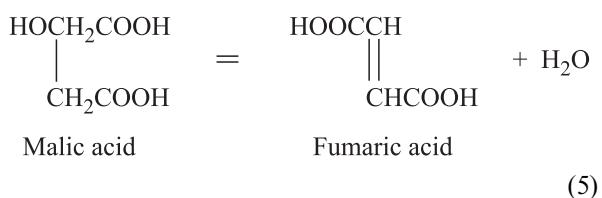

When the enzyme specificity is limited to a single group (of two or more susceptible groups), the name of the group is given as a prefix of hydrolase. For example, enzymatic hydrolysis of a compound such as N-acetyl-L-alanine ethyl ester [Eq. (4)] can occur at either the acetyl-nitrogen bond or the ethoxy-oxygen bond, depending on the specificity of the enzyme.

In reaction 1 [Eq. (4)], the enzyme is an acyl amino-hydrolase (EC 3.5.) while in reaction 2 [Eq. (4)], the enzyme is an acyl oxygenhydrolase (esterase, EC 3.1.). There is no crossreactivity between the two enzymes, as they are specific for hydrolysis of only one of the scissile bonds, unlike HCl.

## 4. Lyases

Lyases are enzymes that remove groups from their substrates (not by hydrolysis) to give a double bond in the product, or which conversely add groups to double bonds. The systematic name is formed as “substrate prefix-lyase.” Prefixes such as “hydro-” and “ammonia-” are used to indicate the type of reaction—for example, “L-malate hydro-lyase” (EC 4.2.1.2). Decarboxylases are named as “carboxylases.” A hyphen is always written before “lyase” to avoid confusion with hydrolases, carboxylases, etc. An example of a lyase is the removal of HOH from malic acid to give fumaric acid [Eq. (5)]:

by the enzyme (s)-malate hydro-lyase (fumarate hydratase; EC 4.2.1.2; formerly known as fumarase).

## 5. Isomerases

Isomerases are enzymes that cause rearrangement of one or more groups on substrates without changing the atomic composition of the product. The general systematic name is formed as “substrate prefix-isomerase.” The prefix indicates the type of isomerization involved, for example, “maleate *cis-trans*-isomerase” (EC 5.2.1.1) [Eq. (6)].

**Table 1** Key to Numbering and Classification of Enzymes<sup>a</sup>

**1. Oxidoreductases**

- 1.1 Acting on the CH–OH group of donors
- 1.2 Acting on the aldehyde or oxo group of donors
- 1.3 Acting on the CH–CH group of donors
- 1.4 Acting on the CH–NH<sub>2</sub> group of donors
- 1.5 Acting on the CH–NH group of donors
- 1.6 Acting on NADH or NADPH
- 1.7 Acting on other nitrogenous compounds as donors
- 1.8 Acting on a sulfur group of donors
- 1.9 Acting on a heme group of donors
- 1.10 Acting on diphenols and related substances as donors
- 1.11 Acting on hydrogen peroxide as acceptor
- 1.12 Acting on hydrogen as donor
- 1.13 Acting on single donors with incorporation of molecular oxygen (oxygenases)
- 1.14 Acting on paired donors with incorporation of molecular oxygen
- 1.15 Acting on superoxide radicals as acceptor
- 1.16 Oxidizing metal ions
- 1.17 Acting on CH<sub>2</sub> groups
- 1.18 Acting on reduced ferredoxin as donor
- 1.19 Acting on reduced flavodoxin as donor
- 1.97 Other oxidoreductases

**2. Transferases**

- 2.1 Transferring one-carbon groups
- 2.2 Transferring aldehyde or ketone residues
- 2.3 Acyltransferases
- 2.4 Glycosyltransferases
- 2.5 Transferring alkyl or aryl groups, other than methyl groups
- 2.6 Transferring nitrogenous groups
- 2.7 Transferring phosphorous-containing groups
- 2.8 Transferring sulfur-containing groups

**3. Hydrolases**

- 3.1 Acting on ester bonds
- 3.2 Glycosidases

**3.3 Acting on ether bonds**

- 3.4 Acting on peptide bonds (peptidases)
- 3.5 Acting on carbon–nitrogen bonds, other than peptide bonds
- 3.6 Acting on acid anhydrides
- 3.7 Acting on carbon–carbon bonds
- 3.8 Acting on halide bonds
- 3.9 Acting on phosphorus–nitrogen bonds
- 3.10 Acting on sulfur–nitrogen bonds
- 3.11 Acting on carbon–phosphorus bonds

**4. Lyases**

- 4.1 Carbon–carbon lyases
- 4.2 Carbon–oxygen lyases
- 4.3 Carbon–nitrogen lyases
- 4.4 Carbon–sulfur lyases
- 4.5 Carbon–halide lyases
- 4.6 Phosphorus–oxygen lyases
- 4.99 Other lyases

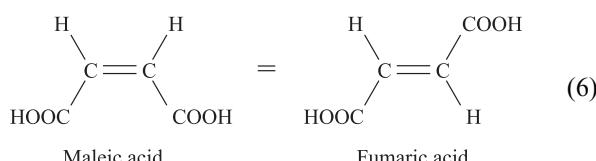

**5. Isomerases**

- 5.1 Racemases and epimerases
- 5.2 *cis-trans*-isomerase
- 5.3 Intramolecular oxidoreductases
- 5.4 Intramolecular transferases (mutases)
- 5.5 Intramolecular lyases
- 5.99 Other isomerases

**6. Ligases**

- 6.1 Forming carbon–oxygen bonds
- 6.2 Forming carbon–sulfur bonds
- 6.3 Forming carbon–nitrogen bonds
- 6.4 Forming carbon–carbon bonds
- 6.5 Forming phosphoric ester bonds

<sup>a</sup> The third and fourth levels of classification are given in Ref. 1:v-xi.

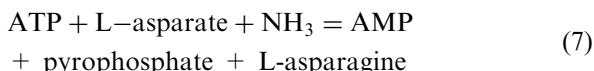

Enzymes that catalyze an aldose-ketose interconversion are known as “ketal-isomerase (for example, “L-arabinose keto-isomerase”: EC 5.3.1.4). When the iso-

merization consists of an intramolecular transfer of a group, such as 2-phospho-D-glycerate to 3-phospho-D-glycerate, the enzyme is called a “mutase”; a specific example of a mutase is D-phosphoglycerate 2,3-phosphomutase (EC 5.4.2.1). Isomerases that catalyze inversions of asymmetric groups are termed “racemases” or “epimerases,” depending on whether the substrate contains one or more than one center of asymmetry, respectively.

## 6. Ligases

Ligases are enzymes that catalyze the covalent linking together of two molecules, coupled with the breakage of a pyrophosphate bond as in ATP, UTP, or CTP. The systematic name is formed as “X:Y ligase (Z),” where X and Y are the names of the two molecules to be joined together. The compound Z is the product formed from the triphosphate (ATP, UTP, or CTP); they provide energy during the reaction. An example is:

The systematic enzyme name is L-asparate:ammonia ligase (AMP-forming (aspartate-ammonia ligase, EC 6.3.1.1.)

Proteins, carbohydrates, and triacylglycerols are synthesized by specific ligases using ATP, UTP, and CTP, respectively.

## C. Other Considerations in Naming Enzymes

### 1. Organism from Which the Enzyme Is Isolated

Proteins are specific to an organism. When proteins from one organism are injected into a different animal, they elicit antibodies, indicating that they differ from the proteins of the recipient animal. They have differences in amino acid sequences and therefore folding patterns. Enzymes, as proteins, are no different. Therefore, the name of the specific organism from which an enzyme is derived must be given.

### 2. Organ from Which the Enzyme is Isolated

No less important is the organ (of multicellular organisms) from which the enzyme is obtained.  $\alpha$ -Amylases from human saliva are different from those produced by the human pancreas, for example. Therefore, the organ from which the enzyme is obtained must be specified.

### 3. Isoenzymes

Isoenzymes are different protein forms of an enzyme produced in the same organ by different genes, but qualitatively they have the same activity. Perhaps multiple gene expression of isoenzymes is protection against failure of a gene. Or they may occur due to mutation of a nucleotide base in a codon of a gene. Whatever the reason, the protein expressed is different from one gene to another, even from the same cell. The proteins have different protein properties by electro-

phoresis, column chromatography, and other separation methods. Quantitatively, there may be differences in catalytic efficiency of the isoenzymes.

When isoenzyme forms are present, they contain a letter (or number) indicating how they behaved by electrophoresis or the order in which they were eluted from an ion exchange column. For example, the first isoenzyme eluting from a cation exchange column would be isoenzyme-1, the second would be isoenzyme-2, etc.

One might ask whether posttranslational processing of a nascent protein (see [Chapter 1](#)) can give isoenzymes due to different levels of modification. This is a relatively easy question to answer, but it may be difficult to determine experimentally. An example often observed experimentally is that the extent of glycosylation of a seed protein (for example) is often different depending on the maturity of the seed. The glycosyl groups are covalently attached to the protein at the hydroxyl group of seryl residues and  $\beta$ -amino groups of asparaginyl residues, as determined by the genetic code, immediately following translation (and before the protein folds into the native form; see [Chapter 1](#)). The glycosyl groups may then be shortened by cytoplasmic carbohydrazes *after folding* of the protein to the native state (“age”-related processing). Are these isoenzymes? They are not products of different genes and so do not qualify as isoenzymes. Native human hemoglobin is glycosylated over time at a level depending on its age *and* the concentration of glucose in the blood. Hemoglobin *a* levels are used clinically to determine the severity of diabetes in humans. No one would describe the age-related modified hemoglobin as an isoprotein! Multiple electrophoretic bands (> 30 sometimes) occur with peroxidase because of different levels of glycosylation. The benzoquinones formed due to the activity of polyphenol oxidase action on phenols during extraction and purification of proteins (including polyphenol oxidase itself) lead to multiple bands since the benzoquinones quickly modify the  $\epsilon$ -amino group of lysyl residues. These different bands are not due to isoenzymes!

### 4. In Summary

In naming an enzyme, one must not only describe it by the overall type of reaction catalyzed (under standard conditions), but also by the source of the enzyme (organism, organ) and by isoenzyme number. With the excellent tools available today, there is no basis for publishing quantitative data on the activity of an enzyme until the degree of purity of the enzyme has

been established and one can associate the activity with one unique protein catalyst.

### III. WHY ARE ENZYMES HIGHLY SPECIFIC AND EFFICIENT CATALYSTS?

#### A. How Efficient Are Enzymes as Catalysts?

**Table 2** provides data on the relative rates of a few enzyme-catalyzed reactions in relation to the noncatalyzed and non-enzyme-catalyzed reactions at 25°C. All relative rates are based on a 1 molar concentration of catalyst for comparison. First, look at the relative rates of the reactions at 25°C. Catalase is  $3.5 \times 10^8$  times more effective in conversion of H<sub>2</sub>O<sub>2</sub> to H<sub>2</sub>O and O<sub>2</sub> than is the noncatalyzed reaction and  $1.7 \times 10^5$  times more effective than the I<sup>-</sup> catalyst. Sucrose can be hydrolyzed by acids (by the H<sup>+</sup>) as well as by invertase. Invertase is  $5.6 \times 10^{10}$  times more effective than the H<sup>+</sup>. Carbonic anhydrase, important in our respiratory exchange of O<sub>2</sub> and CO<sub>2</sub>, is  $3 \times 10^6$  more effective than no catalyst. In our kidney, urease is important in the conversion of urea to ammonia and CO<sub>2</sub>. Urease is  $4.3 \times 10^{11}$  times more effective than the H<sup>+</sup>.

Table 2, column 3, gives the Arrhenius activation energy,  $E_a$ , required to convert the substrate to products. Notice that in all cases, the  $E_a$  for the enzyme-catalyzed reaction is significantly lower than for the non-enzyme-catalyzed or noncatalyzed reaction. Therefore, one can correctly conclude that the enzymes are successful in lowering the activation energy for conversion of substrate to product. To

fully grasp the effectiveness of lowering  $E_a$  one must appreciate that the rate of a reaction, as controlled by the rate constant,  $k$ , is logarithmically related to  $E_a$  as shown in Eq. (8).

$$k = Ae^{-E_a/RT} \quad (8)$$

where  $A$  is the Arrhenius constant,  $e$  is the base of the natural logarithm,  $E_a$  is the Arrhenius activation energy,  $R$  is the universal gas constant, and  $T$  is Kelvin temperature.

The effect of temperature on the rate of reactions (including enzyme-catalyzed reactions) is given by the Boltzmann distribution equation:

$$n'/n = -E_a/RT \quad (9)$$

where  $n'$  is the number of molecules per unit volume of a compound having activation energy  $E_a$  or greater (see [Fig. 1](#)) and  $n$  is the total number of molecules per unit volume of a compound. The  $A$  factor in Eq. (9) is the product of the kinetic energy of the system due to Brownian movement and the probability ( $P$ ) that two molecules will collide with proper orientation of reactive groups.  $P$  approaches 1 in enzyme-catalyzed reactions because the substrates are properly bound noncovalently in the active site adjacent to the catalytic group(s) required for catalysis (see Ref. 2, pages 314ff).

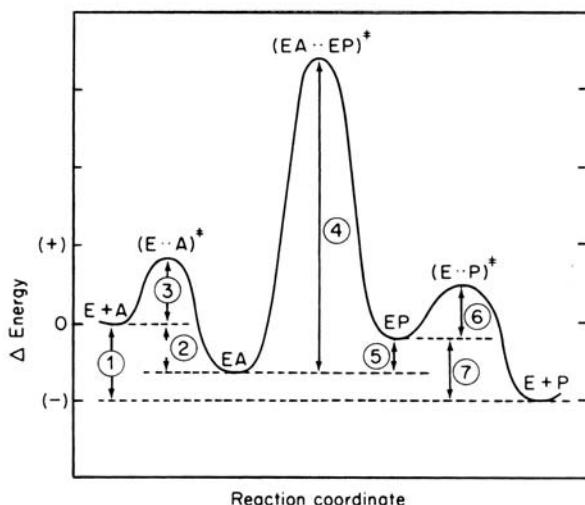

[Figure 1](#) shows the change in energy (both activation energy (steps 3, 4, and 6) and thermodynamic energy (steps 1, 2, 5, and 7) as the enzyme binds with substrate and catalyzes conversion of the substrate (A) to product (P) in the reaction. The rate-limiting step requires the most energy (step 4 in [Fig. 1](#)). This energy is the activation energy,  $E_a$ , as shown in Eq. (8).

**Table 2** Effect of Catalyst on  $E_a$  and on Relative Rates of Some Reactions

Substrate	Catalyst	$E_a$ (kcal/mol)	$n'/n^a$ (25°C)	Relative rate (25°C)
$H_2O_2$	None	18.0	$5.62 \times 10^{-14}$	1.00
	I <sup>-</sup>	13.5	$1.16 \times 10^{-10}$	$2.07 \times 10^3$
	Catalase	6.4	$1.95 \times 10^{-5}$	$3.47 \times 10^8$
Sucrose	H <sup>+</sup>	25.6	$1.44 \times 10^{-19}$	1.00
	Invertase	11.0	$8.04 \times 10^{-9}$	$5.58 \times 10^{10}$
Carbonic acid	None	20.5	$8.32 \times 10^{-16}$	1.00
	Carbonic anhydrase	11.7	$2.46 \times 10^{-9}$	$2.96 \times 10^6$
Urea	H <sup>+</sup>	24.5	$9.33 \times 10^{-19}$	1.00
	Urease	8.7	$3.96 \times 10^{-7}$	$4.25 \times 10^{11}$

<sup>a</sup>  $n/n'$  values were calculated by use of Eq. (9) and are approximate only, since differences in  $\Delta S^\ddagger$  for the comparison reactions are ignored.

The numbers refer to steps in thermodynamic states (ground states); 1, 2, 5, and 7 and transition states (activated states); steps 3, 4, and 6 in the forward reaction pathway. (From Ref. 2.)

### B. Binding of Substrate by Enzyme

Very few compounds are substrates for a given enzyme. In the case of urease, really only urea is a good substrate. For other enzymes, such as alkaline phosphatase, a number of compounds serve as substrate (phenylphosphate, *p*-nitrophenyl phosphate,  $\beta$ -glycerol phosphate, etc.). However, all substrates for alkaline phosphatase have an ortho-phosphate group. By competitive inhibition studies with ortho-phosphate, and with different substrates, it is relatively easy to establish that the major recognition group on the substrate for the enzyme is the ortho-phosphate group. This example can be extended to most other enzymes and their recognition of substrates. Analogs of substrates are good inhibitors of enzymes, which tells us that the enzyme *must recognize and bind with the compounds*.

In 1902, Henri (3) and Brown (4) independently proposed that the observed effect of substrate concentration on the velocity of conversion of substrate to product (Fig. 2) is due to the essentiality of an intermediate substrate-enzyme noncovalent complex prior to catalysis [Eq. (10)].

**Figure 2** Variation of initial velocity with substrate concentration for an enzyme-catalyzed reaction according to Eq. (2). (From Ref. 2.)

When all of the enzyme is bound to substrate, the maximum velocity,  $V_{\max}$ , of the reaction is achieved. Many researchers have verified by other methods that formation of the  $E \cdot S$  complex is essential before conversion of substrate to product is possible. How does this binding contribute to the specificity and efficiency of enzyme-catalyzed reactions? This question is addressed in the following way.

#### 1. Nature of the Binding Site

Table 3 lists the characteristics of the active site of an enzyme. The active site is a small area (with  $\sim 10$  amino acid residues brought together from distant

**Table 3** Active Site Characteristics of an Enzyme

1. Small area on surface of native protein
2. Shape can be crevice or hole
3. Active site binds substrate(s) and cofactors
  - a. Stereospecifically with at least three points of contact
  - b. Converts substrate to products
4. Ionizable groups in active site (side chains of amino acid residues)
  - a. May be involved in binding
  - b. Involved in catalysis
5. Active site flexible (induced fit) and can accommodate substrate(s)
6. Active site may contain cofactor(s)
7. Active site with substrate bound is hydrophobic

parts of the primary structural chain to the surface of the enzyme). The substrate can diffuse rapidly to the active site and binds stereospecifically by a minimum of three noncovalent bonds. In lysozyme, Glu35, Asn37, Asn44, Asp52, Asp59, Try63, Asp101, Arg 114, and the carbonyl oxygen of the peptide bonds between Phe34–Glu35, Gln57–Leu58, and Ala107–Try108 all appear to be in proximity in the active site (5). In ribonuclease, Lys7, Arg10, His12, Lys41, and His119 are known to be in the active site (6).

Carboxypeptidase A and lysozyme form five and 12 noncovalent contacts with the substrates benzylloxycarbonylglycyl-L-phenylalanine and hexa-N-acetylchitohexaose, respectively (2). When bound properly in the active site, the substrate is positioned in proximity to the catalytic groups that convert it to product(s), along with any cofactors that are required. On binding of substrate into the active site most of the water molecules are forced out so that the reaction takes place under hydrophobic conditions. For hydrolases, one water molecule binds stereospecifically as a second substrate in proximity to the first substrate.

Table 4 summarizes the factors accounting for the catalytic effectiveness of enzymes. Conversion of the enzyme and substrate (plus any cofactors) from an intermolecular reaction to an intramolecular reaction (the *E*·*S* complex) increases the rate by  $10^4$  for one substrate,  $10^9$  for two substrates, and  $10^{15}$  for three substrates. Even five to six component reactions are possible with enzymes, such as the RNA polymerases. There is an increase in entropy of the reaction because of the highly structured nature of binding of substrate(s) and cofactors with respect to the catalytic groups, increasing the rate by a factor of  $\sim 10^3$ . Since water is expelled when

the substrate(s) and cofactors bind in the active site, the concentration of the catalytic groups of the enzyme increase to  $\sim 10$  M, giving a rate enhancement of  $10^3$ – $10^4$ .

In some cases, the scissile bonds of the substrate may be distorted during the bonding process (induced fit [8]), contributing to increase in rate. For example, in the case of lysozyme, binding of the sugar substrate to the enzyme's active site results in a glucosyl oxocarbonium ion intermediate with an enzyme-induced distortion of a glucosyl residue at the scissile bond into a half-chair conformation (5). Electrostatic stabilization of the transition state in an enzyme reaction also plays an important role. For example, the Asn155–oxyanion interaction in subtilisin contributes 3.7 kcal/mol activation energy to the transition stabilization (9). Bender et al. (10) showed that restriction of rotation of the N-acetyl-L-tryrosyl-(acyl group intermediate) chymotrypsin, in comparison with the small acetyl-L-chymotrypsin (acyl group intermediate) increased  $\Delta S^\ddagger$  from  $-35.9$  to  $-13.4$  eu (cal mol $^{-1}$  deg $^{-1}$ ), thereby increasing the rate of deacetylation by 3540 times (10). In summation, the stereospecific binding of the substrate into the active site of the enzyme may increase the rate by  $10^{12}$ - to  $10^{26}$ -fold.

## 2. Catalysis

During the catalytic step(s), concerted general acid/general base catalysis or nucleophilic/electrophilic catalysis increases the overall rate enhancement by a factor of  $10^2$ – $10^3$  times. The overall rate enhancement predicted for an enzyme-catalyzed reaction is  $\sim 10^{18}$ – $10^{36}$ . Catalase- and peroxidase-catalyzed reactions reach values near  $10^{18}$  enhancement.

**Table 4** Factors Accounting for Catalytic Effectiveness of Enzymes

Factor	Rate enhancement <sup>a</sup> (approximate)
1. Formation of stereospecific enzyme-substrate complex (conversion from inter- to intramolecular reaction)	$10^4$ ; $10^9$ ; $10^{15}$ <sup>b</sup>
2. Increased entropy of reaction	$10^3$
3. Concentration of reactive catalytic groups when substrate binds	$10^3$ – $10^4$
4. Distortion of substrate when bound	$10^2$ – $10^4$
5. General acid/general base catalysis	$10^2$ – $10^3$
6. Nucleophilic/electrophilic catalysis	$10^2$ – $10^3$
7. Use of several step process	$10^2$ – $10^4$
Overall rate enhancement	$10^{18}$ – $10^{36}$

<sup>a</sup>In some cases, these values can be approximated by model experiments. In others, they are the best estimates available.

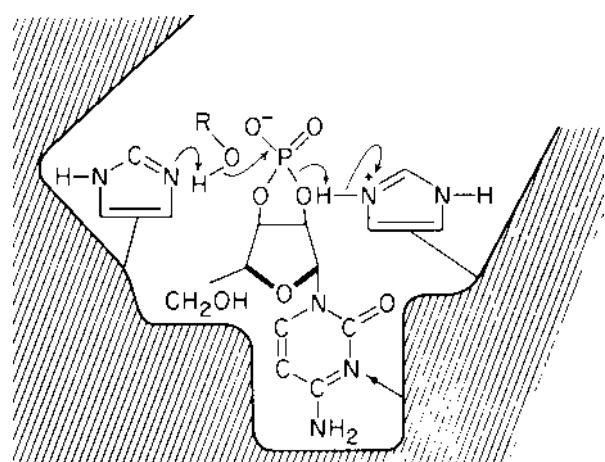

<sup>b</sup>For one, two, and three substrate reactions, respectively.

Source: Ref. 7.

Proteins of 25,000–100,000 molecular weight ( $\sim 200$ –890 amino acid residues per molecule) are synthesized on the ribosome by polymerases in  $\sim 2$ –6 min at  $37^\circ\text{C}$ .

Figure 3 depicts the active site of ribonuclease with the substrate, cytidine 2', 3'-phosphate bound in the active site. The catalytic groups of the enzyme are two imidazole side chains of two histidine residues. The distance between reactive groups on the enzyme and the scissile bond is  $\sim 2 \text{ \AA}$ , nearly covalent bond dimensions. The imidazole group on the left side of the active site functions as a general base to remove a hydrogen from a water molecule (shown as ROH in Fig. 3) to form a hydroxide ion ( $\text{HO}^-$ ) in proximity to the cyclic phosphate of the substrate. The imidazole group on the right side of the active site functions as a general acid by protonating the oxygen adjacent to the P–O bond, thereby facilitating the breakage of the cyclic P–O bond. Therefore, the hydrolysis by ribonuclease is a general base/general acid-concerted mechanism. No covalent bonds are formed between the enzyme and a substrate intermediate.

In the nucleophilic/electrophilic mechanism, intermediate covalent bonds between the enzyme and a portion of the substrate are formed which are then broken in a second step. The proteolytic enzymes trypsin, chymotrypsin, papain, etc., are known to hydrolyze the

**Figure 3** Proposed orientation of substrate and catalytic groups in the ribonuclease-catalyzed hydrolysis of the substrate cytidine 2',3'-phosphate. Two imidazole groups of histidine of ribonuclease are involved in catalysis, one as a general base (left) and another as general acid (right). The arrow at the lower right corner indicates the binding site for the pyrimidine ring of the substrate which probably involves several groups on the enzyme protein, and largely determines the specificity. (From Ref. 6.)

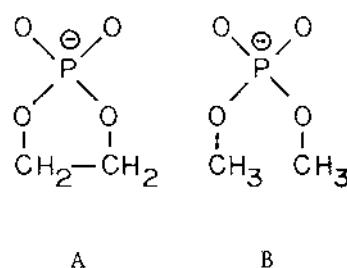

substrate by nucleophilic/electrophilic catalysis. Intermediate acyl-enzymes are hydrolyzed in a second step with water as the substrate at a rate  $\sim 10^9$  times faster than serine esters of similar structures (11).

### 3. Summary

Enzymes are very efficient catalysts because they bind substrates (and cofactors) into the active site with the scissile bond stereospecifically oriented in proximity to the catalytic groups that carry out the reactions. In forming the enzyme-substrate complex, most of the water is removed from the active site. Therefore the catalytic reaction is largely in a hydrophobic environment. Kato et al. (12) tested the effect of excluding water from the active site during the catalytic reaction by using glutathione synthetase, which requires the two substrates  $\gamma$ -glutamyl cysteine and glycine with ATP as cofactor. In the wild-type enzyme, containing a 17 amino acid loop of the peptide chain that closes the active site to exclude water when the reactants are in place, the rate constant,  $k_o$ , was  $151 \text{ sec}^{-1}$ . When the lid was removed by genetic engineering, the rate constant was  $0.163 \text{ sec}^{-1}$ , thus decreasing the rate by 930-fold by letting some water in.

The role of change in entropy on rates of enzymatic reactions was tested by use of N-acetyl-L-tyrosyl-chymotrypsin (A), where the large N-acetyl-L-tyrosyl group was tightly bound into the binding site, versus N-acetyl-chymotrypsin (B), where the small N-acetyl group can rotate freely in the binding site; the relative rate of A/B was 3540 (10).  $\Delta S^\ddagger$  was  $-13.4$  and  $-35.9 \text{ cal mol}^{-1} \text{ deg}^{-1}$  for the N-acetyl-L-tyrosyl-chymotrypsin and N-acetyl-chymotrypsin, respectively. Most of the other factors that have been proposed above to explain why enzymes are so specific and efficient have been tested by model systems.

Nature is blessed to have such efficient catalysts, the enzymes, to make life possible! But we must keep our

**Figure 4** Ethylene phosphate (A) and dimethyl phosphate (B)

perspective and respect for very simple chemical examples of enhanced reaction rates. The relative alkaline hydrolysis rates for ethylene phosphate (A) compared to the structurally similar compound, dimethyl phosphate (B) (Fig. 4) is  $\sim 1.0^8$  times (A/B). This is because of the restriction of rotation of the ethylene group in A relative to the free rotation of the methyl groups of B (Ref. 2, p. 134).

## Enzyme-Catalyzed Reactions

### Experimental Factors that Affect Rates

**John R. Whitaker**

*University of California, Davis, Davis, California, U.S.A.*

#### I. INTRODUCTION

##### A. Kinetic vs. Static Processes

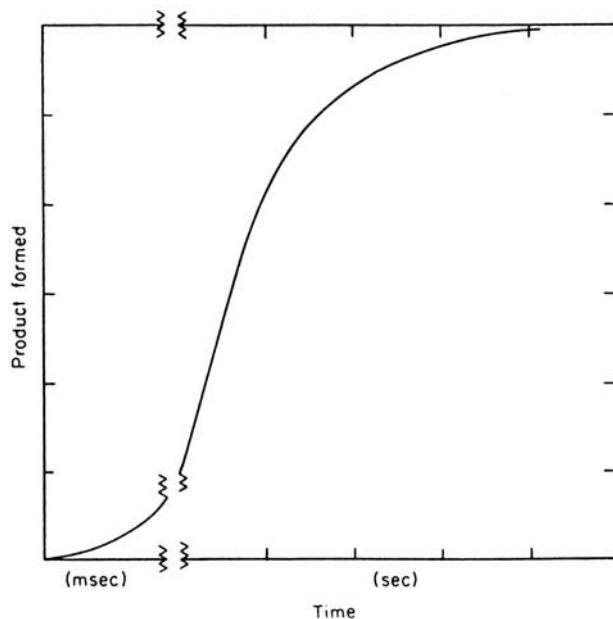

There are basically two types of determinations in science. The first type is to determine the rate of change of a parameter, whether it be a chemical reaction, the enlargement of a cell, organ, or an organism, or other changes. The second determination is primarily a compositional one in which chemical or physical analyses determine one or more compounds, cells, etc., at a given time. The first example is followed by change per unit time, a kinetic process. The second example is a static process, where change with time is undesirable. Enzyme-catalyzed reactions must be investigated by a rate-of-change process.

Chapter 1 dealt with the history of development of enzyme kinetics. Undoubtedly, from the beginning researchers must have noted that the conversion of substrate to product occurred as a function of time and that the rate of change over time was not constant under all conditions as shown in Figure 1, especially when a significant amount of substrate was converted to product.

##### B. Pathway of Enzymatic Reactions

Before proceeding further with discussion of rates, it is important to understand the pathway by which all enzyme-catalyzed reactions occur. This was first appre-

ciated by Brown (in 1902) and Henri (1903) independently (2, 3) when they suggested that the substrate saturation effect observed for rates of enzyme-cata-

**Figure 1** Typical enzyme-catalyzed reaction showing the pre-steady-state (msec), the constant rate, and the declining rate parts of the progress curve. (From Ref. 1)

lyzed reactions as a function of substrate concentration,  $[A]$ , resulted from an obligatory intermediate, the enzyme-substrate complex,  $[EA]$ , prior to product,  $P$ , formation [Eq. (1)]:

Based on this premise, which has been shown now to be universal for all enzyme-catalyzed reactions, Michaelis and Menten in 1913 (4) developed an equation to numerically describe the observed relationship between velocity,  $v$ , and  $[A]$ . The derivation of the Michaelis-Menten equation is shown below, using the more modern concepts of initial velocity  $v_o$ , and the steady-state assumption. The EA complex has a non-covalent bond.

Let  $[E]_o$  = total enzyme concentration

$[A]_o$  = total substrate concentration, which is assumed to be much larger than  $[E]_o$ ; therefore,  $[A] = [A]_o$  during initial velocity,  $v_o$ , measurements ( $< 5\% A$  converted to  $P$  during time of experiment)

$[EA]$  = enzyme-substrate concentration, which is a noncovalent complex

$[P]$  = product concentration (one product is formed in the general derivation; more than one product may be formed and released in a sequential manner in many examples)

$[E]$  = free enzyme concentration

The rate of formation of  $EA$  is [see Eq. (1)]:

$$dEA/dt = k_1[E][A]_o \quad (2)$$

While the rate of disappearance of  $EA$  is

$$-dEA/dt = k_{-1}[EA] + k_2[EA] \quad (3)$$

When steady-state conditions are reached (within a few msec),  $dEA/dt = -dEA/dt$  so that

$$k_1[E][A]_o = k_{-1}[EA] + k_2[EA] = (k_{-1} + k_2)[EA] \quad (4)$$

Rearranging:

$$[E][A]_o/[EA] = (k_{-1} + k_2)/k_1 = K_m \quad (5)$$

$K_m$ , the Michaelis constant, is given by either  $[E][A]_o/[ES]$  or  $(k_{-1} + k_2)/k_1$ .

The free enzyme concentration,  $[E]$ , cannot be measured experimentally but it is related to  $[E]_o$  by the conservation equation

$$[E] = [E]_o - [EA] \quad (6)$$

Substitution of Eq. (6) for  $[E]$  in Eq. (5) gives

$$\begin{aligned} ([E] - [EA])[A]_o/[EA] &= K_m = [E]_o[A]_o \\ &\quad - [EA][A]_o/[EA] \end{aligned} \quad (7)$$

Rearranging Eq. (7):

$$[E]_o[A]_o = K_m[EA] + [EA][A]_o = [EA](K_m + [A]_o) \quad (8)$$

Rearranging Eq. (8):

$$[EA] = [E]_o[A]_o(K_m + [A]_o) \quad (9)$$

$[EA]$  cannot be determined directly in most cases but it can be substituted for since the rate of formation of product,  $P$ , is

$$dP/dt = k_2[EA] = v_o \quad (10)$$

Rearranging Eq. (10):

$$[EA] = v_o/k_2 \quad (11)$$

Therefore

$$v_o = k_2[E]_o[A]_o/(K_m + [A]_o) \quad (12)$$

The maximum velocity,  $V_{max}$ , is attained when all active sites of the enzyme are combined with substrate so that  $[EA] = [E]_o$ . Therefore,

$k_2[E]_o$  equals  $V_{max}$  and Eq. (12) gives Eq. (13):

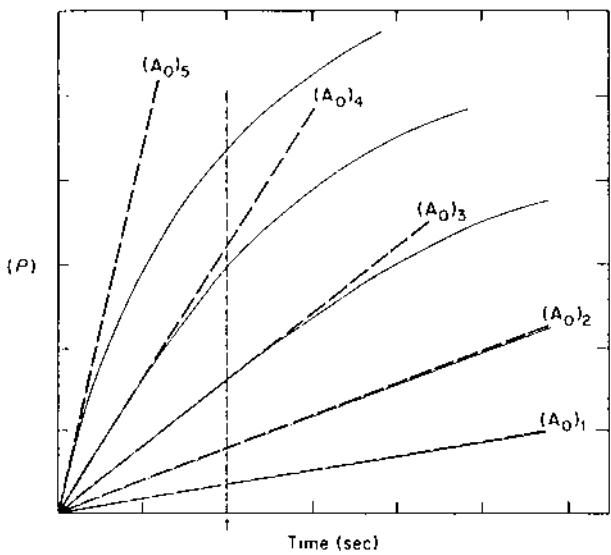

$$v_o = V_{max}[A]_o/(K_m + [A]_o) \quad (13)$$

### C. Concept of Initial Velocity in Enzymology

The importance of determining the initial velocity of enzyme-catalyzed reactions was not fully appreciated and articulated until the early 1960s. Up to that time, rates of enzyme-catalyzed reactions were frequently based on one-point assays—i.e., at a given time of the reaction. Also, reactions often were designed so that many minutes or hours were used in the assays. Another reason is that the kinetics of non-enzyme-catalyzed reactions by chemists are designed to determine the order of reactions which must be done under conditions of several half-lives of the reaction; i.e.,  $> 90\%$  of the substrate must be converted to product to give four half-lives.

The order of chemical reactions is of major importance in determining the mechanisms of reactions. Often the order is not zero, first or second order, but is a fractional order (such as 1.5 for example). Not so with enzyme-catalyzed reactions, which are first, zero, or mixed order, depending on  $[A]_o$  in relation to  $K_m$  for reasons explained later in this chapter.

Figure 2 shows the results of determining the velocity of an enzyme-catalyzed reaction at the same pH,

**Figure 2** Method of determining initial velocities of reaction. The solid lines are the experimentally determined data; the dashed lines are tangents drawn to the initial slope of the experimental data in order to determine the initial velocity,  $v_0$ . (From Ref. 1.)

temperature, and cofactor concentration (if needed), but at different substrate concentrations. At low substrate concentrations the experimental lines (solid) and the initial velocity ( $v_0$ ) lines (dashed) coincide because the concentration of product formed is < 5 % of the original substrate concentration. As the substrate concentration is increased, and the rate of formation of product increases (data for  $[A]_{03}$ ,  $[A]_{04}$ , and  $[A]_{05}$ ) the experimental and  $v_0$  values diverge more and more.

There are several reasons why the experimental lines and the  $v_0$  lines are not the same and why initial velocities,  $v_0$ , are important in enzymology. Use of  $v_0$  has the advantages of (a) not being greatly affected by instability of the enzyme (the reaction should be initiated by adding the enzyme last), (b) not being influenced by product concentration since this is zero initially (product can influence the velocity by being a competitive inhibitor or by giving backward reaction), and (c) the initial substrate concentration changes very little in the reaction (when < 5% product is formed during determining of  $v_0$ ).

With modern-day instrumentation, including recorders, it is possible to determine  $v_0$  with excellent precision using 5 min, or less, overall reaction times. There are no reasons why data based on single data point assays should ever be reported in enzymology.

## D. Rates of Enzyme-Catalyzed Reactions

As will be shown later in this chapter, the velocities of enzyme-catalyzed reactions depend on substrate concentration, enzyme concentration, cofactor concentration, inhibitor concentration, pH, and temperature. We will discuss each of these factors separately. But at this point, it is useful to provide some data on some numerical values of the velocity constants shown in Eq. (1) calculated to 1 molar concentrations of enzymes and substrates at the pH optimum and standard temperature (usually 25–30°C).

Velocity constants ( $k_1$ ) for formation of the enzyme-substrate complex are in the range of  $10^4$ – $10^9 M^{-1} \text{ sec}^{-1}$  for the enzymes given in Table 1(5); these values are typical for many other enzymes. However, there are exceptions where the formation of the complex can be the rate-controlling step as for lactate dehydrogenase combining with the cofactor  $\text{NAD}^+$  ( $\sim 50 M^{-1} \text{ sec}^{-1}$ ).

The dissociation constant of the  $EA$  complex,  $k_{-1}$ , ranges from < 1.4 to  $3.1 \text{ sec}^{-1}$  for peroxidase and liver alcohol dehydrogenase, respectively, to  $> 4.5 \times 10^4 \text{ sec}^{-1}$  for fumarase (Table 1). The overall molar catalytic rate constant  $k_o$  [ $k_2$  in Eq. (1), often called  $k_{\text{cat}}$  because more than one step may be involved] ranges from  $10^1 \text{ sec}^{-1}$  for papain to  $10^7 \text{ sec}^{-1}$  for catalase. Therefore, one must conclude that  $k_1$ ,  $k_{-1}$ , and  $k_2$  differ markedly among enzymes. Some enzymes are more efficient than others as measured numerically by the ratio of  $k_o/K_m$ , a generally accepted measure since it includes all the rate constants of Eq. (1). The “goodness” of different substrates for the same enzyme is also measured by  $k_o/K_m$ .

## II. EFFECT OF SUBSTRATE CONCENTRATION ON RATES OF ENZYME-CATALYZED REACTIONS

Section I has treated effect of substrate concentration on rates of enzyme-catalyzed reactions in a general way. Section II will deal with more specific details of how to determine  $K_m$  and  $k_o$  for one- and two-substrate enzymes, as well as allosteric behavior of enzyme–substrate interactions.

### A. Initial Velocity vs. Substrate Concentration

This section will deal only with enzyme–substrate relationships obeying Michaelis-Menten kinetics. The expected relation between  $v_0$  and  $[A]_0$  is shown in

**Table 1** Rate Constants for Some Selected Enzymes

Enzyme	Substrate	$k_1^a$ ( $M^{-1} \text{ sec}^{-1}$ )	$k_1^b$ ( $\text{sec}^{-1}$ )	$k_0^c$ ( $\text{sec}^{-1}$ )
Fumarase	Fumarate	$> 10^9$	$> 4.5 \times 10^4$	$10^3$
Acetylcholinesterase	Acetylcholine	$10^a$	—	$10^3$
Liver alcohol dehydrogenase	$\text{NAD}^+$	$5.3 \times 10^5$	74	$10^3$
	NADH	$1.1 \times 10^7$	3.1	
	Ethanol	$> 1.2 \times 10^4$	$> 74$	
Catalase	$\text{H}_2\text{O}_2$	$5 \times 10^6$	—	$10^7$
Peroxidase	$\text{H}_2\text{O}_2$	$9 \times 10^6$	$< 1.4$	$10^6$
Hexokinase	Glucose	$3.7 \times 10^6$	$1.5 \times 10^3$	$10^3$
Urease	Urea	$> 5 \times 10^6$	—	$10^4$
Chymotrypsin				$10^2$ to $10^3$
Trypsin				$10^2$ to $10^3$

<sup>a</sup>Rate constant for formation of enzyme–substrate complex.

<sup>b</sup>Rate constant for dissociation of enzyme–substrate complex.

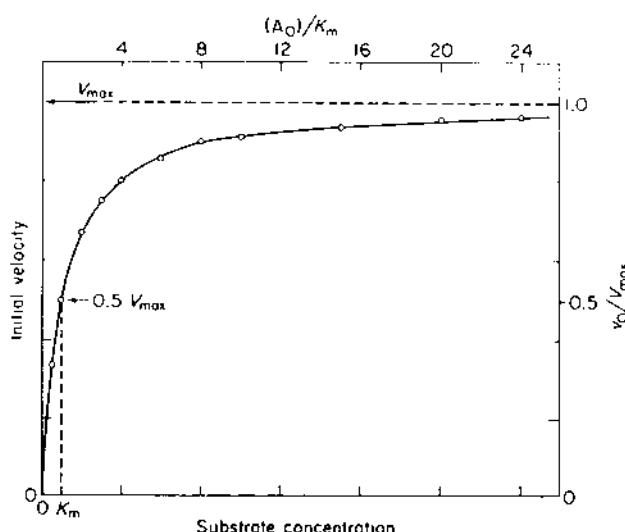

<sup>c</sup>Order of magnitude of the turnover number in moles of substrate converted to product per second per mole of enzyme:  $k_0$  ( $= k_{\text{cat}}$ ) is the observed rate constant and may or may not involve a single rate-limiting step.

Source: Ref. 5.

Figure 3. At low substrate concentrations ( $[A]_o \leq 0.05 K_m$ ) the order of the reaction with respect to  $[A]_o$  is first order and fits Eq. (14).

$$dA/dt = k[A]_o = -dp/dt \quad (14)$$

At very high  $[A]_o$  ( $[A]_o \geq 100 K_m$ ), the enzyme is  $> 90\%$  saturated with substrate. Thus, the rate is independent of  $[A]_o$ , and is zero order. This is described by Eq. (15).

**Figure 3** Variation of initial velocity,  $v_o$ , with substrate concentration for an enzyme-catalyzed reaction. (From Ref. 1.)

$$dA/dt = k = -dp/dt \quad (15)$$

It is often difficult, if not impossible, to do reactions at  $> 100 K_m$  because of (a) insolubility of the substrate, (b) cost of the substrate, or (c) the high substrate concentration becomes inhibitory of the enzyme as two molecules bind to the enzyme simultaneously, one as the substrate and the second as an inhibitor. Such behavior is observed frequently.

Between  $[A]_o \leq 0.05 K_m$  and  $[A]_o \geq 100 K_m$  is where most of the effect of  $[A]_o$  on  $v_o$  is found and where most experiments are performed. Over this range of  $[A]_o$ , the order of the reaction is mixed order; i.e., it is the sum of first order and zero order as shown by Eq. (16), which is the differentiated form of the Michaelis-Menten equation [see Eq. (12)].

$$[E]_o k_o t = 2.3 K_m \log[A]_o / ([A]_o - [P]) + [P] \quad (16)$$

At  $[A]_o < 0.05 K_m$ , the first-order term,  $2.3 K_m \log[A]_o / ([A]_o - [P])$  predominates, while at  $[A]_o > 100 K_m$ , the zero-order term  $[P]$  predominates. At  $[A]_o = K_m$  the two terms are equally predominate.

### 1. Determination of $K_m$ and $V_{\max}$ for One-Substrate Reactions

For reasons discussed above,  $K_m$  and  $V_{\max}$  cannot be precisely determined from a plot of  $v_o$  vs.  $[A]_o$ , primarily because  $V_{\max}$  cannot be experimentally determined.

In 1934 Lineweaver and Burk (6) published a milestone paper showing that by taking the reciprocal of the Michaelis-Menten equation, a straight line relationship between  $1/v_o$  and  $1/[A]_o$  is obtained, which gives  $K_m$  and  $V_{\max}$  as shown by Eq. (17) and Figure 4.

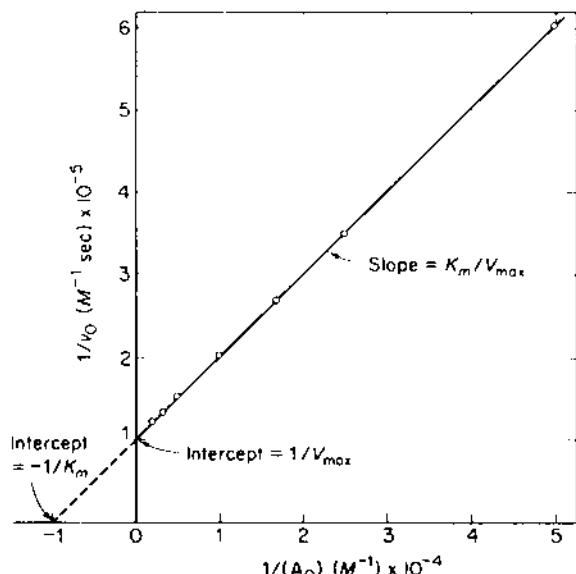

$$1/v_o = K_m/(V_{\max}[S]_o) + 1/V_{\max} \quad (17)$$

The intercept on the y-axis is  $1/V_{\max}$  and the slope of the line is  $K_m/V_{\max}$ . The intercept on the  $-x$  axis is  $-1/K_m$ . This is one of the most cited references in the kinetics of enzymology.

Later on, Augustinsson and Eadie and Hofstee (see Ref. 1) rearranged the Lineweaver-Burk equation to two other linear transforms of the Michaelis-Menten equation. For whatever reason, these two methods are rarely used, but they can be useful analyses as in more complex reaction pathways they may give curvilinear relationships indicating the reaction may contain additional intermediates. In 1954, King and Altman (7) published a useful method for determining the equation for more complex enzyme-catalyzed reactions (see Ref. 1).

## 2. Determination of $K_m$ and $V_{\max}$ for Two-Substrate Reactions

There are relatively few one-substrate reactions in enzymology. Most of these occur in the class EC 5

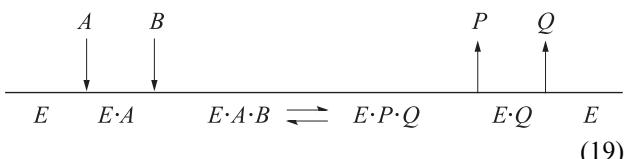

**Figure 4** Plot of the reciprocal of initial velocity,  $v_o$ , versus reciprocal of initial substrate concentration,  $[A]_o$ , according to the Lineweaver-Burk method. (From Ref. 1.)

enzymes. (For the isomerases see Chapter 3). For the class EC 3 enzymes, the hydrolases are pseudo-first-order reactions in that the second substrate is water. At 55.4 M water concentration compared to  $10^{-4}$ – $10^{-2}$  M for the second substrate, the change in water concentration during the reaction is very small and is ignored.

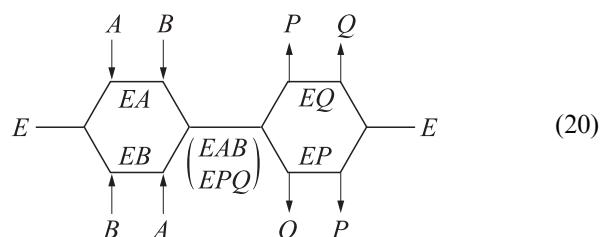

In the late 1950s and early 1960s, attention was given to development of equations for two and more substrate enzyme reactions (see Chapter 1 on protein structure and kinetics). Cleland, in a series of papers, provided a clear rationale for dealing with these reactions which follow the general Eq. (18) for two substrate/two product reactions.

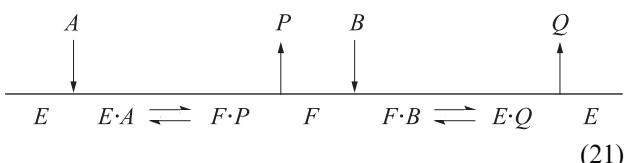

He developed equations for when  $A$  must bind in the active site of the enzyme before  $B$  can bind [Ordered Mechanism; Eq. (19)];

when either  $A$  or  $B$  can bind first to the enzyme active site [Random Mechanism; Eq. (20)];

and when  $A$  binds first and is converted to product before  $B$  binds and is converted to product [Ping Pong Mechanism; Eq. (21)].

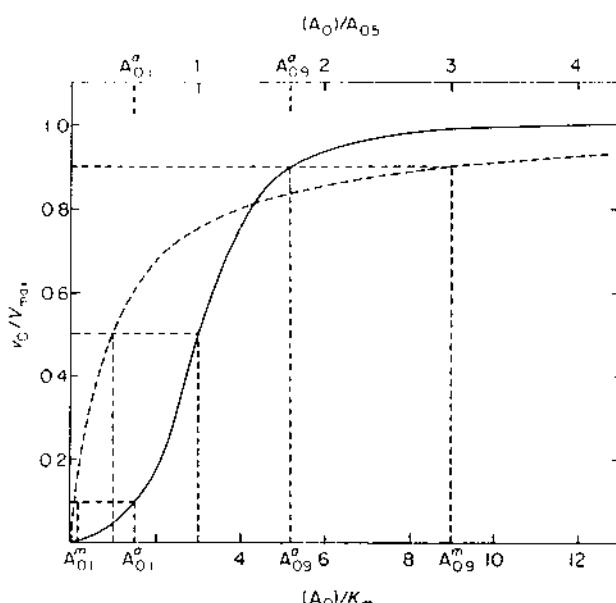

These are very important concepts and equations for the serious enzymologist. More information on this subject is found in the three key articles by Cleland (8). A detailed discussion is found in Whitaker (1) on how to experimentally translate these concepts into practice.

### 3. Behavior in Multisite–Multisubunit Enzymes

Many enzymes have multiple subunits, each with a substrate binding and catalytic site for substrate(s). Some enzymes have two or more domains (independent folding segments on the same polypeptide chain) that bind, and may catalyze substrates to products. If each of the active sites binds and catalyzes the substrate independently of other active sites, then the kinetics follow Michaelis-Menten behaving enzymes. On the other hand, if binding of substrate into an active site affects either binding or catalysis in a second active site, then the kinetics do not follow expected Michaelis-Menten kinetics.

a. *Multiple-Subunit Enzymes.* As demonstrated by Monod et al. in 1965 (9), some multiple-subunit enzymes give the kinetic behavior shown in Figure 5 for a plot of  $v_o$  vs.  $[A]_o$ . Note the marked difference between the curves for the allosteric-behaving enzyme and the Michaelis-Menten-behaving enzyme. The allosteric-behaving enzymes follow Eq. (22):

$$v_o = V_{\max}[A]_o^n/(K + [A]_o^n) \quad (22)$$

**Figure 5** Comparison of effect of substrate concentration, relative to  $K_m$ , versus initial velocity,  $v_o$ , relative to  $V_{\max}$  for a Michaelis-Menten-behaving enzyme (dashed line) versus a positive allosteric-behaving enzyme (solid line). The vertical and horizontal dashed lines are for calculating  $R_s = [A]_o$  at  $0.9 v_o/V_{\max}/[A]_o$  at  $0.1 v_o/V_{\max}$  for the Michaelis-Menten-behaving enzyme and for the allosteric-behaving enzyme. (From Ref. 1.)

where the substrate concentration is raised to power of  $n$ . For linear plotting, Eq. (22) is rearranged to Eq. (23).

$$\log v_o/(V_{\max} - v_o) = n \log [A]_o - \log K \quad (23)$$

where  $n$  is the product of the number of subunits and strength of binding of substrate of interacting sites and  $K$  is the average of all the individual  $K_{eq}$  values involved in the various steps of binding and transformation of substrate to product.

Koshland et al. (10) developed an equation to measure the cooperativity of the interaction based on the experimental data. This is given in Eq. (24).

$$R_s = [A]_o \text{ at } 0.9 v_o/V_{\max}/[A]_o \text{ at } 0.1 v_o/V_{\max} \quad (24)$$

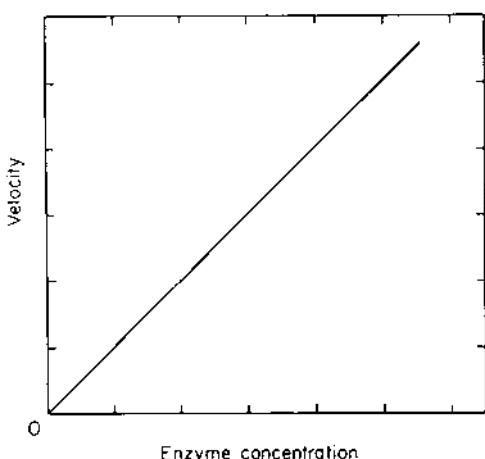

For a Michaelis-Menten-behaving enzyme,  $R_s$  is 81. For a positive allosteric-behaving enzyme,  $R_s$  is  $< 81$  while for a negative allosteric behaving enzyme  $R_s$  is  $> 81$  (see Fig. 5).

b. *Single Active Site, Multiple-Substrate Binding Enzymes.* Examples of this type of enzyme are trypsin and carboxypeptidase A. A substrate molecule that binds into the active site is converted to product. If a second substrate molecule binds at a second site and increases the rate of catalysis at the active site, it is an activator; if the rate is reduced on binding of the second substrate molecule, it is an inhibitor. Generally,  $K_{eq}$  for binding of the second substrate molecule is about 10 times larger than is  $K_m$  for the active site bound substrate molecule.

### III. EFFECT OF ENZYME CONCENTRATION ON RATE OF ENZYME-CATALYZED REACTIONS

Rates of enzyme-catalyzed reactions are generally expected to be directly proportional to the enzyme concentration as shown in Figure 6. This relationship between  $v_o$  and  $[E]_o$  holds whatever the  $[A]_o$  is with respect to  $K_m$  as long as all other conditions are held constant and initial velocities are used.

This linear relationship between  $v_o$  and  $[E]_o$  is very important from an analytical perspective. Any analysis where  $[E]_o$  is important to know depends on this relationship. In the food, nutritional, and medical fields, enzyme assays are used to determine how much active enzyme is present. In the frozen food industry, for example, polyphenol oxidase,  $\alpha$ -amylase, and protease activities affect the storage stability and storage time of the product. Levels of selected enzyme activities of blood are used in diagnostics of diseases and bacterial

**Figure 6** Expected relationship between initial velocity and enzyme concentration. Substrate concentration, pH, temperature, and buffer are kept constant. (From Ref. 1.)

infections. Purity of enzymes are based on their specific activities (activity/mg protein) and the absence of unwanted activities.

But one must not assume that the linear relationship shown in Figure 6 holds. It is the responsibility of the enzyme user to prove this relationship holds under the conditions used. There are at least five valid reasons why the relationship between  $v_o$  and  $[E]_o$  can be nonlinear (1). These are listed below. More details can be found in Whitaker (1).

#### A. Limitations on Substrate Concentration

1. One of the Substrates is a Gas, Such as Oxygen

Oxygen has limited solubility in aqueous solution. The solubility of  $O_2$  is 0.24 mM at 25°C. In such reactions, the analyst usually depends on the  $O_2$  used to be replenished by absorption from the atmosphere to maintain a constant  $O_2$  concentration. As the  $[E]_o$  is increased, the rate of depletion of  $O_2$  is increased. This often leads to a nonlinear relation between  $v_o$  and  $[E]_o$ . Only by adequate stirring rate or bubbling 100%  $O_2$  through the solution can the  $O_2$  concentration be kept constant.

2. The Substrate Is a Polymer

Starch, largely a homopolymer, is used often to measure  $\alpha$ - and  $\beta$ -amylase activities. As hydrolysis occurs, the product fragments continue to be substrates. Initially, the molar concentration of substrates

increases. As the substrate size decreases the  $K_m$  may increase so that the enzyme is less saturated with substrate. Therefore, there may be changes in  $v_o$  as a function of  $[E]_o$ .

Proteins are heteropolymers, being composed of 20 different amino acid residues. Proteases hydrolyze peptide bonds selectively based on their specificity for the amino acid residues on either side of the peptide bond. Trypsin will be used as a specific example of a protease. It hydrolyzes peptide bonds only where a lysyl or arginyl residue provides the carboxyl group of the peptide bond. The nitrogen side of the peptide bond can be any of the 20 amino acids. However, the relative rate of hydrolysis of the peptide bond is affected by the specific nature of the amino acid. Thus, there are a minimum of 40 different rates of hydrolysis, not counting the decreasing size of the peptides. The best peptide bonds are hydrolyzed more rapidly than the less good bonds. This leads to a decrease in  $v_o$  vs.  $[E]_o$  as the enzyme concentration increases.

#### B. Coupled Enzyme Reactions

A coupled enzyme reaction is given by Eq. (25) where

Substrate  $A$  is converted to product  $B$  by enzyme  $E_1$ . But  $B$  may be hard to determine analytically so  $E_2$  is also added to the reaction to convert product  $B$  to product  $C$ , which can be more readily determined (e.g., by spectrophotometry). To be successful with the assay,  $B$  must be converted to  $C$  just as fast as it is produced, so that the rate-determining step remains  $A$  to  $B$  conversion even as  $[E]_o$  is increased. Several commercially available enzyme kits for enzyme analyses depend on coupled reactions.

Similar problems may arise when two coupled enzyme reactions depend on a common cofactor, such as  $NAD^+$ . As the concentration of  $E_1$  is increased it may limit the concentration of  $NAD^+$  required by  $E_2$ .

#### C. Presence of Irreversible Inhibitor in Reaction System

Examples of irreversible inhibitors are  $Pb^{2+}$ ,  $Hg^{2+}$ , and  $Ag^+$  ions that might be in the water used. Sulfhydryl enzymes (where the sulfhydryl group of cysteine is essential for enzyme activity), which are 25–30% of all enzymes, would be affected. Experimentally, no enzymatic activity would be

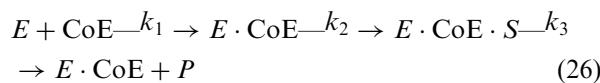

found until sufficient enzyme is added to bind all the inhibitor. Then, enzyme activity will be seen. This case is easily recognized as the intercept on the x-axis of the  $v_o$  vs.  $[E]_o$  plot would be on the right side of the zero intercept.

#### D. Presence of Reversible Inhibitors in the System

The amount of inhibition found would be dependent on the substrate concentration used (the lower the  $[A]_o$ , the greater the effect) and the enzyme concentration. In general, there would be a nonlinear response between  $v_o$  and  $[E]_o$ , with a downward curvature of the relationship between  $v_o$  and  $[E]_o$ .

#### E. Need for an Essential Coenzyme (CoE)

A coenzyme is a nonenzyme compound that binds reversibly in the active site of the enzyme and is required for enzyme activity. The B vitamins, for example, are a part of a coenzyme (see Sec. IV). The example is best illustrated by use of Eq. (26).

At a fixed concentration of CoE and a low  $[E]_o$ , not all the enzyme may be bound to CoE to give  $E \cdot \text{CoE}$ , which is required for the substrate to bind. As  $[E]_o$  increases, more CoE will be bound owing to mass

action effect, and  $v_o$  will increase. Such effects were observed as early as the 1940s and were called "dilution effects," meaning as one diluted the enzyme concentration the activity observed was less than that expected.

### IV. KINETIC CONSEQUENCES OF COFACTORS

#### A. Nature and Essentially of Cofactors

Cofactors are small, mostly nonpeptide compounds which are required for activity of some enzymes. These include organic compounds, such as  $\text{NAD}^+$  (nicotinamide adenine dinucleotide), FAD (flavin adenine dinucleotide), coenzyme  $B_{12}$ , triphosphates of adenosine (ATP), cytidine (CTP), and uridine (UTP), as well as many others (see Ref. 1 and references cited therein). They also include many inorganic cations and anions as well as metallo derivatives of organic compounds (coenzyme  $B_{12}$ , metal-porphyrin cofactors). See Table 2 for some specific examples.

The cofactors are essential components of the active site of many enzymes. They may be required for binding of the substrate into the active site and/or they may be essential for the chemical conversion of the substrate(s) to product(s). Therefore, in most cases they are absolutely essential for activity of the enzyme. Two examples, of many, explain this importance. There are > 150 enzymes in the human that require  $\text{Zn}^{2+}$  as a

**Table 2** Importance of Phosphate, Ribose, and Purine and Pyrimidine Bases in Cofactors

Enzyme	Cofactor	Vitamin	Phosphate	Ribose	Base
Oxidoreductases	$\text{NAD}^+$	Niacin	+	+	Adenine

Source: Ref. 1.

cofactor. Without adequate  $Zn^{2+}$  intake, which can be compromised by dietary compounds such as phytic acid, by pregnancy, etc.,  $> 150$  enzymes may not function at desirable rates. The second example is for the  $Fe^{3+}$ -prophyrin-containing enzymes catalase and peroxidase. The  $Fe^{3+}$ -prophyrin alone converts  $H_2O_2$  to  $O_2$  and water at the rate of about  $10\text{ sec}^{-1}$ . The protein portion of the enzyme alone has no activity on  $H_2O_2$ . The complete enzyme has a catalytic rate of  $10^7$  moles  $H_2O_2$  converted to product per second per mole of catalase (turnover No.).  $H_2O_2$  is formed by metabolic processes of the cells. It has strong oxidative activity on cellular components. It is absolutely essential to convert  $H_2O_2$  to  $O_2$  and water as fast as it is formed.

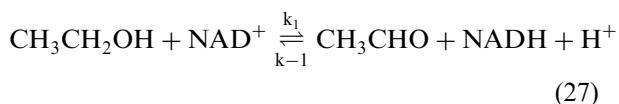

## B. Unique Features of Cofactors

Only limited examples of unique features of cofactors can be given in this chapter. The reader is referred to Whitaker (1) and specific references therein devoted to detailed treatment of this very large topic.

### 1. Two Types of Cofactors

Mechanistically, the cofactors can be divided into two groups, the coenzymes and the prosthetic groups. The coenzymes are loosely bound to the protein and generally act as a substrate in the catalyzed reaction. The prosthetic groups are more tightly bound, some covalently, and they are regenerated to the starting form at the end of the reaction. An example of each type will clarify these differences.

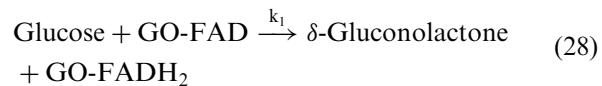

There are many enzymes that require  $NAD^+$  or  $NADH$  as coenzymes. The reaction catalyzed by alcohol dehydrogenase is shown in Eq. (27).

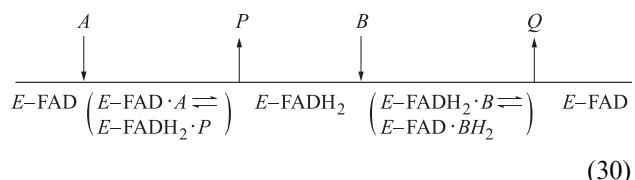

This is a reaction requiring the substrate ethanol and the coenzyme  $NAD^+$ .  $NAD^+$  must bind to the enzyme first, followed by binding of the ethanol. After catalysis, the product acetaldehyde dissociates from the enzyme, followed by  $NADH$ . This is an ordered BiBi Mechanism (see Sec. II.A.2). The reaction is a two-substrate–three-product (counting the  $H^+$ ) reaction. It is a reversible reaction with the backward reaction favored. Coenzymes, being loosely bound to the enzyme, are generally lost during purification of the enzyme. The researcher must add the coenzyme back to the inactive enzyme to restore activity. The concentration of both the apoenzyme and coenzyme will

determine the overall rate of the reaction. The maximum rate,  $V_{max}$ , will be obtained when all the enzyme is in the  $E \cdot CoE \cdot A$  form.

Glucose oxidase (GO-FAD) is a typical example of an enzyme that requires a prosthetic group for activity. This enzyme requires FAD (flavin adenine dinucleotide) as the prosthetic group. FAD is bound tightly to the enzyme so that it is not lost during purification or during the reaction as shown by Eqs. (28) and (29).

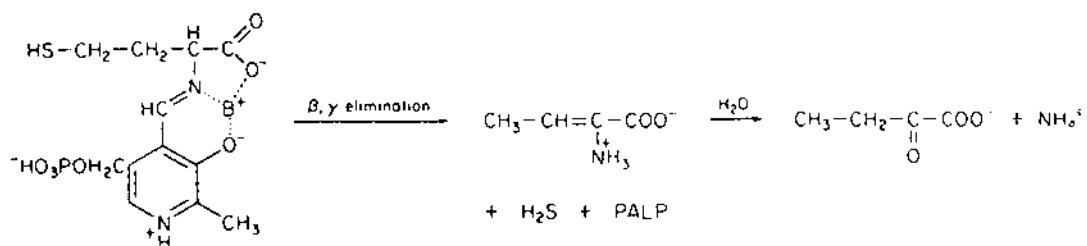

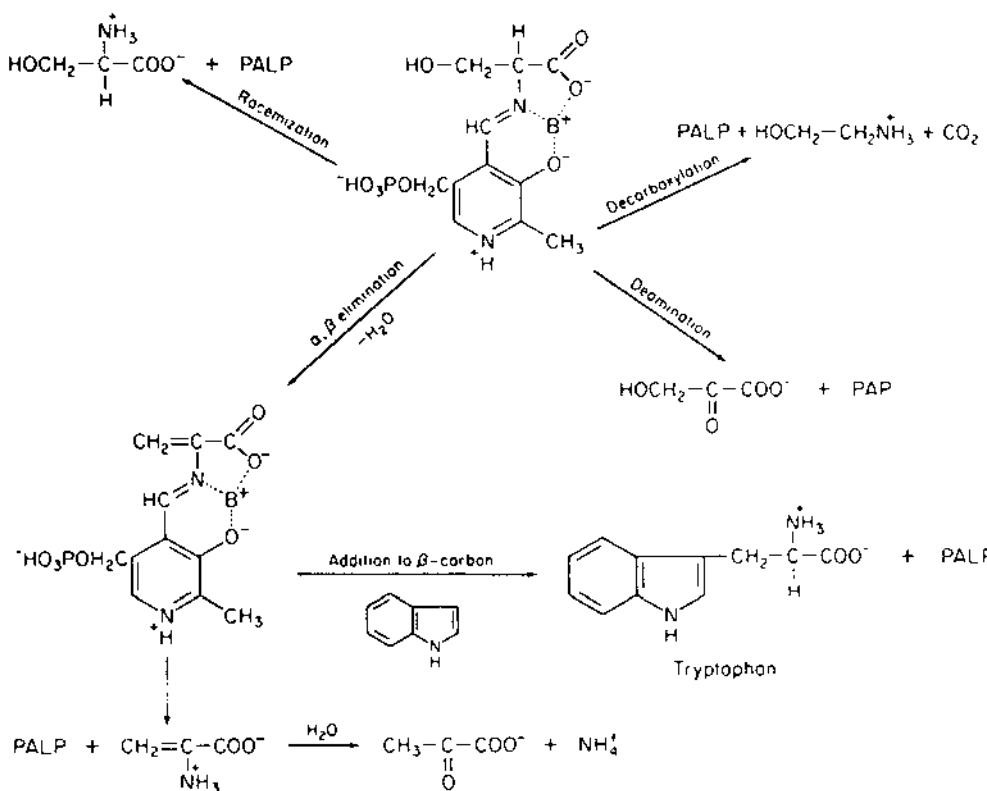

These reactions [Eqs. (28) and (29)] follow a Ping-Pong BiBi Mechanism, as described by the Cleland nomenclature (Eq. 30).

Note that the prosthetic group FAD remains bound tightly to the enzyme ( $E\text{-FAD}$  indicates covalent bond), the  $E\text{-FAD}$  is reduced to  $E\text{-FADH}_2$  by removal of the two hydrogens from  $C_1$  of glucose and that the  $E\text{-FADH}_2$  is oxidized back to  $E\text{-FAD}$  by  $O_2$ , permitting it to be recycled catalytically in the process. The reaction takes place in two steps with only one substrate bound to the enzyme at a time.

### 2. Same Cofactor, Different Reactions

Earlier in this chapter, it was stated that  $Zn^{2+}$  serves as cofactor for  $> 150$  different enzyme-catalyzed reactions. But the example chosen here to explain this concept is the prosthetic group pyridoxal phosphate. Pyridoxal phosphate is involved in amino acid conversion to different products, as shown in Figure 7. The prosthetic group binds to the amino acid in the same way, forming a Schiff base intermediate, as shown by the upper central formula. Which of the reactions is catalyzed depends on the specificity of the protein (apoenzyme) and the specific nature of the amino acid. Therefore, pyridoxal phosphate and apoenzyme together bind to the amino acid (substrate) to perform racemization, decarboxylation, deamination,  $\alpha,\beta$  elimination,  $\beta,\gamma$  elimination, and addition reactions (to indole to form tryptophan) to give a variety of products.

**Figure 7** Schematic representation of six enzyme reactions in which pyridoxal phosphate is the cofactor. A common Schiff base intermediate between serine and pyridoxal phosphate is shown in the upper center. The type of enzyme involved determines the nature of the reaction. (From Ref. 1.)

## V. KINETIC CONSEQUENCES OF ENZYME INHIBITORS

### A. Nature of Inhibitors

Enzyme inhibitors are defined as any compound, except  $\text{H}^+$  ions (see pH effects), which decrease the activity when added to an enzyme reaction. Many enzyme inhibitors are known. They are used to kill insects or unwanted plants (herbicides) or animals (rotenone). They are used to prevent browning or preserve “fresh-

ness” of fruits and vegetables. Many pharmaceutical compounds are designed to kill microorganisms by selectively inhibiting their enzyme systems.

Mechanistically, there are two major groups of enzyme inhibitors. One group inhibits enzymes by reactions involving covalent bond formation (irreversible inhibitors); the other group inhibits enzymes by reversible noncovalent bond formation (reversible inhibitors). Both types are important as they decrease or eliminate enzyme activity.

The rate and extent of inhibition of enzymes by irreversible inhibitors will depend on concentration of inhibitor, concentration of the enzyme, and the specific group modified on the enzyme, as well as pH and temperature. The rate of the inhibition will be relatively slow (minutes or hours) as a covalent bond is formed. The reaction cannot be reversed to regain enzyme activity.

## B. Reversible Inhibitors

The rate and extent of inhibition of enzymes by reversible inhibitors also depend on the factors listed above. However, the rate of inhibition is very rapid (msec) as a noncovalent complex is formed. Also, the inhibition can be reversed by removing the inhibitor (by dialysis or gel filtration). Our attention in this chapter is focused on the reversible enzyme inhibitors. Defined kinetically, a reversible inhibitor is one that reacts with an enzyme in a reversible manner as shown in Eq. (32), where  $K_i$  is an equilibrium (dissociation) constant.  $K_i = [E][I]/E \cdot I$ .

The reaction occurs within a few msec and the extent of inhibition is controlled by the concentration of  $E$  and  $I$  and  $K_i$ . Generally,  $K_i$  for the reversible inhibitors will be in the range of  $10^{-2}$ – $10^{-7}$  M. If the  $K_i$  is  $\leq 10^{-8}$  M, the dissociation rate is so slow that there is not a true equilibrium of the process when perturbed by addition of substrate.

Based on their different effects on the rates of enzyme-catalyzed reactions, the reversible inhibitors can be divided into three types, as shown in Figure 8. The three types are the competitive inhibitors (C), noncompetitive inhibitors (N), and the uncompetitive inhibitors (U). The competitive inhibitors (C) compete with the substrate for binding to the active site of the enzyme. Therefore, the equilibrium involves the species  $E$ ,  $EA$ , and  $EC$  and the free  $A$  and  $C$  (Fig. 8). The noncompetitive inhibitors (N) affect the rate of the enzyme-catalyzed reaction by binding outside the active site in a way that permits substrate to bind into the active site but no catalysis of substrate to product occurs. As shown in Figure 8, the species  $E$ ,  $A$ ,  $EA$ ,  $EA'$ ,  $EN$ ,  $EAN$ ,  $EA'N$ , and  $N$  can be present. The

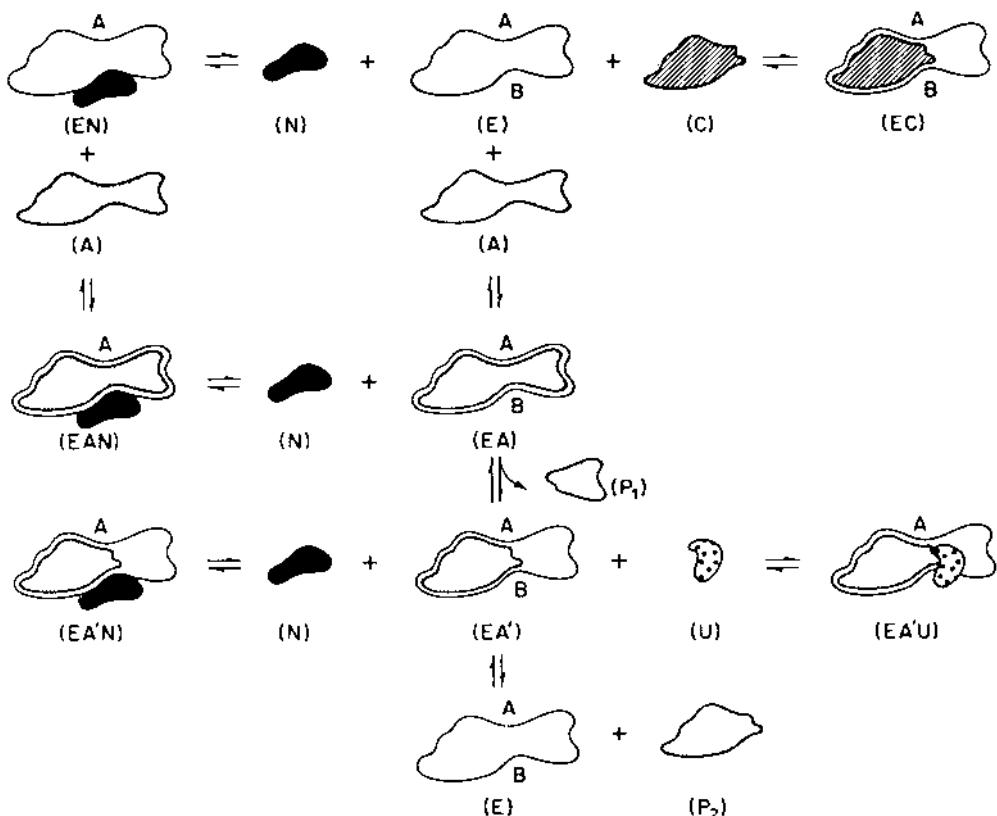

uncompetitive inhibitors (U) bind to the enzyme only after the substrate has bound. The uncompetitive inhibitors can also bind to other intermediate enzyme–product complexes. As shown in Figure 8, at equilibrium the species  $A$ ,  $E$ ,  $U$ ,  $EAU$ , and  $EP'U$  can exist. Actually, the three types of inhibitors are distinguishable only experimentally where different effects on the kinetics are shown. The experiments must be performed in the absence and presence of the reversible inhibitor.

Figure 9 shows the kinetic effect of a competitive inhibitor on the rate of an enzyme-catalyzed reaction, when the data are plotted by the Lineweaver-Burk method. As noted, there is no effect of inhibitor on the y-axis intercept. Therefore  $V (= V_{max})$  is the same in the presence and absence of the competitive inhibitor. But the slope of the line is larger in the presence of the competitive inhibitor, reflecting the effect of the inhibitor on  $K (= K_m)$  for the reaction as shown also by the difference in the  $-x$  intercept. The numerical difference in slopes and  $-x$  intercepts in the presence and absence of inhibitors is  $1 + [I]_o/K_i$ . Knowing the  $[I]_o$  added to the reaction,  $K_i$  can be calculated. These data were determined for a linear competitive inhibitor.

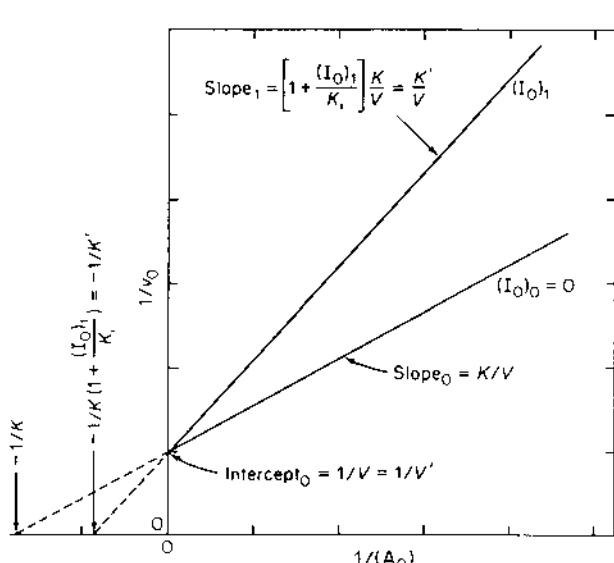

Figure 10 shows the kinetic effect of a noncompetitive inhibitor when added to an enzyme-catalyzed reaction. Again, data must be obtained for a control with no inhibitor and one with a fixed concentration of the inhibitor. Figure 10 shows that both the slope and the y-intercept are changed by the term  $1 + [I]_o/K_i$ . There is no effect on the  $-x$  intercept. This is the definition of a simple linear noncompetitive inhibitor.

Figure 11 shows the effect of an uncompetitive inhibitor when added to an enzyme-catalyzed reaction. Again, a control without inhibitor must be included. There is no effect of the uncompetitive inhibitor on the slope of the lines, while there is a marked difference in the y-intercept (and the  $-x$  intercept). The difference in y-intercept is given by  $1 + [I]_o/K_i$ . The example chosen is for a linear uncompetitive inhibitor.

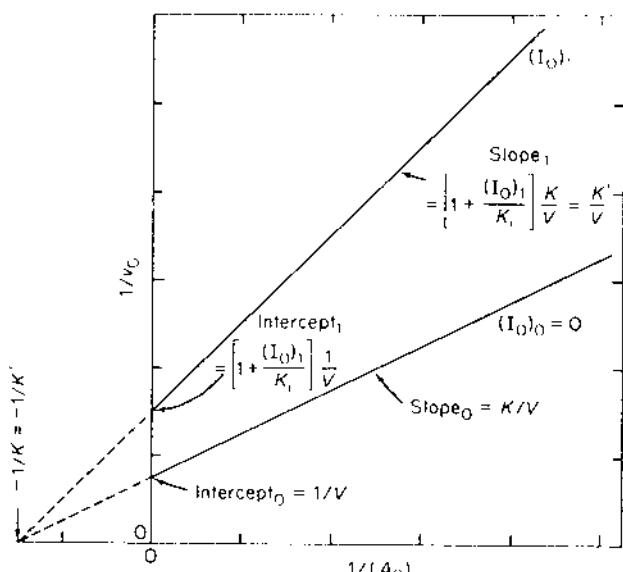

The examples given in Figures 9–11 are linear-behaving inhibitors, as defined in Figure 12. This is determined from a plot of slope (or intercept) vs.  $[I]_o$  where experiments at several different  $[I]_o$  are done. In many cases, one finds that the type of inhibition is linear. Generally, they will be linear for most competitive inhibitors. But for noncompetitive and uncompetitive inhibitors there are more opportunities for observing hyperbolic or parabolic type behavior.

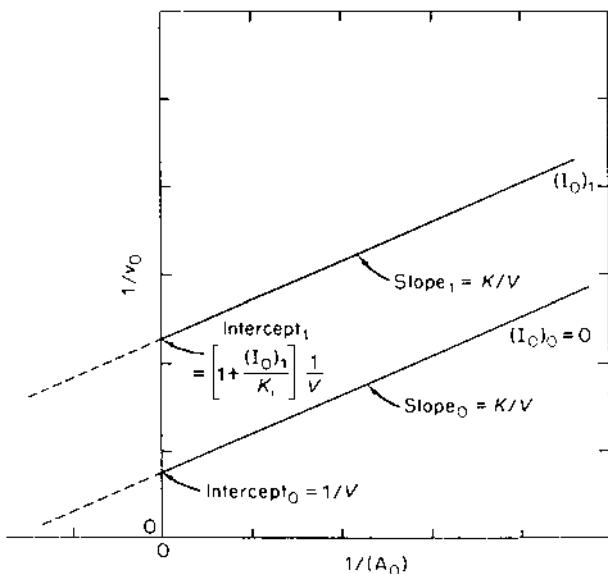

**Figure 8** Schematic representation of inhibition of enzyme activity by various types of reversible inhibitors. The model for E shows only the active site with the binding locus (inner void) and the transforming locus, with catalytic groups A and B. The symbols for the species involved (in parentheses) are: E, free enzyme; EA, enzyme-substrate complex; EA', acylenzyme intermediate; C, competitive inhibitor; N, noncompetitive inhibitor; U, uncompetitive inhibitor; P<sub>1</sub> and P<sub>2</sub> are products formed from the substrate, A, and EN, EAN, EA'N, EC, and EA'U are complexes with respective enzyme species and inhibitors. All complexes formed involve noncovalent bonds except EA', where a covalent bond is formed with catalytic group A. (From Ref. 1.)

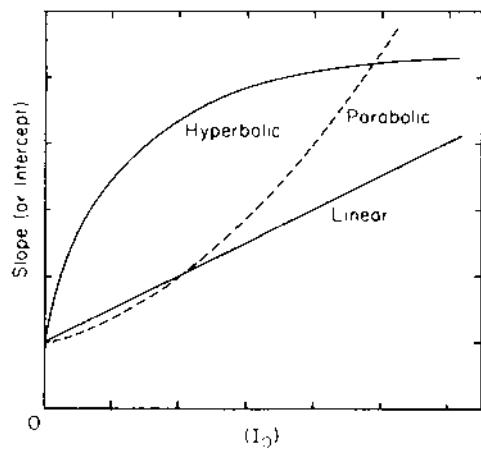

**Figure 9** Linear competitive inhibition, plotted by the Lineweaver-Burk method.  $V = V_{\max}$  in absence of inhibitor.  $V' = V_{\max}(1 + (I_0)/K_i)$  in presence of inhibitor,  $K = K_m$  in absence of inhibitor.  $K' = (1 + (I_0)/K_i)$  in presence of inhibitor. (Ref. 1.)

**Figure 10** Simple linear noncompetitive inhibition, plotted by the Lineweaver-Burk method. See Figure 9 for additional explanation. (From Ref. 1.)

**Figure 11** Linear uncompetitive inhibition, plotted by the Lineweaver-Burk method. See [Figure 9](#) for additional explanation. (From Ref. 1.)

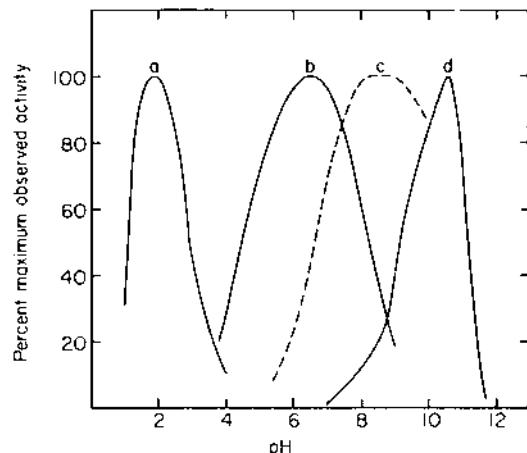

**Figure 12** Linear, hyperbolic, and parabolic inhibition patterns of enzyme reactions. (From Ref. 1.)

## VI. EFFECT OF pH ON ENZYME-CATALYZED REACTIONS

### A. Some Data on pH Versus Activity for Enzymes

Figure 13 shows the effect of pH on activity of porcine pepsin, *Ficus glabrata* peroxidase, bovine trypsin, and milk alkaline phosphatase. The pH activity curves are

**Figure 13** pH effect on activity of several enzymes. (a) Pepsin acting on acetyl-L-phenylalanyl-L-diiodotyrosine at 36.7°C with  $5 \times 10^{-4}$  M pepsin, reaction time 15 min (11). (b) *Ficus glabrata* peroxidase acting on 0.03 M guaiacol and 0.005 M H<sub>2</sub>O<sub>2</sub> at 30.0°C (12). (c) Trypsin acting on casein (13). (d) Hydrolysis of  $5 \times 10^{-4}$  M *p*-nitrophenyl phosphate by crude milk alkaline phosphatase at 35°C in 0.1 M sodium glycinate buffer, reaction time 15 min (J.R. Whitaker, unpublished data). (From Ref. 1.)

generally bell-shaped, but the left side of the pH curve for pepsin and the right side of the pH curve for alkaline phosphatase are steeper than the other side. We will return to this point later. Not all pH activity curves are bell-shaped. They may be sigmoidal or they may be horizontal lines, as is the case for bovine catalase over the pH range of 3–10.

[Table 3](#) lists the pH optima for 24 enzymes. The pH optima range from 2 to pepsin to 10 for alkaline phosphatase. A number of the enzymes have pH optima near pH 7 (in the range of 6–8). In the following section, the question of why enzymes have pH activity optima will be addressed. But it should be clear to the reader that research must determine the effect of pH on an enzyme in order to know the range in which it has activity and at which pH the maximum activity is found.

### B. Why Do Enzyme-Catalyzed Reactions Have pH Optima?

There are two reasons why pH optima are found for enzyme-catalyzed reactions. The first is because of pH instability of the enzymes. The second is because of ionization of groups in the active site of enzymes, of the substrates, or of cofactors.

**Table 3** pH Activity Optimum of Several Enzymes<sup>a</sup>

Enzyme	pH optimum
Acid phosphatase (prostate gland)	5
Alkaline phosphatase (milk)	10
$\alpha$ -Amylase (human salivary)	7
$\beta$ -Amylase (sweet potato)	5
Carboxypeptidase A (bovine)	7.5
Catalase (bovine liver)	3–10
Cathepsins (liver)	3.5–5
Cellulase (snail)	5
$\alpha$ -Chymotrypsin (bovine)	8
Dextran sucrase <i>(Leuconostoc mesenteroides)</i>	6.5
Ficin (fig)	6.5
Glucose oxidase ( <i>Penicillium notatum</i> )	5.6
Lactate dehydrogenase (bovine heart)	7 (forward reaction) 9 (backward reaction)
Lipase (pancreatic)	7
Lipoxygenase-1 (soybean)	9
Lipoxygenase-2 (soybean)	7
Pectin esterase (higher plants)	7
Pepsin (bovine)	2
Peroxidase (fig)	6
Polygalacturonase (tomato)	4
Polyphenol oxidase (peach)	6
Rennin (calf)	3.5
Ribonuclease (pancreatic)	7.7
Trypsin (bovine)	8

<sup>a</sup>The pH optimum will vary with source and experimental conditions. These pH values should be taken as approximate values.

### 1. Effect of pH on Instability of Enzymes

The tertiary and quaternary structures of enzymes are stabilized by noncovalent electrostatic bonds, hydrogen bonds, hydrophobic bonds, and covalent disulfide bonds. The electrostatic bonds, formed between negative and positive charges on two groups of the enzyme, are affected by pH. The two predominant prototropic groups in enzymes are the side chain carboxyl groups of aspartic and glutamic acid residues ( $pK_a$  of 3–4) and the side chain ammonium groups ( $pK_a$  of ~9–10) of the lysine side chain residues and the guanidinium groups ( $pK_a$  ~12–13) of arginine residues. In the neutral pH range the ionizable side groups are as  $-COO^-$ ,  $H_3N^+$ , and  $H_2N-C(=N^+H_2)-NH$  groups, which can form strong electrostatic bonds (10–20 kcal/mol). But below pH 3 the carboxyl groups are protonated ( $-COOH$ ) and cannot form electrostatic bonds.

Above pH 10, the ammonium groups are nonproto-nated ( $-NH_2$ ) and do not form electrostatic bonds.

The active site of bovine catalase has no ionizable carboxyl or amino groups. Below pH 3 and pH 10, the electrostatic bonds are nonexistent and the enzyme loses activity owing to instability. The sharp decrease in activity of pepsin at pH < 2.0 is because of instability. The sharp decrease in activity of alkaline phosphatase at high pH is due to loss of electrostatic bonds to stabilize the enzyme.

### 2. Effect of pH on the Active Site Essential Ionizable Groups

**Table 4** shows six ionizable groups, their ionization,  $pK_a$ , and  $\Delta H_{ion}$  that can be a part of the active site of enzymes. Kinetically, ionization of one essential ionizable group gives a sigmoidal pH activity curve, while two essential ionizable groups, one in the ionized form and one in the protonated form, give a bell-shaped curve. In the case of pepsin there is an aspartic acid carboxyl group with  $pK_a$  of ~1 that is responsible for the left side of the pH activity curve. This group must be as  $-COO^-$  for the pepsin to be active. The right side of the pH activity curve is due to ionization of another aspartic acid arboxyl group that must be in the protonated form ( $-COOH$ ) for pepsin to be active. Therefore, the active site of pepsin has two ionizable carboxyl groups.

Trypsin has a pH optimum of 7.8. The left side of the activity curve is due to an imidazolium group ( $pK_a$  5.6–7.0) in the active site that must be in the unproto-nated form (Table 4) for activity of the enzyme. The right side of the bell-shaped curve is due to the ionization of the  $\alpha$ -amino group ( $pK_a$  8.0–8.5) of the N-terminal leucyl residue No. 16 (using the protrypsin numbering). For activity, the amino group must be in the protonated form.

Effect of pH on the observed activity of enzymes can be due to any of the components of the reactions [see Eq. (1)]. This includes ionization of groups on the free enzyme ( $E$ ), the enzyme-substrate complex ( $EA$ ), the substrate or any cofactor involved. To be able to interpret the effect of pH on an enzyme-catalyzed reaction, the researcher must know the stability of the enzyme at different pHs at the temperature to be used for activity measurements, the effect of pH on ionization of group(s) on the substrate and any cofactor. Equally important, the researcher must control the conditions of the experiment so that the pH effect can be on the free enzyme ( $[A]_o \leq 0.05 K_m$ ) or on the enzyme-substrate complex ( $[A]_o \geq 100 K_m$ ). The reader is

**Table 4** Prototropic Groups That May Be Involved in Enzyme Catalysis

Group	Ionization	$pK_a$	$\Delta H_{ion}$ (kcal/mol)
Carboxyl	$\text{---COOH} \rightleftharpoons \text{---COO}^\ominus + \text{H}^\oplus$	$\alpha^a$ $\beta, \gamma$	3.0–3.2 3.0–4.7 $\pm 1.5$

referred to the detailed discussion of Whitaker (1) on this subject. Properly performed experiments are essentially the only way to determine the essential ionizable groups in the active site of an enzyme and whether they are involved in binding of substrate or in catalysis of substrate to product.

## VII. EFFECT OF TEMPERATURE ON ENZYME-CATALYZED REACTIONS

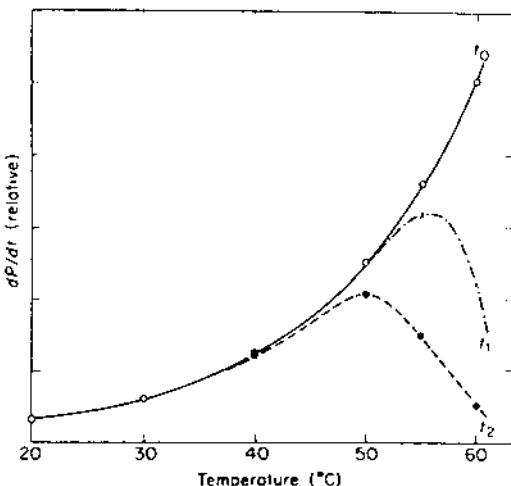

### A. General Discussion

Figure 14 shows (solid line) the effect of different temperatures on the velocity of an enzyme-catalyzed reaction. At 20°C, the velocity is constant over the time period used. At 40°C, there is a small deviation from a constant velocity (compare the solid experimental line and the dashed initial velocity line). At 50°C there is more deviation from a constant velocity. At 55°C and 60°C the constant velocity is maintained for only a very short time of reaction. As expected,  $v_o (= dp/dt)$  will be different depending on the time of the reaction ( $t_0$ ,  $t_1$ , and  $t_2$  indicated on the x-axis of Fig. 14). These results are plotted in Figure 15 as  $dp/dt$  vs. temperature. The

**Figure 14** Effect of temperature on rate of product formation. The solid lines are for experimental data; the dashed lines are based on initial velocity,  $v_o$ . (From Ref. 1)

plot of initial velocities vs. temperature is curvilinear. As explained below, this is the expected relationship according to the Arrhenius equation. The velocities at time  $t_1$  coincide with the expected relationship up to 50°C. Above 50°C, the velocity slows down and then

**Figure 15** Velocity of formation of product as function of temperature. Data are from [Figure 14](#), taken at time  $t_0$ ,  $t_1$ , and  $t_2$ . (From Ref. 1.)

decreases. At time  $t_2$ , the data follow the expected relationship only to  $40^\circ\text{C}$ , slows at  $50^\circ\text{C}$ , and decreases at  $55^\circ\text{C}$  and  $60^\circ\text{C}$ . Therefore, the temperature optima are  $60^\circ\text{C}$ ,  $55^\circ\text{C}$ , and  $50^\circ\text{C}$  for the reactions at times  $t_0$ ,  $t_1$ , and  $t_2$ , respectively. The difference between the three is due to the effect of temperature on the velocity of denaturation of the enzyme. Therefore, effect of temperature on velocity of denaturation of the enzyme is an important factor when one is studying the effect of temperature on rates of enzyme-catalyzed reactions.

Two other general factors affect the velocity of enzyme-catalyzed reactions. The factors are the effect of temperature on equilibria and on the catalytic efficiency of the enzyme.

## B. Effect of Temperature on Equilibria

There are numerous equilibria in an enzyme-catalyzed reaction. These include: (a) solubility of substrates, especially gases ( $\text{O}_2$  solubility is  $2.17 \times 10^{-3} M$  at  $0^\circ\text{C}$  and  $1.12 \times 10^{-3} M$  at  $30^\circ\text{C}$ ); (b)  $\text{pK}_a$  of ionizable groups on the enzyme (see  $\Delta H_{\text{ion}}$  in [Table 4](#)); (c) change in pH of buffers (Tris buffer  $\text{pK}_a$  changes 0.24 units/ $10^\circ\text{C}$ ; see also [Table 4](#)); (d) formation and dissociation of the enzyme-substrate complex and others (see Whitaker [1] for a more detailed discussion).

## C. Effect of Temperature on Catalytic Rates

The catalytic rate of conversion of the substrate-enzyme complex to product is controlled by  $k_2$  [see

[Eq. \(1\)](#)]. To eliminate the effect of factors listed in [Section VII.A](#) and [B](#), the enzyme should be saturated with substrate and performed at the pH optimum for the enzyme-catalyzed reaction, over a temperature range where the enzyme is stable.

The rate constant,  $k_2 = V_{\text{max}}/[E]_0$ , under the above conditions is plotted according to the Arrhenius equation:

$$k_2 = Ae^{-E_a/RT} \quad (33)$$

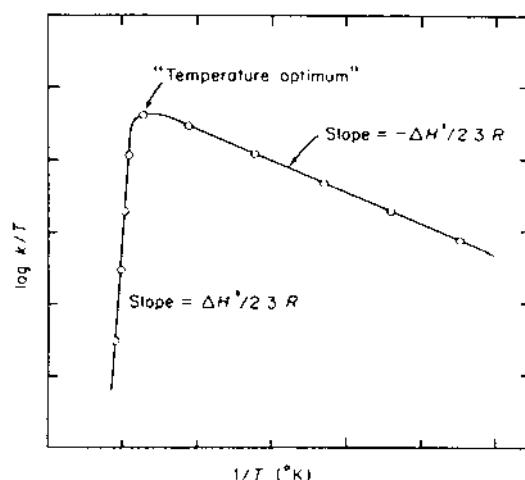

where  $A$  is the Arrhenius constant,  $E_a$  is the Arrhenius activation energy,  $R$  is the universal gas constant (1.98 cal/mol deg), and  $T$  is degrees Kelvin. The plot is shown in [Figure 16](#). From the right-hand slope,  $E_a$  is obtained. The positive slope (left side of [Fig. 16](#)) gives  $E_a$  for denaturation of the enzyme. The relationship between  $E_a$  and  $\Delta H^\ddagger$  from the Absolute Reaction Rate theory is given by [Eq. \(34\)](#).

$$\Delta H^\ddagger = E_a - RT \quad (34)$$

The numerical difference between  $\Delta H^\ddagger$  and  $E_a$  is 0.6 kcal/mol at  $25^\circ\text{C}$ .

## D. Effect of Catalyst on $E_a$ and Relative Rates

[Table 5](#) shows the effect of different catalysts on relative rates of some reactions. For example, the conversion of  $\text{H}_2\text{O}_2$  to  $\text{O}_2$  and  $\text{H}_2\text{O}$  relative to no catalyst is  $2.07 \times 10^3$  times faster for the  $\text{I}^-$  and  $3.47 \times 10^8$  times

**Figure 16** Effect of temperature on rate of an enzyme-catalyzed reaction, plotted according to the Absolute Reaction Rate Theory. The positive slope on the left is for rate of inactivation of the enzyme. The negative slope on the right is for effect of temperature on  $k_2$  for conversion of EA to products. (From Ref. 1.)

**Table 5** Effect of Catalyst on  $E_a$  and on Relative Rates of Some Reactions

Substrate	Catalyst	$E_a$ (kcal/mol)	$n'/n$ (25°C)	Relative rates <sup>a</sup> (25°C)
$\text{H}_2\text{O}_2$	None	18.0	$5.62 \times 10^{-14}$	1.00
	$\text{I}^-$	13.5	$1.16 \times 10^{-10}$	$2.07 \times 10^3$
	Catalase	6.4	$1.95 \times 10^{-5}$	$3.47 \times 10^8$
Sucrose	$\text{H}^+$	25.6	$1.44 \times 10^{-19}$	1.00
	Invertase	11.0	$8.04 \times 10^{-9}$	$5.58 \times 10^{10}$
Carbonic acid	None	20.5	$8.32 \times 10^{-16}$	1.00
	Carbonic anhydrase	11.7	$2.46 \times 10^{-9}$	$2.96 \times 10^6$
Urea	$\text{H}^+$	24.5	$9.33 \times 10^{-19}$	1.00
	Urease	8.7	$3.96 \times 10^{-7}$	$4.25 \times 10^{11}$

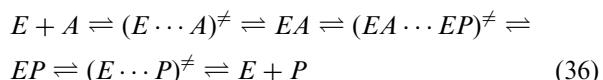

<sup>a</sup>Relative rates calculated are approximate since differences in  $\Delta S^\ddagger$  are ignored.

Source: Ref. 1.

faster for catalase.  $n'/n$ , the fraction of molecules  $n$  with activation energy equal to  $E_a$  or greater, is calculated from Eq. (35):

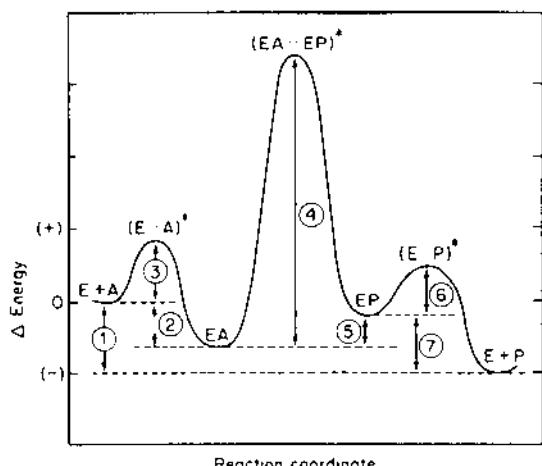

$$n'/n = e^{-E_a/RT} \quad (35)$$

Equation (1) has been used in this chapter to describe enzyme-catalyzed reactions. Only ground state species are shown. In reality, activated state species should also be included, as shown in Figure 17. When this is done the complete equation is Eq. (36).

The rate-determining step is number 4 in Figure 17. This is the step that requires the most activation energy. Activation energy is required to convert a ground state species to an activated species [Eq. (33)]. The thermodynamic energy difference between two ground state species is calculated using the Van't Hoff equation [Eq. (37)].

$$\frac{d \ln K_{\text{eq}}}{dT} = \frac{\Delta H}{RT^2}; (\ln K_2/K_1 = \frac{\Delta H(T_2 - T_1)}{T_2 T_1}) \quad (37)$$

**Figure 17** Change in energy along the reaction coordinate during conversion of A to P in an enzyme-catalyzed reaction according to Eq. (36). The numbers refer to steps in the thermodynamic and transition states in the forward direction. (From Ref. 1.)

## E. Factors Accounting for Catalytic Efficiency of Enzymes

Enzymes are superior biological catalysts as shown in Table 5. The factors that account for their catalytic effectiveness are listed in Table 6. Factors 1–4 account for the rate enhancement due to binding of the substrate stereospecifically (at least three points of attachment) into the active site of enzymes. Factor 1 accounts for much of the rate enhancement, especially for binding of two or more substrates into the active site simultaneously ( $10^9$  and  $10^{15}$  enhancement for two and three substrates, respectively). The polymerases involved in biosynthesis of proteins bind five or more substrates and cofactors simultaneously into the active site. Factors 5–7 account for the rate enhancement during the chemical conversion of the substrate(s) to product(s).

**Table 6** Factors Accounting for Catalytic Effectiveness of Enzymes

Factor	Rate enhancement <sup>a</sup>
1. Formation of stereospecific enzyme-substrate complex (conversion from inter- to intramolecular reaction)	$10^4$ ; $10^9$ ; $10^{15}$ <sup>b</sup>
2. Decreased entropy of reaction	$10^3$
3. Concentration of reactive catalytic groups	$10^3$ – $10^4$
4. Distortion of substrate	$10^2$ – $10^4$
5. General acid/general base catalysis	$10^2$ – $10^3$
6. Nucleophilic/electrophilic catalysis	$10^2$ – $10^3$
7. Using several steps	$10^2$ – $10^4$
Overall rate enhancement	$10^{18}$ – $10^{36}$

<sup>a</sup>In some cases these values can be approximated by model experiments. In others, they are the best estimates available.

<sup>b</sup>For 1, 2, and 3 substrates, respectively.

Source: Ref. 1.

The overall theoretical rate enhancement shown in Table 6 is  $10^{18}$ – $10^{36}$ . The best enzymes, such as catalase and peroxidase, have rate enhancements  $\sim 10^{20}$ . Therefore the catalytic efficiency of enzymes can be explained by well-known chemical principles: enzymes are not magicians.

## Inactivation of Enzymes

### From Experimental Design to Kinetic Modeling

**Ann Van Loey, Indrawati, Chantal Smout, and Marc Hendrickx**

*Katholieke Universiteit Leuven, Leuven, Belgium*

#### I. INTRODUCTION

Enzymes occur naturally in many biological raw materials and can, together with processing, affect functional properties of foods in many ways. Endogenous enzymes can have beneficial or detrimental effects on foods. Some enzymes are positively utilized during food processing for recovery of byproducts, for developing new food products, for achieving higher rates and levels of extraction, or for improving food quality in terms of, e.g., flavor, texture. On the other hand, enzymes might also have detrimental effects. Food spoilage can be caused by enzymes naturally present in the food, or by enzymes produced by certain microorganisms—for example, enzymatic browning reactions in fruits and vegetables by polyphenoloxidases, or rancidity caused by the presence of endogenous lipases and lipoxygenases.

As a consequence of the beneficial and detrimental effects of enzymes, in most food-processing steps control of enzymatic activity is required. Either one wants to promote the beneficial effects of the enzyme by enhancing the enzymatic activity during processing; in this case knowledge on enzyme stability under the relevant processing conditions is required for process design (e.g., its thermostability, resistance toward acid environments). On the other hand, in the case of detrimental enzymatic action, one wants to eliminate or retard the enzymatic reaction, which is often performed

by inactivation of the enzymes by physical methods (e.g., thermal blanching) or by inhibition of the enzymatic reaction using additives, a chemical method.

The current chapter will particularly focus on the inactivation of enzymes by the processing factors temperature and pressure, discussing the experimental design and modeling of kinetic inactivation studies of enzymes, illustrated by some examples. An extended overview on thermal and pressure inactivation kinetics of enzymes is given by Ludikhuyze et al. (1).

#### II. A GENERAL SCHEME FOR ENZYME INACTIVATION

A general scheme for thermal enzyme inactivation was proposed by Lumry and Eyring (2): a reversible partial unfolding, followed by an irreversible reaction step

where  $N$  represents the native,  $U$  the reversibly unfolded and  $I$  the irreversibly inactivated enzyme.  $K$  ( $= [N]/[U]$ ) and  $k_{ir}$  symbolize the unfolding equilibrium constant and the rate constant of the irreversible reaction step, respectively. In the literature, some evidence can be found as to an analogous general scheme for pressure inactivation of enzymes (3).

If we consider this simple inactivation scheme, the rate of inactivation is given by Eq. (1):

$$v = k_{ir}[U] \quad (1)$$

Since the measurement of residual activity involves  $[N] + [U]$  ( $U$  will renature upon cooling), the observed rate of inactivation ( $k_{obs}$ ) is:

$$k_{ir}[U] = k_{obs}([N] + [U]) \quad (2)$$

Because  $K = [N]/[U]$ , assuming rapid equilibrium, the experimentally measured rate constant  $k_{obs}$  can be mathematically expressed as Eq. (3).

$$k_{obs} = \frac{k_{ir}}{1 + K} \quad (3)$$

At "high" temperature or pressure, where the concentration of the native form ( $[N]$ ) is much smaller than the concentration of the reversibly unfolded form ( $[U]$ ), the second step becomes rate limiting and the above equation can be simplified to Eq. (4).

$$k_{obs} = k_{ir} \quad (4)$$

i.e., when the inactivation is examined at "high" inactivation temperature or pressure (far above the denaturation temperature or pressure), the influence of the unfolding–refolding equilibrium is negligible and the inactivation is only determined by the secondary irreversible step.

### III. EXPERIMENTAL DESIGN FOR KINETIC ENZYME INACTIVATION STUDIES

Enzyme inactivation kinetics can be determined using either steady-state or un-steady-state procedures (4, 5), the steady-state procedure being the most straightforward approach to study thermal or pressure inactivation kinetics. A classical steady-state experiment consists of subjecting an enzymic sample to a square wave temperature and/or pressure profile.

To study thermal inactivation, batch or flow methods can be used for sample heating and cooling. Whatever method being used, care has to be taken to ensure that heating and cooling are quasi-immediate, or else appropriate compensation for thermal lags has to be taken into account (e.g., 6, 7), especially when the heating or cooling lag is not sufficiently small relative to the half-life\* of the reaction. For isothermal batch treatments, enzyme solutions are usually enclosed in small, preferably highly conductive vials or tubes (e.g., glass capillaries, thermal death tubes, thermal

death cans) to minimize heating and cooling lags. The samples are immersed in a temperature-controlled heating bath at constant inactivation temperature for predetermined time intervals. Immediately upon withdrawal from the heating bath, the samples are cooled in ice water to stop the thermal inactivation, and the residual enzymatic activity is measured.

For pressure inactivation studies, today only batch methods are available. For pressure treatments, the enzymic samples should be contained in flexible containers (e.g., microtubes, plastic bags). Because of adiabatic heating, pressure buildup is inevitably associated with temperature increase. At the prevailing high pressure, this temperature increase might provoke a significant reduction of enzyme activity during pressure buildup. The temperature reached during pressure buildup can seriously be reduced by decreasing the rate of compression. To avoid problems arising from the temperature increase during pressure buildup, a possible approach is to exclude the nonisobaric/non-isothermal phase from the inactivation data by starting the time course of the experiment ("zero point") after reaching the desired pressure and an additional equilibration period to allow temperature to evolve to its desired value. At that moment, the pressure vessel is decompressed and the activity of the corresponding enzyme sample is considered as the blank. The use of this zero-point approach is merely allowed for first-order reactions (including the special cases of biphasic and first-order fractional conversion reactions). After pressure–temperature treatment, enzyme solutions are cooled in ice water to stop inactivation and reactivation, and the residual enzymatic activity is measured. To perform kinetic experiments at elevated pressure (up to 1000 MPa), specialized high-pressure equipment, consisting of several individual thermostated pressure vessels, is often used (Fig. 1). Such equipment allows submission of several samples simultaneously to treatments at the same pressure and temperature for preset times.

Upon removal of the denaturing agents (i.e., temperature or pressure), regeneration of enzyme activity might occur (see above). Hence, it should be experimentally verified whether enzyme reactivation occurs within a reasonable experimental time after treatment.

### IV. MODELING ENZYME INACTIVATION KINETICS

Kinetics of the enzyme inactivation process describe its progress in time. The way in which the inactivation

\*The half-life of a reaction is the time required to reduce the concentration (enzyme activity in case of enzyme inactivation studies) to half of its initial value.

**Figure 1** An example of a multivessel high-pressure equipment.

progresses as a function of time is expressed by the mathematical form of the kinetic model. The rate of inactivation is reflected by the numerical values of the kinetic parameter estimates.

Dealing with kinetic studies of thermal or pressure inactivation of enzymes, the first step of the data analysis procedure involves the identification of an adequate inactivation rate equation (e.g., first order, biphasic, *n*th order) and the identification of a temperature and/or pressure coefficient model (e.g., Thermal Death Time model, Arrhenius model, Eyring model), while the second step is the selection of a regression method to estimate kinetic parameter values with the highest probability of being correct.

#### A. Determination of an Inactivation Rate Equation

The general rate law to describe the decrease of enzyme activity (*A*) as a function of processing time (*t*) can be written as

$$\frac{dA}{dt} = -k_{\text{obs}} A^n \quad (5)$$

where *A* is the enzymatic activity at time *t*, *k* the reaction rate constant, and *n* the reaction order. The order of reaction can be determined by many different methods that are briefly discussed by Hill and Grieger-Block (8) and Laidler (9). Under simple initial and boundary conditions, the integration of differential Eq. (5) results in analytical solutions describing the enzymatic activity (*A*) as a function of time. In case of isobaric-isothermal inactivation experiments (i.e.,

rate constant *k* not varying with time), Eq. (6) or Eq. (7) is obtained depending on the reaction order (with respect to time).\*

$$n = 1 \quad A = A_0 \exp(-kt) \quad (6)$$

$$n \neq 1 \quad A^{(1-n)} = A_0^{(1-n)} + (n-1) kt \quad (7)$$

By trial-and-error procedures an estimate of the reaction order *n* (with respect to time) can be obtained by analyzing graphically the trends and/or deviations from a linear behavior. However, a complication in determining the order of a reaction from the method of integration is that little or no distinction can be made among zero-, first-, and second-order reactions with respect to time when the response value changes only little (10). Even when a linear plot is obtained, conclusions must be drawn cautiously from the data, especially if the data points correspond to no more than 10–20% conversion because many mathematical functions are roughly linear over a sufficiently small range of variables. According to Arabshahi and Lund (7), reactions should be followed, where possible, through at least four to five half-lives (or 1–2 log reductions). If the method of analysis is not sufficient to measure response values as low as this, the longest heating times possible should be used (11). According to Hill and Grieger-Block (8), one should perform at least experimental runs in which data are taken at 40%, 50%, or higher conversions.

#### 1. First-Order Model

Thermal or pressure inactivation of enzymes can often be described by a first-order reaction [Eq. (6)] (1). This feature is remarkable since enzyme inactivation is a complex process involving several events, such as formation and/or disruption of different interactions and/or bonds, decomposition of amino acids, aggregation, and/or dissociation. It is therefore suggested that in case of apparent first-order inactivation processes, one of these reactions predominates over the others. If several reactions occur at more or less the same rate, complex non-first-order inactivation kinetics are expected (12).

\*Note that in the context of enzyme inactivation, the concept of reaction order is purely empirical and gives no direct information about the mechanism of the reaction. This procedure provides a model which describes the kinetics of a reaction, but this model should not necessarily be interpreted as representing the actual mechanism of the reaction.

Under isothermal-isobaric conditions a first-order reaction can be expressed as Eq. (6), which can be linearized by a logarithmic transformation, yielding Eq. (8).

$$\ln\left(\frac{A}{A_0}\right) = -kt \quad (8)$$

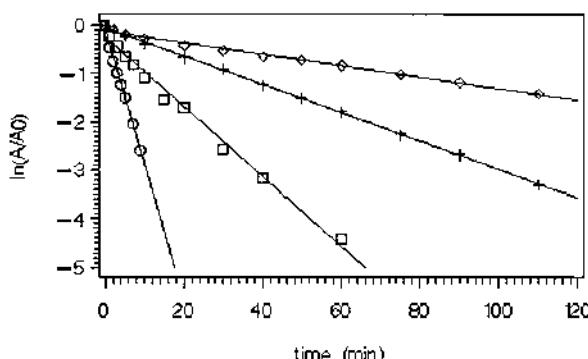

where  $A$  is enzymatic activity at time  $t$ ;  $A_0$  is initial enzymatic activity;  $t$  is treatment time; and  $k$  is the first-order inactivation rate constant. As an example, Figure 2 depicts thermal inactivation of tomato pectin methylesterase, which can be adequately described by a first-order reaction (adapted from 13). In case of a first-order inactivation model, the rate constant at a given temperature and pressure can be estimated by linear regression analysis of  $\ln(A/A_0)$  versus inactivation time at constant inactivation temperature and pressure, or alternatively based on Eq. (6) by nonlinear regression analysis (see below).

In the area of food science and technology, it is common to characterize first-order reactions using the Thermal Death Time concept. The decimal reduction time (D-value) is the time, at a given temperature and pressure, needed for a 90% reduction of the initial activity. For a first-order inactivation, D-values and rate constants are directly related [Eq. (9)].

$$D = \frac{\ln(10)}{k} \quad (9)$$

Substitution of Eq. (9) into Eq. (8) yields Eq. (10).

$$\log\left(\frac{A}{A_0}\right) = -\frac{t}{D} \quad (10)$$

**Figure 2** Thermal inactivation curves of tomato pectin methylesterase (PME) dissolved in 20 mM Tris-HCl (pH 7) at 60°C ( $\diamond$ ), 62.5°C (+), 65°C ( $\square$ ), and 67.5°C ( $\circ$ ).  $A_0$  and  $A$  are initial tomato PME activity and activity after thermal treatment, respectively. (From Ref. 13.)

The decimal reduction time at a given inactivation temperature and pressure can be calculated from the slope of a linear regression analysis of  $\log(A/A_0)$  versus inactivation time at constant inactivation temperature and pressure, or alternatively by nonlinear regression analysis (see below).

The validity of a first-order inactivating behavior can be examined by plotting residual enzyme activity versus treatment time on a semilogarithmic scale and evaluation of the goodness of fit by means of, e.g., lack-of-fit test, coefficient of determination ( $R^2$ ), analysis of the distribution of residuals.\* Residuals of an appropriate fit represent only the experimental error and should therefore be randomly distributed. The existence of trends in residuals (with respect to either the independent or dependent variable[s]) suggests that some systematic behavior is present in the data that is not accounted for by the model (14), in this case by a first-order inactivation.

The model for inactivation of enzymes according to first-order kinetics may be applied in many cases. However, often more complex inactivation kinetics are found, because inactivation may occur by consecutive or parallel processes, or owing to the presence of isozymes, enzyme inhibitors, or other food components. Several mathematical expressions have been suggested for modeling a non-first-order inactivation behavior. A “biphasic” inactivation behavior where a fast inactivation period is followed by a decelerated decay, eventually leading to an activity plateau, has been attributed to the occurrence of isozymes with different stabilities (~distinct isozyme model), to the presence of a resistant enzyme fraction (~fractional conversion model), or to intermediate (first-order) steps in the overall inactivation process (~consecutive step model).

## 2. Distinct Isozyme Model

Enzymes characterized by several isozymes can often be subdivided into two (or more) fractions with different processing stability, e.g., one more thermal (pressure) resistant than the other and both inactivating according to a first-order decay kinetic model. For constant extrinsic (e.g., pressure, temperature) and intrinsic factors and assuming that the inactivation of both fractions is independent of each other, the inactivation can be modeled according to Eq. (11).

\*Residuals are the differences between experimentally observed dependent variable values and those predicted by the regression equation.

$$A = A_l \exp(-k_l t) + A_s \exp(-k_s t) \quad (11)$$

where  $A_s$  is the activity of the more stable enzyme fraction,  $A_l$  the activity of the labile enzyme fraction,  $k$  the first-order inactivation rate constant where the subscripts  $s$  and  $l$  for  $k$  denote thermostable and thermolabile, respectively. As an example of inactivation according to a distinct isozyme model, thermal inactivation of tomato polygalacturonase (PG) dissolved in 40 mM Na acetate buffer pH 4.4 is depicted in Figure 3.

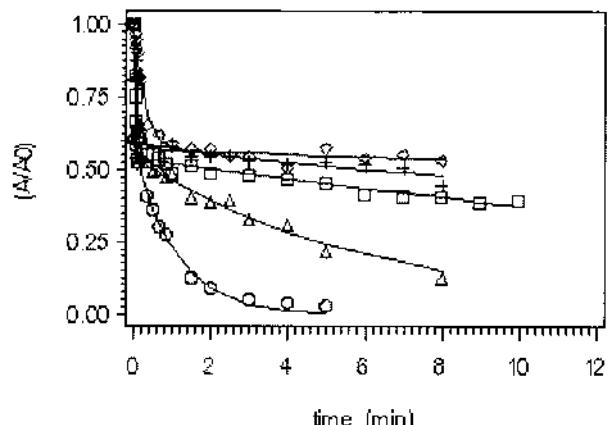

By plotting the residual activity after different time intervals versus time, the inactivation rate constant of the labile fraction ( $k_l$ -value), the inactivation rate constant of the stable fraction ( $k_s$ -value), and the activity of both fractions can be estimated using nonlinear regression analysis.

### 3. Fractional Conversion Model

Fractional conversion refers to a (first-order) inactivation process that takes into account a nonzero activity upon prolonged heating and/or pressurizing ( $= A_\infty$ ). A fractional conversion model can be expressed mathematically as Eq. (12).

$$A = A_\infty + (A_0 - A_\infty) \exp(-kt) \quad (12)$$

This relation is valid in the temperature and/or pressure domain where only the labile enzyme fraction inactivates whereas the activity of the stable fraction ( $A_\infty$ -value) does not change with respect to time. This nonzero activity may or may not be a function of

**Figure 3** Thermal inactivation curves of tomato polygalacturonase (PG) dissolved in 40 mM Na acetate buffer (pH 4.4) at 70°C ( $\diamond$ ), 75°C (+), 80°C ( $\square$ ), 85°C ( $\Delta$ ), and 90°C ( $\circ$ ), modeled using a distinct isozyme model.  $A_0$  and  $A$  are initial tomato PG activity and activity after thermal treatment, respectively. (From Ref. 15.)

applied temperature and pressure. As an example of fractional conversion, thermal inactivation of the heat-labile fraction of tomato PG dissolved in 40 mM Na acetate buffer pH 4.4 is depicted in Figure 4.

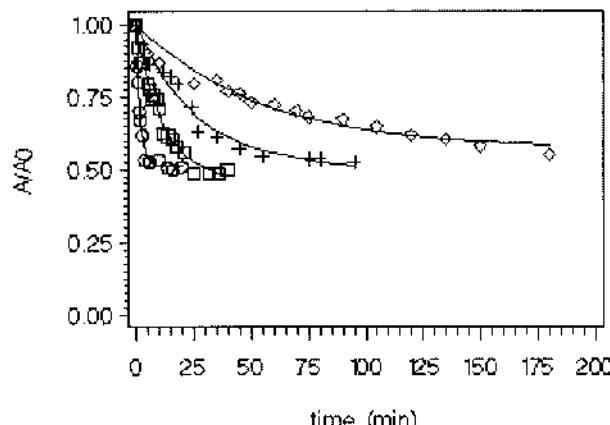

By plotting residual activity after different time intervals versus time, the inactivation rate constant ( $k$ -value) and the remaining activity after prolonged treatment ( $A_\infty$ -value) can be estimated using nonlinear regression analysis.

### 4. Consecutive Step Model

The consecutive step model is based on a succession of (two) irreversible (first-order) reaction steps—an irreversible conversion of the native enzyme to an intermediate with lower specific activity, and the subsequent irreversible conversion of the intermediate to an inactive enzyme form. A consecutive two-step model can be mathematically expressed as Eq. (13).

$$A = \left( A_1 - A_2 \left( \frac{k_1}{k_1 - k_2} \right) \right) \exp(-k_1 t) + A_2 \left( \frac{k_1}{k_1 - k_2} \right) \exp(-k_2 t) \quad (13)$$

By plotting the residual activity after different time intervals versus time, the inactivation rate constants  $k_1$  and  $k_2$  and the activity of both fractions can be estimated using nonlinear, regression analysis.  $k_1$  and  $A_1$  refer to step 1,  $k_2$  and  $A_2$  refer to step 2.

**Figure 4** Thermal inactivation curves of tomato polygalacturonase (PG) dissolved in 40 mM Na acetate buffer (pH 4.4) at 58°C ( $\diamond$ ), 60°C (+), 62°C ( $\square$ ), 65°C ( $\circ$ ), and 68°C ( $*$ ), modeled using a fractional conversion model.  $A_0$  and  $A$  are initial tomato PG activity and activity after thermal treatment, respectively. (From Ref. 15.)

## B. Determination of a Temperature and Pressure Coefficient Model

### 1. Temperature Dependence at Constant Pressure

The temperature dependence of the rate constant  $k$  is often expressed by an activation energy,  $E_a$ , as indicated in the Arrhenius relationship [Eq. (14)] (16).

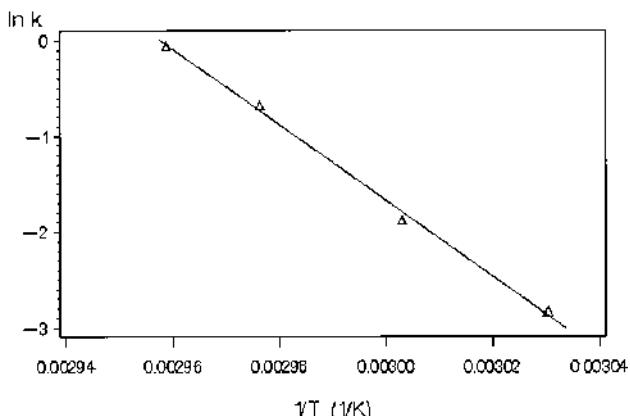

$$k_{\text{obs}} = k_{\text{obs,refT}} \exp\left(\frac{E_a}{R_g} \left(\frac{1}{T_{\text{ref}}} - \frac{1}{T}\right)\right) \quad (14)$$

where  $k_{\text{obs,refT}}$  is the inactivation rate constant at  $T_{\text{ref}}$ ,  $T_{\text{ref}}$  the reference temperature,  $E_a$  the activation energy, and  $R_g$  the universal gas constant ( $R_g = 8.314 \text{ J/Kmol}$ ). Equation (14) can be linearized which allows the activation energy at a certain pressure to be estimated based on linear regression analysis of the natural logarithm of  $k$  versus the reciprocal of the absolute temperature (Fig. 5). Alternatively, the activation energy can be estimated based on the nonlinearized Arrhenius relationship [Eq. (14)] using nonlinear regression analysis (see below).

In the Thermal Death Time model, the temperature dependence of the  $D$ -value is given by the  $z_T$ -value [Eq. (15)]. The  $z_T$ -value equals the temperature increase necessary to obtain a 10-fold decrease of the  $D$ -value.

$$D_{\text{obs}} = D_{\text{obs,refT}} 10^{\frac{T_{\text{ref}} - T}{z_T}} \quad (15)$$

where  $D_{\text{obs,refT}}$  is the inactivation rate constant at  $T_{\text{ref}}$ ,  $T_{\text{ref}}$  the reference temperature, and  $z_T$  the  $z$ -value. After linearization of Eq. (15), the  $z$ -value at a certain pressure can be estimated based on linear regression analysis of the 10-based logarithm of the decimal

**Figure 5** Arrhenius plot for thermal inactivation of orange pectinmethyl esterase, dissolved in distilled water. (From Ref. 17.)

reduction time versus temperature. Alternatively, the  $z$ -value can be estimated directly using nonlinear regression analysis based on Eq. (15).

Food technologists sometimes use the  $Q_{10}$ -factor to describe the temperature dependence of a reaction rate. The temperature dependence parameter  $Q_{10}$  is defined as the factor by which the reaction rate is increased if the temperature is raised by  $10^\circ\text{C}$ .

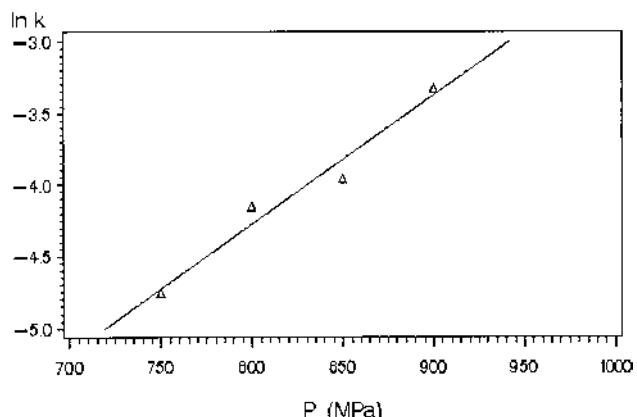

### 2. Pressure Dependence at Constant Temperature

The pressure dependence of the rate constant is often expressed by an activation volume ( $V_a$ ), as indicated in the Eyring equation [Eq. (16)] (18).

$$k_{\text{obs}} = k_{\text{obs,refP}} \exp\left(\frac{-V_a}{R_g T} (P - P_{\text{ref}})\right) \quad (16)$$

where  $k_{\text{refP}}$  is the inactivation rate constant at  $P_{\text{ref}}$ ,  $P_{\text{ref}}$  the reference pressure,  $V_a$  the activation volume at a certain temperature,  $T$  the absolute temperature, and  $R_g$  the universal gas constant ( $R_g = 8.314 \text{ cm}^3 \text{ MPa/Kmol}$ ). Also the Eyring equation can be linearized by a logarithmic transformation. Hence, plotting the natural logarithm of the rate constant in function of pressure, the activation volume at a certain temperature can be derived from the slope of the regression line (Fig. 6). Alternatively, the activation volume can be estimated based on the nonlinearized Eyring relationship [Eq. (16)] using nonlinear regression analysis (see below).

Analogous to the log-linear relationship between  $D$ -value and temperature, there is often a log-linear rela-

**Figure 6** Eyring plot for pressure inactivation at  $45^\circ\text{C}$  of avocado polyphenoloxidase, dissolved in phosphate buffer (pH 7, 0.1 M). (From Ref. 19.)

tionship between  $D$ -value and pressure [Eq. (17)], whereby  $z_p$  is defined as the pressure increase necessary to obtain a 10-fold decrease of the  $D$ -value.

$$D_{\text{obs}} = D_{\text{obs,ref}} 10^{\frac{P_{\text{ref}} - P}{z_p}} \quad (17)$$

where  $D_{\text{obs,ref}}$  is the decimal reduction time at  $P_{\text{ref}}$ ,  $P_{\text{ref}}$  the reference pressure, and  $z_p$  the  $z$ -value at a certain temperature. Also the  $z_p$ -value can be estimated using two different regression approaches: plotting the 10-based logarithm of  $D$  in function of pressure, the  $z_p$ -value at a certain temperature can be derived from the slope of the regression line, or the  $z_p$ -value can be estimated using nonlinear regression analysis (see below).

Analogous to the validity evaluation of a first-order kinetic model, the appropriateness of the coefficient models to describe the temperature or pressure dependency of the inactivation rate constant can be evaluated by determination of the goodness of fit of  $\ln k$  vs.  $1/T$  (Arrhenius model),  $\log D$  versus  $T$  (TDT model),  $\ln k$  vs.  $P$  (Eyring model), or  $\log D$  vs.  $P$  (PDT model).

### 3. Combined Pressure-Temperature Dependence

Based on experimentally determined inactivation rate constants for an elaborated set of pressure-temperature combinations, an iso-rate contour plot, connecting pressure-temperature combinations resulting in the same inactivation rate constant can be constructed. Iso-rate contour diagrams for pressure-temperature inactivation of enzymes as well as of microorganisms are often elliptically shaped. These elliptical pressure-temperature kinetic diagrams can be modeled on a thermodynamic basis.

The basic thermodynamic equation governing the behavior of a system during a pressure and a temperature change can be represented as Eq. (18).

$$d(\Delta G) = -\Delta SdT + \Delta VdP \quad (18)$$

Since the entropy change ( $\Delta S$ ) and the volume change ( $\Delta V$ ) vary with pressure and temperature [Eqs. (19) and (20), respectively], Eq. (18) can be reformulated as Eq. (21) (20, 21).

$$d(\Delta S) = \left( \frac{\partial \Delta S}{\partial T} \right)_P dT + \left( \frac{\partial \Delta S}{\partial P} \right)_T dP \quad (19)$$

$$d(\Delta V) = \left( \frac{\partial \Delta V}{\partial T} \right)_P dT + \left( \frac{\partial \Delta V}{\partial P} \right)_T dP \quad (20)$$

$$\begin{aligned} \Delta G &= \Delta G_o + \Delta V_o(P - P_o) - \Delta S_o(T - T_o) \\ &\quad + \frac{1}{2} \Delta \kappa (P - P_o)^2 + \Delta \zeta (P - P_o)(T - T_o) \\ &\quad - \Delta C_p \left[ T \left( \ln \frac{T}{T_o} - 1 \right) + T_o \right] \end{aligned} \quad (21)$$

where  $\Delta C_p$  is the heat capacity change ( $T \delta \Delta S / \delta T$ )<sub>P</sub>,  $\Delta \zeta$  the thermal expansibility factor ( $(\delta \Delta V / \delta T)_P = -(\delta \Delta S / \delta P)_T$ ), and  $\Delta \kappa$  the compressibility factor ( $\delta \Delta V / \delta P$ )<sub>T</sub>. This thermodynamic model can be converted into a kinetic model through the transition state theory of Eyring, suggesting that enzyme inactivation is accompanied by the formation of a metastable activated state ( $\neq$ ) which exists in equilibrium with the native enzyme. This conversion is based on the substitution of Eq. (22) and Eq. (23) in Eq. (21), obtaining Eq. (24) to describe the combined pressure-temperature dependence of the inactivation rate constant.

$$\Delta G^\neq = -RT \ln(K^\neq) \quad (22)$$

$$K^\neq = \frac{kh}{rk_B T} \quad (23)$$

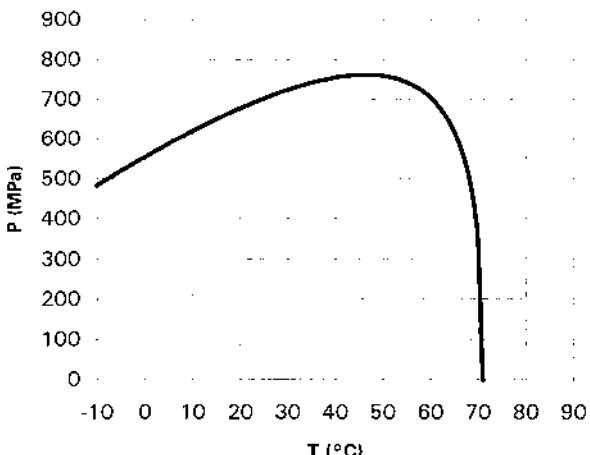

$$\begin{aligned} \ln(k_{\text{obs}}) &= \ln(k_0) - \frac{\Delta V_0^\neq}{RT}(P - P_o) \\ &\quad + \frac{\Delta S_0^\neq}{RT}(T - T_o) - \frac{1}{2} \frac{\Delta \kappa^\neq}{RT}(P - P_o)^2 \\ &\quad - \frac{\Delta \zeta^\neq}{RT}(P - P_o)(T - T_o) \\ &\quad + \frac{\Delta C_p^\neq}{RT} \left[ T \left( \ln \frac{T}{T_o} - 1 \right) + T_o \right] \end{aligned} \quad (24)$$

The model parameters can be estimated using a nonlinear regression analysis, involving an iterative numerical procedure based on the minimal sum of squares. Figure 7 depicts an iso-rate contour diagram for pressure-temperature inactivation of soybean lipoxygenase, modeled using Eq. (24).

### C. Selection of a Regression Model and Method for Kinetic Parameter Estimation

Several regression models (linear vs. nonlinear models\*) and methods (two-step regression vs. one-step

\*A model is linear if the first (partial) derivatives of the model with respect to the parameters are independent of the parameters and consequently higher-order derivatives are zero whereas in a nonlinear model at least one of the derivatives of the model function with respect to the parameters depends on at least one of the parameters.

**Figure 7** Iso-rate contour diagram ( $k = 0.23 \text{ min}^{-1}$ ) for pressure-temperature inactivation of soybean lipoxygenase in Tris HCl buffer (pH 9, 0.01 M). (From Ref. 22.)

regression) can be applied to obtain kinetic parameter estimates. In this paragraph, the selection between a linear or a nonlinear kinetic model and between a two-step or a one-step regression method will be discussed.

### 1. Selection Between Linear Versus Nonlinear Models

Because linear least-squares fitting is easier to solve than nonlinear least-squares fitting, an approach frequently used is to perform (a) nonlinear transformation(s) of the dependent variable so that a linear model is obtained from which the least squares estimators of the linear model parameters can be calculated straight. Typical examples in the context of enzyme inactivation include linearization of the first-order rate equation by a logarithmic transformation of the inactivation data, or linearization of the temperature and pressure coefficient models by a logarithmic transformation of the rate constants. However, one of the assumptions inherent to least-squares fitting (for both linear and nonlinear) is that the experimental errors (in the dependent variables) are normally distributed (23). Hence, one should not perform any nonlinear transformation of the dependent variables (such as, e.g., a logarithmic transformation) that will alter the error distribution structure if the original data contain Gaussian uncertainties. When the model is nonlinear in the parameters no explicit analytical solutions are available for the parameters or the confidence intervals, and a solution must be found iteratively by linear approximation. Starting from an initial estimate of the

parameter values provided by the user, a numerical algorithm (e.g., Gauss-Newton, Marquardt, DUD) is used to provide successively better approximations until the sum of squared residuals do not change within some specified limit (convergence criterion is met) so that finally a set of parameter values satisfying the least-squares criterion is presented. To be more certain that the minimum found is actually the global minimum desired and not a local one – it is advisable to start the nonlinear least-squares procedure at several different starting estimates of the parameters. If the final results are independent of the initial values, there is more confidence that the final parameter values describe a global minimum.

With the present availability of computing power, ease of parameter estimation is no longer a valid reason for linearizing models. It may nevertheless be useful to perform a nonlinear transformation in order (a) to produce a linear plot from which the validity of the model can easily be interpreted graphically, or (b) to be able to use a simple linear regression analysis to obtain reasonable starting values for the subsequent nonlinear regression routine of the untransformed data.

### 2. Selection Between Two-Step Versus One-Step Regression

It is common practice to estimate kinetic inactivation parameters by an individual, or two-step, regression method: one estimates at first inactivation rate constants (and possibly other kinetic parameters such as enzyme fraction, reaction order) from inactivation data at constant temperature or pressure by linear or nonlinear regression analysis. In a second step, one estimates temperature or pressure coefficients from regression analysis of the obtained inactivation rate constants as a function of temperature and pressure.

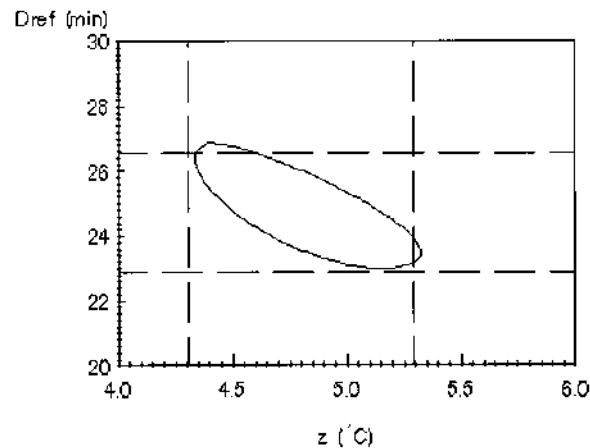

In a global, or one-step, regression approach, one is considering the inactivation data obtained at different inactivation temperatures or pressures simultaneously. To model a global inactivation data set, the temperature or pressure coefficient model is being incorporated in the inactivation rate equation. Using nonlinear regression analysis, one gets estimates of the inactivation rate constant at reference conditions and a temperature or pressure coefficient.

With regard to the choice between an individual or a global approach, in the literature, the effectiveness of several least-squares regression methods for the estimation of kinetic parameters has been assessed mainly based on comparison of the confidence region for the parameters estimates and on the quality of fitting (24,

25). These authors concluded that the two-step regression approach gives the least accurate estimates probably because it estimates too many intermediate values, and does not gain strength in the regression by considering the data set as a whole. Two-step regression has the disadvantage of applying regression on regression parameter estimates. Errors on the first regression estimates are not transformed to the second. On the contrary, they found a global regression procedure a very good method which yielded unbiased and precise estimates of the parameters without estimating unnecessary ones. Because of several disadvantages inherent to the two-step approach, one is advised to analyze kinetic data sets by a global fit considering the data set as a whole. Probably the use of a global fit will not provide the best individual fit at each temperature or pressure, but the whole set of results will be better described.

### 3. Confidence Intervals of Parameter Estimates

Next to the determination of parameter values with the highest probability of being correct, it is essential to obtain a realistic measure of the statistical confidence of the estimated parameters. In the case of linear models, confidence intervals for the parameter estimates are exactly defined and symmetrical and their determination is straightforward while in case of nonlinear models confidence intervals are not symmetric and only approximate confidence intervals are provided (26). The most commonly used method for the evaluation of the confidence intervals of parameters estimated in a nonlinear regression procedure is the use of asymptotic standard errors, computed based on linearizing assumptions. However, they nearly always provide incorrect estimates of the actual confidence limits of the determined parameters because they neglect the covariances of the simultaneously determined parameters and assume normal distribution of parameters. According to several authors (23, 27–29), asymptotic standard errors should not be used in case of nonlinear least-squares analysis since there are many other published methods that provide realistic estimates of the confidence intervals of parameters determined by nonlinear least-squares methods—e.g., the construction of joint confidence regions for the parameters. Joint confidence regions take into account the correlation between the simultaneously estimated parameters. Although the use of joint confidence regions for simultaneously estimated parameters is well described in statistical handbooks, it is rarely encountered in scientific publications.

**Figure 8** 90% joint confidence contour of the kinetic parameter estimates for thermal inactivation of alkaline phosphatase in raw bovine milk ( $T_{\text{ref}} = 60^\circ\text{C}$ ) (correlation between  $z$  and  $D_{\text{ref}}$  is 0.786). (From Ref. 31).

100(1− $\varphi$ )% joint confidence regions can be constructed using Eq. (25) (30).

$$SSQ \leq SSQ(\theta) \left\{ 1 + \frac{p}{m-p} F(p, m-p, 1-\varphi) \right\} \quad (25)$$

where  $SSQ(\theta)$  represents the error sum of squares associated with the least-squares estimate  $\theta$ ,  $p$  the number of parameters estimated simultaneously,  $m$  the number of observations, and  $F$  the upper  $1-\varphi$  quantile for an  $F$  distribution with  $p$  and  $m-p$  degrees of freedom. An example of a joint confidence region for a set of parameter estimates that are highly correlated is given in Figure 8. It can be seen from Figure 8 that if the parameters are rather highly correlated no attempt should be made to interpret the individual confidence intervals simultaneously by constructing a rectangular joint confidence interval because a parameter pair may be well within the individual confidence interval but is very unlikely to occur since it is very far outside the joint confidence region. Only if the correlation between the simultaneously estimated parameters is close to zero will the rectangular region defined by the individual confidence intervals approximate to the correct joint confidence region.

## Regulatory Issues of Enzymes Used in Foods from the Perspective of the E.U. Market

Danielle P. Praaning

*DSM Food Specialties, Delft, The Netherlands*

### I. INTRODUCTION

Enzymes were used for food production 2000 years before the birth of Christ. Good examples are bread, cheese, and beer production. Of course, it was unknown at the time that it was the enzymes that were doing the job. Nowadays, the production of food enzymes has become industrialized. European enzyme manufacturers are market leaders and cater ~70% of the world's need for food enzymes, and this market is still increasing with an annual growth of about 2%.

These developments have triggered the creation of national laws and regulations to ensure both the safety of the consumer and fair trade. Although many laws in the European Union have been harmonized over the last few decades, this has not (yet) happened in the case of enzymes.

The European Association of Manufacturers of Fermentation Enzyme Products (AMFEP), which was founded in 1977, has set as one of its major aims the achieving of the widest possible harmonization of regulatory requirements for enzymes in the European Union (E.U.). To achieve this, AMFEP has initiated discussions with the European Commission, national authorities, and the food industry. This chapter presents an overview of the tangle of present regulations that are applicable for enzymes when used in food.

### II. OVERVIEW OF APPLICABLE LAWS

In the European Union, there are so-called horizontal and vertical laws. Horizontal laws are those that cover all foods. Examples are the laws regarding additives and those regarding the labeling of foodstuffs. Vertical laws cover foods with a so-called standard of identity, also called compositional regulations or "recipe laws." Examples of products for which such standards exist are cheese and bread.

In both cases, vertical as well as horizontal, there are laws that have been harmonized throughout the E.U. and laws that are still subject to national legislation. This situation will probably remain so, especially in view of the fact that in the treaty signed in Maastricht in February 1992 (1), the European Union officially laid down the "principle of subsidiarity," which states that the European Commission should not regulate what could be done just as well or better at the national level.

For products regulated solely at the national level, the principle of mutual recognition applies. If a product is legally produced in one E.U. country, it can also be sold in another E.U. country, unless this country has well-founded arguments to reject the product on the grounds of protection of consumer health, or one of the other reasons listed in Article 30 of the Treaty establishing the European Community (2). Other than in this situation, member states are not allowed to create unjustified trade barriers.

If one wants to place a new enzyme on the market, any of the four cases (horizontal versus vertical, harmonized versus national) can be applicable, meaning that all possibilities have to be assessed. The following factors are of importance when establishing how a specific enzyme is regulated.

1. The purpose of its use. Is the enzyme used only during processing of the food, or does it still have a specific function in the final food that is sold to the consumer?

2. The type of food in which the enzyme is to be used. Does the food in question have a standard of identity?

3. The country in which the enzyme is to be used in food. Applicable nonharmonized regulations will differ country by country.

4. The origin or source of the enzyme. Industrial enzymes can be obtained from plant, animal, or microbial sources. These may be regulated differently. Moreover, some countries have special requirements for enzymes produced by genetically modified organisms (gmos).

### **III. E.U. HARMONIZED LAWS**

#### **A. Horizontal Harmonized Laws**

The relevant harmonized E.U. Directive is the “Council Directive 89/107/EEC Concerning Food Additives Authorized for Use in Foodstuffs Intended for Human Consumption,” also called the Additives Framework Directive (3).

According to this directive, additives are everything added to food that is not normally used as a characteristic ingredient (a characteristic ingredient would, for instance, be milk in cheese or flour in bread). In the directive, food additives are divided into those that have a technological effect in the finished product and those that do not have a technological effect in the finished product. Additives of the first category may only be used if they have been authorized and included in a positive list together with their so-called E-number and, if applicable, permitted applications. Moreover, their presence in the final food has to be declared in the ingredient list of the foodstuff. Additives of the second category are exempt from these obligations; thus they do not have to be authorized, or labeled on the final foodstuff. It is rather confusing in practice that only products in the first category are called additives, whereas products in the second category are called processing aids.

The precise definition of processing aid according to the Additives Directive is:

“Processing aid” means any substance not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, food or their ingredients, to fulfill a certain technological purpose during treatment or processing and which may result in the unintentional but technically unavoidable presence of residues of the substance or its derivatives in the final product, provided that these residues do not present any health risk and do not have any technological effect on the finished product.

In the case of enzymes, the distinction between the use as processing aid or additive (or even ingredient) is not always easy. The existing definitions in E.U. law are open to interpretation on a number of points. This makes it difficult to decide in certain applications whether an enzyme has the status of a processing aid or an additive. The lack of consistency in the legislation has already led to regulatory uncertainty and difficulties surrounding enzymes, which until now had been regarded as processing aids, suddenly being considered to be additives.

Recent attempts to bring an increasing number of enzymes within the scope of the definition of food additives have principally been based on the argument that it is only possible to speak of a “residue” when there has been a conscious effort made to remove the enzyme. However, the interpretation of the food industry, and most authorities shared this interpretation until now, has always been that if an enzyme does not have a technological function in the final food, it is a processing aid, even if it remains in the final food in the small quantity (ppm) in which it was added.

If an enzyme does have a technological function in the final food, however, it will fall under the Additives Directive. There are at present only two enzymes falling under the Additives Directive:

1. Lysozyme, when used as preservative in ripened cheese.
2. Invertase, when used for soft centered confectionery.

Confusingly, these very same enzymes may also be used as processing aids for other food applications!

Thus, in the case of enzymes, one and the same enzyme can fall under both categories, depending on its application. If the enzyme has a technological function in the final food, it will fall under the Additives Directive. If it does not have a function in the final

food, it is a processing aid and exempt from the Additives Directive.

Only when use of an enzyme falls under the Additives Directive does specific approval by the European Commission need to be obtained if a company wants to market a new enzyme. This means that the functionality of the enzyme product has to be proved and its safety has to be evaluated by a specific group of experts called the Scientific Committee on Food (SCF).

In 1991 the SCF published guidelines for the presentation of data on food enzymes (4). To obtain approval, toxicological data need to be submitted. According to the guidelines, two mutagenicity studies and a 90-day oral toxicity study in rat are required as a general standard. However, safety data are not required for enzymes originating from edible plants or animals. Presumably, the SCF did not think about enzymes obtained from genetically modified plants at the time these guidelines were made.

In the case of microbial enzymes, no safety data are needed if the microorganism in question has a long history of safe use in food and belongs to a species for which documented evidence exists that no toxins are produced, and the actual strain used is of well-documented origin. To date, the only such microorganism accepted by the SCF is *Saccharomyces cerevisiae* (baker's yeast).

## B. Vertical Harmonized Laws

There are only two vertical harmonized directives, those on fruit juices and on wines, in which the use of certain enzymes is expressly provided for. The Fruit Juice Directive (5) states that only pectolytic, proteolytic, and amylolytic enzymes may be used in fruit juices. The Wine Regulation (6) permits the use of pectolytic enzymes and of  $\beta$ -glucanase from the microorganism *Trichoderma harzianum* only. No other enzymes can be used unless specific authorization, resulting in an amendment of the law, is given.

## IV. NATIONAL LAWS

National laws covering the use of enzymes are:

1. The general National Food Safety Laws. Even when an enzyme is not regulated in a specific Member State, its use would be subjected to the requirements of General Food Safety Legislation, which stipulates that nothing must be added to food which renders it injurious to health.

2. Horizontal enzymes regulations. There are three E.U. countries having specific horizontal enzyme regulations: Denmark, France and the United Kingdom (see below).

3. Before Spain and Portugal had to implement the harmonized E.U. Additives Directive, these countries regarded all enzymes, whether used as additive or processing aid, as additives. As a consequence, they were mentioned on the positive additive list and had to be authorized as such. It may be confusing for these countries that only very few enzymes are mentioned on the positive list of the E.U. Additives Directive, while all other enzymes can still be used, albeit only as processing aids. These countries may see this as a legal vacuum.

4. In addition to the above-mentioned regulations, most Member States have vertical laws for cheese, flour, bread, etc., regulating the use of enzymes. These vertical legislations differ from country to country, which may not only create trade barriers but also contribute to a very complicated picture for enzyme producers and users alike.

Unfortunately, this is also an area where mutual recognition between Member States does not function properly. If an enzyme is approved for a certain use in one Member State, this does not automatically mean that it is approved for the same use in another Member State.

## A. Horizontal Enzyme Regulations

In the 1970s, the Joint Expert Committee on Food Additives (JECFA) of the FAO/WHO developed toxicological requirements for enzyme products (7) based on the following classification system: enzymes from edible tissues of animals; enzymes from edible parts of plants; and enzymes from microbial origin, including microorganisms known to be present or used for food, microorganisms known to be harmless contaminants in food, and microorganisms unknown in food.

The main conclusion from this classification was that no numerical Acceptable Daily Intake or toxicity studies are necessary for enzyme preparations derived from edible tissues of animals, from edible portions of plants, or from microorganisms that are traditionally accepted as constituents of foods or are normally used in the preparation of foods.

Moreover, JECFA also established specifications to which enzyme products should comply (8). These specifications cover limits for certain heavy metals, microbial contamination, antibiotic activity, and mycotoxin con-

tent. In their guidelines, the SCF has largely followed the JECFA safety classification and specifications.

Shortly after JECFA development of specifications and toxicological requirements, the United Kingdom, France, and Denmark started developing guidelines for food enzymes. These guidelines were all largely based on the JECFA requirements and specifications. Only the French and Danish guidelines have been turned into genuine enzyme legislation. In the United Kingdom, it became a Code of Practice to ask for authorization for a new enzyme preparation on the basis of the U.K. regulations.

In principle, the French, Danish, and U.K. enzyme regulations did not mean to differentiate between the use of enzymes as additive or processing aid. However, since the use of an enzyme as additive now falls under the harmonized E.U. Additives Directive, these national laws now apply to enzymes used as processing aids only.

In all other E.U. Member States, there is no specific enzyme legislation. As a result, enzymes when used as processing aids are merely subjected to the general National Food Safety Laws if the country in question has no horizontal law regulating enzymes and if the application of the enzyme is not regulated in a vertical way. In such cases, no authorization is needed if a company wants to put a new enzyme on the market.

## 1. National Enzyme Law in France

The French Enzyme Decree (9) permits the use of all enzymes mentioned in an Annex to the Decree. This positive listing of enzymes is by function, enzyme name, source, foods in which the enzymes are permitted, and special conditions for use. The list is updated regularly.

The French Decree also lays down specifications of purity, which are very similar to the specifications laid down by JECFA. Furthermore, permitted preservatives and diluents for enzyme preparations are listed.

To obtain approval for a new enzyme, a dossier has to be filed with the authorities. This dossier should contain proof of the functionality of the enzyme ("case-of-need") and the results of safety studies as described in the SCF guidelines. In case an already approved enzyme is to be marketed for a new food application, only the case-of-need is required.

## 2. National Enzyme Law in Denmark

In contrast to France, the Danish law (10) does not contain a positive listing system. All enzyme products and their applications are simply subjected to a notifi-

cation procedure. Notification is valid only for a specific brand or trade name.

The user or importer of an enzyme preparation is responsible for such notification. It was recently decided that the information to be contained in the notification should follow the guidelines laid down by the SCF. Although the term "notification" is used, there is in practice no real difference between this procedure and an authorization. The authorities evaluate the dossier, and the product cannot be marketed until all questions about the dossier have been satisfactorily answered.

## 3. National Enzyme Regulation in the United Kingdom

In the United Kingdom, the Ministry of Agriculture, Fisheries and Food published the Food Advisory Committee's (FAC) Report on the Review of Enzyme Preparations in 1982 (11). This document was meant to form the basis for a national horizontal enzyme legislation.

The FAC recommended that food enzymes be approved only when a technical case-of-need had been established and they were considered safe for use in food. General specification requirements were also outlined. Moreover, the FAC established a positive list based on source and main enzyme activity. In this list, enzymes are divided into two groups, A and B. Group A are enzymes of vegetable or animal origin, for which no further specifications are necessary. Group B is a selection of microbial enzymes, which are temporarily approved for use in food. It was recommended that these enzymes be reviewed within 2 years of publication of the report.

As a basis for such a review, the FAC recommended the development of a nonspecific screening test to prevent the marketing of microbial enzyme preparations containing mycotoxins. However, the development of the test turned out to be impossible for technical reasons.

As an alternative, the U.K. Committee on Toxicity (COT) published Guidelines for the Safety Assessment of Microbial Enzyme Preparations in 1993 (12). These guidelines are comparable, although somewhat stricter, to those of the SCF. No U.K. guidelines exist for enzymes obtained from animals or plants.

Although these COT guidelines have not been converted into a genuine law, they have the same effect from a practical point of view. Authorization on basis of the guidelines is required to achieve marketing approval for a new enzyme preparation.

## **B. Regulations for Enzymes Produced by Genetically Modified Organisms (gmos)**

The SCF guidelines and the national regulations in the United Kingdom, Denmark, and France also cover specific provisions for enzymes made by gmos. In simplified terms this means that the genetic modification will be evaluated by the authorities before the enzyme can be approved and that the enzyme preparation should be free of the gmo and recombinant DNA.

JECFA has also written down general considerations and specifications for enzymes from genetically modified microorganisms (13). This has not been done for enzymes obtained from genetically modified plants or animals. As has been the case for classical enzymes, these considerations might be used for future E.U. regulations.

In the Netherlands, a Novel Food Law was passed in July 1993, covering, among others, all additives and processing aids made by genetic modification. This law was issued because of the delays in the adoption of the harmonized European Novel Food Regulation, but it has now been replaced by the latter.

The E.U. Novel Food Regulation was finally adopted in January 1997 and entered into force in May of that year (14). This regulation covers novel foods and food ingredients, but, in contrast to the Dutch Novel Food Law, additives (including processing aids) are outside its scope.

During the prolonged discussions on this regulation, the European Parliament obtained a commitment from the European Commission that an investigation would be carried out as to the need to fill gaps in the area regulating the protection of public health, particularly with respect to processing aids (e.g., enzymes), and that furthermore, where necessary, these gaps would be filled by proposals for additional legislation.

As a result, the Commission added the following statement to the Novel Food Regulation:

The Commission confirms that should it appear in the light of experience, that there are gaps in the system of protection of the public health provided for by the existing legal framework, in particular in respect of processing aids, it will formulate appropriate proposals in order to fill those gaps.

In an attempt to include gmos enzymes when used as processing aids into the scope of the E.U. Novel Food Regulation, the Dutch authorities in July 1997 wrote a proposal to regard enzymes that are not removed from the final food as ingredients instead of processing aids. In this way, such gmos enzymes would

be covered by the E.U. Novel Food Regulation. Owing to strong opposition of the French authorities, the Dutch proposal has not been accepted. Instead, the European Commission was asked by the Member States to prepare a paper regarding the present legal situation for food enzymes. The European Commission transferred this task in October 1998 to a so-called Scientific Cooperation (SCOOP) task force, in which experts from various Member States participated. The four objectives of the SCOOP task force were to: make a list of food enzymes in use in E.U.; study the way they have been evaluated for their safety; make overview of the current legal situation; and find criteria for distinguishing between the use of enzymes as additives, processing aids, or ingredients.

The SCOOP task force finished its work at the end of 2000. The report however, has not yet been published at the time of this writing. One of the main conclusions the SCOOP task force drew was that the present definitions on additives and processing aids do not provide sufficient criteria to distinguish between the use of enzymes as an additive or as a processing aid. The problem on how to distinguish between additives and processing aids is also being discussed at international level, namely within the Codex Committee for Food Additives and Contaminants. The results of this discussion, which may take several years, can potentially have a great impact on the way enzymes are regulated in future in the European Union and elsewhere.

In July 2001, the European Commission adopted two new proposals for regulating products derived from gmos: (a) a proposal for regulation of genetically modified Food and Feed (15); (b) a proposal for regulation concerning traceability and labeling of gmos and traceability of food and feed products produced from gmos (16). Before becoming law, the proposals will first have to be accepted by the European Council and Parliament, a process that may take several years. The proposals will replace the above-mentioned E.U. Novel Food Regulation as far as products derived from genetic modification are concerned. Again, enzymes when used as processing aids in food are explicitly exempted from the proposals. Whether this will again lead to discussions within the European Parliament remains to be seen.

## **V. PROBLEMS**

### **A. Consequences of Present Regulatory Situation**

Since mutual recognition among Member States does not function properly, the enzyme industry is con-

fronted with an unnecessary burden to obtain approvals for the use of a new enzyme in food in individual Member States. It goes without saying that it will potentially save cost and time if there were only one approval system. Furthermore, there is not always mutual recognition as regards the type of safety tests to be performed. This may lead to unnecessary use of laboratory animals. The approval of an enzyme is thus governed by the toughest standard in any one country.

There is no harmonized system and there are no fixed time limits for approvals resulting in uncertainty about return on R&D investments for the enzyme industry.

Member States still apply certain national rules on production within their own territory, which leads to so-called reverse discrimination. Enzyme and food producers are particularly affected by this mechanism. Enzyme producers are in principle able to *sell* their products throughout the European Union, but the remaining national rules in some Member States prevent the food producers, in their own Member State, from actually *using* the food enzyme in question, meaning that they simply will not buy the enzyme!

Nevertheless, foodstuffs produced with such enzymes can be imported into these Member States owing to the open E.U. market. Thus, such Member States discriminate against the production of particular foodstuffs in their own country.

The reverse discrimination leads to unequal starting points for food producers in the various Member States and limits their flexibility in shifting manufacturing.

The lack of consistency and clarity in the legislation, such as the different interpretations in Member States, of the terms processing aid, additive and ingredient, leads to legal insecurity for the enzyme producers as well as the food producers. In some cases, Member States use the situation as an argument for not giving approvals: "We are waiting for Brussels." In other cases, Member States expressed their desire to develop their own national enzyme legislation which would result in an even more fragmented situation.

In the absence of a harmonized legal situation, the food industry creates its own rules, leading to an even more complicated and costly situation for the enzyme industry. Political parties, Parliament, and action groups are calling for enzyme regulation, especially for enzymes obtained from gmos.

Especially in countries without an enzyme legislation, like Germany, the lack of regulation can lead to low consumer confidence. Various television programs

and articles have insinuated that enzymes lead to food allergy and that enzymes produced using gmos might lead to an increase in this problem.

For all these reasons, AMFEP is in favor of a clear, simple, and more harmonized regulatory regimen for food enzymes in the European Union. Such a regimen would not only solve mutual recognition problems, but also fill the perceived gap in the E.U. Novel Foods Regulation. It may also contribute to improving public confidence by increasing the transparency of the safety evaluation of food enzymes.

## B. Wishes of the European Enzyme Industry for the Future

The wish of AMFEP is to have a future regulatory regimen for food enzymes which:

1. Leads to only one approval system, thus less burden, less time, less money.
2. Eliminates the present lack of mutual recognition and thus trade barriers.
3. Simplifies and clarifies the legal situation.
4. Removes present legal gaps, giving more legal security to producers and users.
5. Ensures a high level of protection of public health, leading to improved consumer confidence.
6. Ensures that legislation is primarily based on scientific evidence and risk assessment.
7. Improves the image of producers of food enzymes and its users, the food industry.

Whatever future regulatory situation is created, AMFEP would like the following five principles to be fulfilled:

1. Nondiscrimination of gmos enzymes. Gmos enzymes should not end up in a separate legislation, for instance under the E.U. Novel Food Regulation.
2. Grandfathering mechanism. Enzymes that are already on the market should be able to stay on the market.
3. Processing aid status or a category in their own right. There should be no more case-by-case discussions about whether a specific enzyme is applied as processing aid, additive, or ingredient. They should all be given the same status. That might be a category in their own right, as is the case for flavors in the E.U.
4. Application of SCF guidelines for safety testing. There should only be one standardized way to do this.

5. No fragmentation through different legislation. The complicated way enzymes are regulated now should be simplified. All food enzymes should be regulated in a uniform way.

## VI. SUMMARY

There is no overall E.U. regulatory regimen for enzymes. Most enzymes are exempted from the harmonized E.U. Food Additives Directive because they are used as processing aids and not as additives with a function in the final food. Enzymes are, however, subjected to many different national legislations in the E.U. Member States. The result of these differences in legislation is a lack of consistency in the way enzymes are regulated throughout the E.U. Therefore, for the global enzyme producer, the production and marketing of an enzyme product is governed by the toughest standards in any one E.U. country. The enzyme industry is in favor of a more uniform and harmonized regulatory regimen in the European Union.

## Regulatory Issues of Food Enzymes Used in the United States

**John R. Whitaker**

*University of California, Davis, Davis, California, U.S.A.*

### I. INTRODUCTION

Thousands of enzymes are found in all of the raw materials (plants, animals, microorganisms) produced for foods. In those consumed raw, the enzymes are active when ingested but are generally denatured by the acid pH of the stomach. They then become a (small) part of our total daily protein requirement. When foods are processed prior to eating by heating, the enzymes are denatured. In dried and freeze-dried products, the enzymes may be in active form. In fruits and vegetables, such as apricots, apples, dates, plums, potatoes, mushrooms, teas, etc., the enzymes are still active and must be inactivated by blanching ( $\sim 85^{\circ}\text{C}$ ), or controlled by adding enzyme inhibitors such as bisulfite, ascorbic acid, or other specific inhibitors before drying. But these naturally occurring enzymes are not regulated. If an enzyme is added (by biotechnology) to a plant to increase the level of enzyme, such as overproduction of 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS) or cloning a mutant gene encoding EPSPS that is insensitive to glyphosate to prevent killing of the plant by the herbicide glyphosate, while the unwanted grasses and weeds are killed, this is regulated. When an enzyme is added during the processing of a food, this is regulated.

Addition of enzymes, whether to increase the level of the enzyme or to include a new enzyme in a live plant or animal or microbe to be used as food, is regulated by the U.S. Department of Agriculture (USDA) via the Animal and Plant Health Inspection Service (APHIS),

the Food Safety and Inspection Service FSIS), and the Grain Inspection, Packers, and Stockyard Administration (GIPSA) or by a state department of agriculture. Increases, or decreases, of some enzyme levels, such as polyphenol oxidase, can be done by standard breeding methods. The insertion of a new gene and its expression to change the sensory, nutrition, climate tolerance, insect resistance, or storage properties of the living organism is generally done by genetic engineering. The “inventor” must demonstrate that there are no harmful effects to humans or the environment, including other types of activities (allergenic, for example) of the food produced from such modifications. The federal and/or state departments of agriculture are responsible for enforcing such modifications to living potential food sources.

Additions of enzymes to food materials during processing are regulated by the Food and Drug Administration (FDA) unit of the Department of Health and Human Services. Specifically, the Center for Food Safety and Applied Nutrition (CFSAN) of FDA is assigned this responsibility. In carrying out its responsibility, it may request advice from the National Academy of Sciences (NAS) or other expert bodies and scientists. The regulations of FDA become binding when published in the Federal Register (published by the Office of the Federal Register, National Archives and Records Administration of the U.S. Government Printing Office).

The regulations are not only published in the Federal Register, but can be found also on several

electronic Web sites. These web sites include: <http://www.fda.gov/>; <http://vm.cfsan.fda.gov/list.html>; <http://vm.cfsan.fda.gov/~dms/reg-2.html>; <http://vm.cfsan.fda.gov/~dms/eafus.html>; <http://vm.cfsan.fda.gov/~lrd/biotechm.html>; [http://vm.cfsan.fda.gov/cgi-bin/ws.cgi?Q...+and+food+additives+\(or+use+OR+in+place+of+AND\);+http://frwebgate.access.gpo.gov/cgi-bin/multidb.cgi](http://vm.cfsan.fda.gov/cgi-bin/ws.cgi?Q...+and+food+additives+(or+use+OR+in+place+of+AND);+http://frwebgate.access.gpo.gov/cgi-bin/multidb.cgi).

The EAFUS ("Everything" Added to Food in the United States) Web Site (above) is an informational database maintained by the FDA Center for Food Safety and Applied Nutrition (CFSAN) under the program Priority-based Assessment of Food Additives (PAFA).

It contains administrative, chemical and toxicological information on over 2000 substances added to food, including substances regulated by the FDA as direct, "secondary" direct, and color additives, and Generally Recognized As Safe (GRAS) and prior-sanctioned substances. In addition, the database contains only administrative and chemical information on less than 1000 other substances (without toxicological information). The more than 3000 total substances together comprise an inventory often referred to as EAFUS [quoted from EAFUS database].

This list of (of some 3000) substances contains ingredients added directly to food that FDA has either approved as food additives or listed or affirmed as GRAS. Nevertheless, it contains only a partial list of all food ingredients that may in fact be lawfully added to food, because under federal law some ingredients may be added to food under a GRAS determination made independently from the FDA. The list therefore contains many, but not all, of the substances subject to independent GRAS determinations. For information about the GRAS notification program please consult the Inventory of GRAS Notifications [on the EAFUS data base].

The EAFUS database is 201 pages in length.

## **II. ORIGIN AND HISTORY OF THE U.S. FOOD AND DRUG ADMINISTRATION**

### **A. Origin**

Regulations to prevent adulteration or sale of unfit food in Great Britain have existed since the early

13th century. The Sale of Food and Drugs Act of the United Kingdom was passed in 1875. The U.K. Act was amended by the Food and Drug Acts of 1938 and 1955. A major reason for the amendments was to improve the control of the increasingly complex process of food preparation and sale (1). The U.K. Act prohibited the sale of any food in which substances were added or deleted, or in which the food was processed in a manner that might be unsafe to human health. Other offenses included the sale of misbranded, falsely described foods, and misleading claims about the nature of the product, its substance, or its quality.

The United Kingdom in concert with other countries of the European Union (E.U.) have worked to standardize the regulations to simplify trade of foods among the European Union (see [Chapter 6](#) of this book by Praaning).

In the United States, the first Federal Food and Drug Law was established in 1906 (2). The legislation was the basis for passage of several food standards of identity, as well as the prohibition of sale of toxic, unsanitary, adulterated, or misbranded foods. The law required the federal government to prove that suspect foods were toxic or harmful to human health. This law remained in effect until 1938, with two minor revisions in 1907 and 1912. In 1938, Congress enacted the Federal Food, Drug, and Cosmetic Act, following the death of 70 people who took the drug "Elixir Sulfanilamide." The provisions of the act were: (a) the establishment of the FDA, the primary functions of which were administrative and provided only for the prohibition of the use of known toxic substances as food additives; (b) the establishment of standards of identity and food quality, as well as (c) mandates to provide for honest labeling and safe packaging.

In 1958, the Food Additive Amendment was enacted because of increasing concern by physicians and consumers that chemical additives were a possible cause of cancer. Following deliberations of the Delaney Committee, an amendment was passed (1960) that required the FDA to consider "safety factors which, in the opinion of experts qualified by scientific training and experience to evaluate the safety of food additives, are generally recognized as appropriate for the use of animal experimentation data." This amendment required that the safety of ingredients and products be established before the consumer was exposed to them. Thus, the onus of establishing food safety was transferred to the manufacturers, along with the mandated requirement for

animal testing prior to marketing of the food. One clause of the amendment, known as the Delaney clause, caused major scientific and public controversy. It stated: "No food additive shall be deemed to be safe if it is found to induce cancer when ingested by man or animals" (3). The net result was that all the compounds classified as GRAS required new petitions to FDA that not only addressed the safety of the food additives but also the reagents used in preparation and use of the food additives. Since enzymes were classified as food additives in 1906, they had to be analyzed for safety, activity, and usage level in relation to the food in which they were included. Nelson (4), Hickman (5), and Roland (6) have written thorough and thoughtful reviews of the issues and problems caused by this ruling.

## B. Role of the FDA in Regulation of Enzymes in Food

Food enzymes are derived from cells of living plants, animals, and microorganisms. The enzymes, known or unknown, have been a part of the food of humans, as well as animals, as long as humans have been on earth. The enzymes are an essential part of germination of seeds and reproduction of animals and microorganisms, growth of organisms, maturation, storage and utilization in producing the food and in its digestion to the building blocks for proteins, lipids, carbohydrates, and nucleic acids of all animals, including humans. From early times enzymes from plants, animals, and microorganisms were used to modify the taste, aroma, color, texture, and digestibility of agriculture products. Many major food industries (baking, brewing, dairy, meat, and fruits) are dependent on the utilization of enzymes for production of breads, beers, cheese, fruit juices, etc.

Up to 1958, enzymes were considered as food (protein) or food additives but safe, since they had been used in food since humans first appeared on earth. But since 1958, the FDA has viewed enzymes as food additives, not food. However, until 1972 when the FDA suspended the "generally recognized as safe" (GRAS) status, enzymes were considered to be safe, since they came from natural sources and are proteins, and a part of all raw foods. They also had an excellent safety record for many hundreds of years.

The 1958 Food Additive Amendment defined enzymes as food additives, rather than as foods, food-stuffs, or foreign substances found in very small amounts or familiar substances as some other countries did.

Food additives, as defined by the 1958 Food Additive Amendment are:

Any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in it becoming a component or otherwise affecting the characteristics of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; and including any source of radiation intended for such use); if such substance is not generally recognized among experts qualified by scientific training and experience to evaluate its safety as having been adequately shown through scientific procedures (or, in the case of a substance used in food prior to 1 January 1958, through either scientific procedures or experiences based on common use in food) to be safe under the conditions of its intended use.

The term food additive thus covers any substance (i.e., enzyme) directly added to food. Indirect additions to food during processing which become a component of the food are also included.

The 1958 Food Additive Amendment established three categories of food additives for foods. They were:

1. Food substances "grandfathered" into the category Generally Recognized as Safe (GRAS), or those substances for which prior sanctions had been previously established.

2. Substances deemed as automatically unsafe as defined by the Delaney clause, "no additive shall be deemed to be safe if it is found to induce cancer when ingested by man or animal, or if it is found, after tests which are appropriate for the evaluation of the safety of food additives, to induce cancer in man or animals."

3. All other food and color additives which need to be tested for safety on an individual basis.

In 1972, FDA revoked the GRAS or prior sanction status of all pre-1958 additives (which to this time were cleared under the "grandfather clause" of long use that had shown them to be safe, including enzymes) despite a lengthy report by the Ad Hoc Enzyme Technical Committee (AHETC), established in 1969; membership consisted of representatives from most of the firms that manufactured or marketed enzymes in the United States. The sole purpose of the AHETC was, and is, to deal with regulatory issues and requirements involving enzymes with the FAO/WHO Joint Expert

Committee on Food Additives (JECFA), a committee of outstanding scientists with experience in food toxicology from England, France, Japan, Italy, Switzerland, Holland, Australia, Russia, and the United States. After initial review the updated report was submitted to the FDA and to the Subcommittee on Codex Specifications, Committee on Food Protection, National Research Council for inclusion in the Food Chemicals Codex (published in 1974). Despite these extensive efforts by AHETC and JECFA, the FDA made it clear that further information would be required before any enzyme, even those with a long history of use, would be confirmed as GRAS.

At the 1997 Annual Meeting of the Institute of Food Technologists, Corbin Miles of the FDA's Bureau of Foods described the FDA strategy for enzyme GRAS affirmation. A summary of that report is found in Nelson (4), which is quoted here.

FDA will again review information on enzymes and enzyme sources, particularly microbial-derived enzymes. FDA has continued to seek such information, including requests published in the Federal Register. Essentially, FDA will hew to the present requirements for food additive petitions. Any enzyme which was GRAS under the 1958 amendment will require significant safety information before it will be included in the present GRAS list. Mr. Miles stressed that the activity of the enzyme and the utilization of such activity in the manufacture or modification of foods must be described in some detail. Any GRAS regulations on enzymes must include all conditions of use which have been evaluated. Mr. Miles stated that trade secret information (if different than that publically available or proposed) must be submitted. He suggested that trade secret information be submitted via an additive petition which can be exempt from the Freedom of Information Act.

The first impression of those of us familiar with enzymes (biochemists, members of AHETC and JECFA, and perhaps the E.U. Scientific European Committee on enzyme usage in foods) was that this was a very harsh and unjustified position to take on the clearance of enzymes in food processing and manufacture. But when one recalls that commercial enzyme products are at most 1% of the desired enzyme and 99% of other materials including trace amounts of other enzymes, purification materials, etc., the view of FDA can be rationalized. Perhaps,

or not, the use of higher purity enzymes produced by genetic engineering will alleviate some of the problems with extraneous materials, including fragments of microbial cells.

Nelson (4) has discussed the lengthy time required for review of petitions by FDA. The minimum time may be 18 months. But with requirements for toxicology and mutagenicity studies with animals of up to 2 years, the time can be 3 years or more, at a cost of hundreds of thousands of dollars (7). Only enzyme products with high economic value expectations are likely to be submitted for review. Anticipated revenue from food enzyme products in no way compares with that of enzyme products from drug companies, especially since the latter have to be pure!

### C. GRAS Petitions to FDA

A GRAS petition for FDA review looks like the following (6).

1. Clearly state the intent of the petition to demonstrate safety, based on one common use in foods for the enzyme and/or the end product. Alternatively, establish safety through the publication of adequate supporting data.

2. Identification of the enzyme: (a) class; (b) species; (c) strain-variety; (d) enzyme source.

3. Method of preparation: (a) complete medium composition; (b) mechanical units used to produce; (c) fermentation conditions (aeration, agitation, temperature, pH).

4. Enzyme specifications: (a) single enzyme, multiple enzymes, or whole cells; (b) impurities, i.e., heavy metals, solvents; (c) comparative compositional data on a minimum of five processes of the enzyme.

5. Methods of enzyme recovery: (a) types and levels of solvents employed; (b) types of processing aids, i.e., filtration, flocculation; (c) other.

6. Toxicological data on enzyme or microorganism: (a) organism must be non pathogenic; (b) organism must not produce mycotoxins or other toxic chemicals; (c) organism must not produce antibiotics.

Ebert (8), Aunstrup (9) and Grasso (10) have designed formats for typical toxicological evaluations on animals. [Table 1](#) is from a publication of Dr. Ebert (8).

Both FDA and USDA, in reviewing a petition, may ask advice from the National Academy of Sciences, the Federation of American Societies for Experimental Biology, Special Advisory Committees, and individual consultants.

**Table 1** Typical Toxicological Evaluation of Food Additives

Study	Scope
Acute	
Oral LD <sub>50</sub>	Two species (min) range find for subacute studies.
Dermal inhalation LD <sub>50</sub>	As needed (OSHA requirements, etc.).
Subacute	
90-day feeding	Two species: one nonrodent, dog preferred. Three levels (min) plus control. Complete biochemical and histopathologic workup on control, highest level fed. Other levels if needed. Define no-effect level. High level to give effect.
Chronic 2 years <sup>+</sup>	Two species—rat/dog. Carry rat to 25% survival of controls. Perhaps combine with three-generation reproduction study. Three levels plus control. Complete biochemical and histopathologic workup.
Metabolic fate	Search for animal model for man. Absorption, distribution kinetics, organ/tissue concentration (if any) metabolic products defined.
Special	Carcinogenicity, teratology, cytogenicity (host mediated, dominant lethal, chick embryo).
Interaction	Special dietary restrictions, drug interactions.

Source: Ref. 8.

### III. CURRENT STATUS OF ENZYME REGULATIONS (11)

Since the beginning of federal regulations involving enzymes they have been, and continue to be, classified as food additives. As noted earlier in this chapter, they were originally classified as GRAS. But after 1958, when the Food Additive Amendment was passed, safety of the enzyme-containing product had to be addressed, and in 1972, all GRAS status was revoked. As pointed out in Section II above, these changes require extensive data in the petition asking for reinstatement of GRAS status.

Regulation of food additives is covered in the Code of Federal Regulation Title 21, §170–199 (11). Enzymes are covered collectively with other food additives in Part 170—Food Additives, [Chapter 1](#), Food and Drug Administration, Department of Health and Human Services Subchapter B, Food for Human Consumption as to regulation procedures, in §171, Food Additive Petitions; in §173, Secondary Direct Food Additives Permitted in Food for Human Consumption; and in §184, Direct Food Substances Affirmed as Generally Recognized as Safe.

#### A. §170—Food Additives and Food Additive Petitions

§170—Food Additives is a general section for all food additives (pp 5–10). §171—Food Additive Petitions is a general section on how to petition FDA for approval of a food additive (pp 21–26). Both *must* be consulted for the general aspects pertaining to definitions, classification of foods and ingredients, and general policies on food additive regulations. The topics covered are given in [Table 2](#).

#### B. §173—Secondary Direct Food Additives

§173—Secondary Direct Food Additives Permitted in Food for Human Consumption, Subpart B—Enzyme Preparations and for a Human Consumption, Subpart B—Enzyme Preparations and Microorganisms lists those enzymes and microorganisms that have been affirmed by FDA and on what basis they were approved ([Table 3](#)). Note that all the enzymes are from microorganisms.

**Table 2** Code of Federal Registrations 21. Food and Drugs. Part 170—Food Additives<sup>a</sup>

<sup>a</sup>From Code of Federal Regulations 21. Food and Drugs. Part 173, Published in the Federal Register No. 21, pp 111–124, April 1, 2000.

A closer look at the approval use of microbial milk-clotting enzymes is instructive as to understanding the FDA approval process, including the conditions given in §173.150.

Milk-clotting enzymes produced by pure-culture fermentation process may be safely used in the production of cheese in accordance with the following prescribed conditions.

(a) Milk-clotting enzyme is derived from one of the following organisms by a pure-culture fermentation process.

(1) *Endothia parasitica* classified as follows: class, Ascomycetes; order, Sphaeriales; family, Diaporthaceae; genus, *Endothia*; species, *parasitica*.

(2) *Bacillus cereus* classified as follows: class, Schizomycetes; order, Eubacteriales; family, Bacillaceae; genus, *Bacillus*; species, *cereus* (Frankland and Frankland).

(3) *Mucor pusillus* Lindt classified as follows: class, Phycomyces; subclass, Zygomycetes; order, Mucorales; family, Mucoraceae; genus, *Mucor*; species, *pusillus*; variety, *Lindt*.

(4) *Mucor miehei* Cooney et Emerson classified as follows: class, Phycomyces; subclass, Zygomycetes; order, Mucorales; family, Mucoraceae; genus, *Mucor*, species, *miehei*; variety, *Cooney et Emerson*.

(5) *Aspergillus oryzae* modified by recombinant deoxyribonucleic acid (DNA) techniques to contain the gene coding for aspartic proteinase from *Rhizomucor miehei* var. *Cooney et Emerson* as defined in paragraph (a)(4) of this section, and classified as follows: class, Blastodeuteromycetes (Hyphomycetes); order, Phialidales (Moniliales); genus, *Aspergillus*; species, *oryzae*.

(b) The strains of organism identified by paragraph (a) of this section are nonpathogenic and nontoxic in man or other animals.

(c) The additive is produced by a process that completely removes the generating organism from the milk-clotting enzyme product.

(d) The additive is used in an amount not in excess of the minimum required to produce its intended effect in the production of those cheeses for which it is permitted by standards of identity established pursuant to section 401 of the Act [42 FR 14526, Mar. 15, 1977; 42 FR 56728, Oct. 14, 1977, as amended at 62 FR 59284, Nov. 3, 1997].

## C. §184—Direct Food Substances Affirmed as Generally Recognized as Safe (GRAS)

(a) The direct human food ingredients listed in this part have been reviewed by the Food and Drug Administration and determined to be generally recognized as safe (GRAS) for the purposes and under the conditions prescribed. The regulations in this part shall sufficiently describe each ingredient to identify the characteristics of the ingredient that has been affirmed as GRAS and to differentiate it from other possible versions of the ingredient that have not been affirmed as GRAS. Ingredients affirmed as GRAS in this part are also GRAS as indirect human food ingredients, subject to any limitations prescribed in parts 174, 175, 176, 177, 178 or Sec. 179.45 of this chapter or in parts 186 of this chapter. The purity specifications in this part do not apply when the ingredient is used in indirect applications. However, when used in indirect applications, the ingredient must be of a purity suitable for its intended use in accordance with §170.30 (h) (1) of this chapter.

(b) Any ingredient affirmed as GRAS in this part shall be used in accordance with current good manufacturing practice. For the purpose of this part, current good manufacturing practice includes the requirements that a direct human food ingredient be of appropriate food grade; that it be prepared and handled as a good ingredient; and that the quantity of the ingredient added to food does not exceed the amount reasonably required to accomplish the intended physical, nutrition, or other technical effect in food.

(1) If the ingredient is affirmed as GRAS with no limitations on its conditions of use other than current good manufacturing practice, it shall be regarded as GRAS if its conditions of use are consistent with the requirements of paragraph (b), (c), and (d) of this section. When the Food and Drug Administration (FDA) determines that it is appropriate, the agency will describe one or more current good manufacturing practice conditions of use in the regulation that affirms the GRAS status of the ingredient. For example, when the safety of an ingredient has been evaluated on the basis of limited conditions of use, the agency will describe in the regulation that affirms the GRAS status of the ingredient, one or more of these limited conditions of use, which may include the category of food(s), the technical

effect(s) or functional use(s) of the ingredient, and the level(s) of use. If the ingredient is used under conditions that are significantly different from those described in the regulation, that use of the ingredient may not be GRAS. In such a case, a manufacturer may not rely on the regulation as authorizing that use but shall independently establish that that use is GRAS or shall use the ingredient in accordance with a food additive regulation. Persons seeking FDA approval of an independent determination that a use of an ingredient is GRAS may submit a GRAS petition in accordance with §170.35 of this chapter.

(2) If the ingredient is affirmed as GRAS with specific limitation(s), it shall be used in food only within such limitation(s), including the category of food(s), the functional use(s) of the ingredient, and the level(s) of use. Any use of such an ingredient not in full compliance with each such established limitation shall require a food additive regulation.

(3) If the ingredient is affirmed as GRAS for a specific use, without a general evaluation of use of the ingredient, other uses may also be GRAS.

(c) The listing of a food ingredient in this part does not authorize the use of such substance in a manner that may lead to deception of the consumer or to any other violation of the Federal Food, Drug, and Cosmetic Act (the Act).

(d) The listing of more than one ingredient to produce the same technological effect does not authorize use of a combination of two or more ingredients to accomplish the same technological effect in any one food at a combined level greater than the highest level permitted for one of the ingredients.

(e) If the Commissioner of Food and Drugs is aware of any prior sanction for use of an ingredient under conditions different from those proposed to be affirmed as GRAS, he will concurrently propose a separate regulation covering such use of the ingredient under part 181 of this chapter. If the Commission is unaware of any such applicable prior sanction, the proposed regulation will so state and will require any person who intends to assert or rely on such sanction to submit proof of its existence. Any regulation promulgated pursuant to this section constitutes a determination that excluded uses would result in adulteration of the food in violation of section 402, of the Act, and the failure of any person to

come forward with proof of such an applicable prior sanction in response to the proposal will constitute a waiver of the right to assert or rely on such sanction at any later time. The notice will also constitute a proposal to establish a regulation under part 181 of this chapter, incorporating the same provisions, in the event that such a regulation is determined to be appropriate as a result of submission of proof of such an applicable prior sanction in response to the proposal.

(f) The label and labeling of the ingredient and any intermediate mix of the ingredient for use in finished food shall bear, in addition to the other labeling required by the Act:

(1) The name of the ingredient, except where exempted from such labeling in part 101 of this chapter.

(2) A statement of concentration of the ingredient in any intermediate mix; or other information to permit a food processor independently to determine that use of the ingredients will be in accordance with any limitations and good manufacturing practice guidelines prescribed.

(3) Adequate directions for use to provide a final food product that complies with any limitations prescribed for the ingredient(s) [42 FR 14653, Mar. 15, 1977, as amended at 42 FR 55205, Oct. 14, 1977; 48 FR 48457, 48459, Oct. 19, 1983; 62 FR 15110, Mar. 31, 1997].

#### 1. List of Enzymes That Have Been Affirmed as Generally Recognized as Safe

Table 4 lists the enzymes that have been affirmed as generally recognized as safe (GRAS). Note that the list includes enzymes from animals, plants, and microorganisms. The affirmation of rennet and bovine rennet (both animal derived) and chymosin (fermentation derived from microorganisms containing the prochymosin gene) (Section §84.1685) has been chosen to indicate (a) requirements for animal rennet, (b) requirements for microbial chymosin, and (c) requirements for enzymes produced by genetically engineered microorganisms.

#### 2. §184.1685—Rennet (Animal Derived) and Chymosin (Fermentation Derived) Preparation

(a)(1) Rennet and bovine rennet are commercial extracts containing the active enzyme rennin (CAS Ref. No. 9001-98-3), also known as chymosin (International Union of Biochemistry

**Table 4** Enzymes Affirmed as Generally Recognized as Safe<sup>a</sup>

Subsection	Enzyme (or product)	Source (or Substrate)
§184.1012	$\alpha$ -Amylase	<i>Bacillus stearothermophilus</i>
§184.1024	Bromelain (peptide hydrolase)	Pineapple ( <i>Ananas comosus</i> and <i>A. bracteatus</i> L.)
§184.1027	Mixed carbohydrase and protease	<i>Bacillus licheniformis</i>
§184.1034	Catalase	Bovine liver
§184.1148	$\alpha$ -Amylase and $\beta$ -glucanase	<i>Bacillus subtilis</i> or <i>B. amyloliquefaciens</i>
§184.1150	Subtilisin and neutral proteinase	<i>Bacillus subtilis</i> or <i>B. amyloliquefaciens</i>
§184.1250	Cellulase	<i>Trichoderma longibrachiatum</i>
§184.1316	Ficin	Tropical fig trees
§184.1372	Immobilized glucose isomerase (high-fructose corn syrup)	<i>Streptomyces rubiginosus</i> <sup>b</sup>
§184.1387	Lactase	<i>Candida pseudotropicalis</i>
§184.1388	Lactase	<i>Kluyveromyces lactis</i>
§184.1415	Lipase	From forestomach or pancreas of calves, kids, or lambs
§184.1420	Lipase	<i>Rhizopus nireus</i>
§184.1583	Pancreatin	Porcine or bovine pancreas
§184.1585	Papain	Papaya ( <i>Carica papaya</i> L.)
§184.1595	Pepsin	Hog stomach glandular layer
§184.1685	Rennet (animal derived) Chymosin (fermentation derived)	Fourth stomach (abomasa) of calves, kids, or lambs <i>Escherichia coli</i> K-12, <i>Kluyveromyces marxianus</i> var. <i>lactis</i> , or <i>Aspergillus niger</i> van Teighem var. <i>awamori</i> (all the microorganisms contain the calf prochymosin gene)
§184.1914	Trypsin	Bovine pancreas
§184.1924	Urease	<i>Lactobacillus fermentum</i>
§184.1985	Aminopeptidase	<i>Lactococcus lactis</i>
§184.1063	Phospholipase A <sub>2</sub>	Gives enzyme-modified lecithin (enzyme from bovine pancreatin)
§184.1287	Lipases from milk or milk powder	Fats
§184.1857	Acids or enzymes	Corn sugar (glucose)
§184.1859	Acids or enzymes	Invert sugar (glucose + fructose)
§184.1865	Acids or enzymes	Corn syrup
§184.1866	Glucose isomerase	High-fructose corn syrup

<sup>a</sup>From Code of Federal Regulations 21. Food and Drugs. Part 184, sub part B, published in the Federal Register, No. 21, pp 461–556, April 1, 2000.

<sup>b</sup>Other microorganisms approved as a source of glucose isomerase are *Actinoplanes missouriensis*, *S. olivaceus*, *S. olivochromogenes*, and *Bacillus coagulans*.

Enzyme Commission (E.C.3.4.23.4). Rennet is the aqueous extract prepared from cleaned, frozen, salted, or dried fourth stomachs (abomasa) of calves, kids, or lambs. Bovine rennet is the product from adults of the animals listed above. Both products are called rennet and are clear amber to dark brown liquid preparations or white to tan powders.

(2) Chymosin preparation is a clear solution containing the active enzyme chymosin (E.C. 3.4.23.4). It is derived, via fermentation, from a nonpathogenic and nontoxigenic strain of *Escherichia coli* K-12 containing the prochymosin gene. The prochymosin is isolated as an insol-

uble aggregate that is acid-treated to destroy residual cellular material and, after solubilization, is acid-treated to form chymosin. It must be processed with materials that are generally recognized as safe, or are food additives that have been approved by the Food and Drug Administration for this use.

(3) Chymosin preparation is a clear solution containing the active enzyme chymosin (E.C. 3.4.23.4). It is derived, via fermentation, from a nonpathogenic and nontoxigenic strain of *Kluyveromyces marxianus* variety of *lactis*, containing the prochymosin gene. The prochymosin is secreted by cells into fermentation broth and

converted to chymosin by acid treatment. All materials used in the processing and formulating of chymosin must be either generally recognized as safe (GRAS), or be food additives that have been approved by the Food and Drug Administration for this use.

(4) Chymosin preparation is a clear solution containing the active enzyme chymosin (E.C. 3.4.23.4). It is derived via fermentation, from a nonpathogenic and nontoxigenic strain of *Aspergillus niger* van Tieghem variety *awamori* Nakazawa; (Al-Musallam synonym A. *awamori* Nakasawa) containing the prochymosin gene. Chymosin is recovered from the fermentation broth after the acid treatment. All materials used in the processing and formulating of chymosin preparation must be either generally recognized as safe (GRAS) or be food additives that have been approved by the Food and Drug Administration for this use.

(b) Rennet and chymosin preparations meet the general and additional requirements for enzyme preparations of the "Food Chemicals Codex," 3d Ed. (1981), pp. 107–110, which is incorporated by reference in accordance with 5 U.S.C. 552(a). Copies are available from the National Academy Press, 2101 Constitution Avenue NW., Washington, DC 20418, or are available for inspection at the Office of the Federal Register, 800 North Capitol Street, NW., Suite 700, Washington, D.C.

(c) In accordance with §184.1(b)(1), the ingredient is used in food with no limitation other than current good manufacturing practice. The affirmation of this ingredient as generally recognized as safe as a direct human food ingredient is based upon the following current good manufacturing practice conditions of use:

(1) The ingredient is used as an enzyme as defined in §170.03(o)(9) of this chapter; a processing aid as defined in §170.3(o)(24) of this chapter; and a stabilizer and thickener as defined in §170.3(o)(28) of this chapter.

(2) The ingredient is used in the following foods at levels not to exceed current good manufacturing practice: In cheeses as defined in §170.3(n)(5) of this chapter; frozen dairy desserts and mixes as defined in §170.3(n)(20) of this chapter; gelatins, puddings, and fillings as defined in §170.3(n)(22) of this chapter; and milk products as defined in §170.3(n)(31) of this chapter.

(d) Prior sanctions for this ingredient different from the uses established in this section do not exist or have been waived. [FR 10935, Mar. 23, 1990, as amended at 57 FR 6479, Feb. 25, 1992; 58 FR 27202, May 7, 1993].

It is important to specifically point out that FDA has included genetically engineered enzymes as GRAS as food additives, using the same criteria as used for nongenetically engineered sources of enzymes. Under Part 173, Secondary Direct Food Additives Permitted in Food for Human Consumption, Subpart B—Enzyme Preparations, FDA permitted the genetically derived milk-clotting enzyme from *Aspergillus oryzae* to be used (§173.150).

# Properties of Extremophilic Enzymes and Their Importance in Food Science and Technology

Magnús M. Kristjánsson and Bjarni Ásgeirsson

*University of Iceland, Reykjavík, Iceland*

## I. INTRODUCTION

Research during the last two decades has increasingly demonstrated that various microorganisms grow and live in environments that previously were considered unimaginable for the support of life. These habitats are characterized by extreme conditions with respect to temperature, pH, salinity, and pressure. At present the apparent limits for these biologically relevant physical parameters in the biosphere are -40°C to 115°C for temperature, pressures up to 120 MPa (corresponding to hydrostatic pressure in the deep sea), water activity ( $a_w$ ) of ~0.6, (as in salt lakes), and pH values between 1 and 11 (1). In order to survive and to proliferate in such hostile environments, organisms had to adapt their metabolic and other cellular functions to the persisting extreme condition. Especially important is the adaptation of stability and activity of enzymes and other proteins that have to be optimized to function under the extreme conditions. As a result of the requirement for molecular adaption, the properties of proteins, especially enzymes, from extremophiles have been a subject of much interest both for basic studies in biology and chemistry, as well as for potential use as biocatalysts in industrial applications.

Since the discovery of Archaea as a new branch on the phylogenetic tree (2), the number and variety of explored extremophilic organisms have increased enormously, as well as research on the biochemical aspects of extremophilic adaptation. An understanding of the

molecular principles involved in extremophilic adaptive strategies could also be of considerable commercial interest, as the same principles could be used for example in designing industrial processes involving biocatalysts that have to withstand extreme conditions with respect to temperature and pH. Given that there are constantly expanding sources of novel and unusually stable biocatalysts from extremophiles, the prospects of expanding the limits of biocatalysis in both novel, as well as in more conventional processes, could be realized (3). Enzymes with temperature optima ranging from close to the freezing point of water and to that in excess of its boiling point have been isolated, as well as enzymes that function in extreme salinity, over a wide range of pHs, pressures, and in essentially non-aqueous solvents (3).

High thermal stability is a highly desirable trait in many industrial enzymes, as processes involving enzymes are frequently carried out at high temperatures. There are some distinct advantages in running biotechnological processes at elevated temperatures. In fact, most such industrial processes are operated at temperatures > 50°C. Benefits of higher operating temperatures include decreased viscosity, increased diffusion rates, and solubility of most organic compounds, and thus an increase in reaction rates. Higher temperatures also reduce the risks of microbial contaminations in the enzyme reactors (4–6). For these reasons, enzymes from hyperthermophiles have received great attention, as these enzymes are generally found to be

very thermostable. This also makes them ideal experimental models for answering fundamental questions regarding the molecular basis for protein stability.

Enzymes from cold-adapted organisms, or psychrophiles, have gained increasing attention by researchers during the last several years, both as subjects of basic studies on molecular origins of cold-adaptation, and as potential industrial enzymes (7, 8). These enzymes are usually found to have higher specific activities at low temperatures than their counterparts from meso- and thermophiles. That property may be beneficial in several industrial applications, such as in the processing of sensitive biological materials, including foodstuffs, that have to be carried out under chilled or refrigerated conditions. Enzymes from cold-adapted organisms are usually found to be comparatively thermolabile, which may be beneficial in operations when enzyme treatment has to be terminated rapidly, without excessive treatment of the raw material (7).

The molecular basis for function and stability of proteins from organisms living at the extremes of temperature in the biosphere is still not well understood despite extensive research effort. However, understanding which structural principles direct extreme temperature adaptation of proteins are fundamental to our general understanding of their structural stability and function. Such information on structure-function relationships in these enzymes also forms the basis for their utilization as industrial biocatalysts under different, and perhaps novel, sets of conditions.

In this chapter we will attempt to give an overview of the current status of knowledge about enzymes that originate from organisms that are adapted to extremes of temperature.

## II. EFFECT OF TEMPERATURE ON STABILITY AND FUNCTION OF ENZYMES

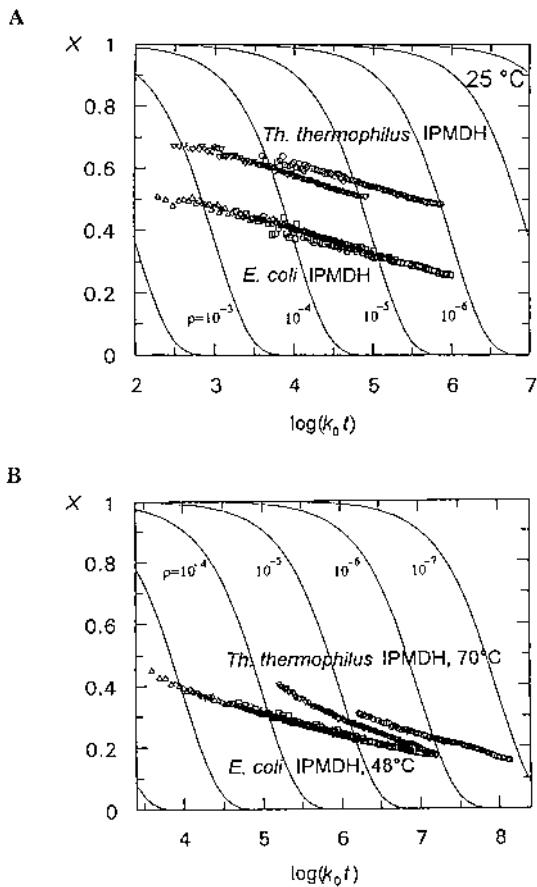

It is important to realize when considering temperature adaptation that the native conformations of proteins are only marginally more stable than their denatured states. Free energies of stabilization of native protein structures are typically of the order 20–80 kJ mol<sup>-1</sup>, or what amounts to only a few weak intramolecular interactions (1, 9, 10). The net stabilization of a native protein is the result of a delicate balance between a relatively large stabilizing and destabilizing forces, the former being a combination of the hydrophobic effect, hydrogen bonding, electrostatic interactions, and van der Waals interactions gained through close

packing in the protein core, and the latter arising mainly by the increase that occurs in conformational entropy on unfolding of the polypeptide (11, 12).

As a result of this delicate balance only minor shifts in the contributions of any of these opposing forces can in principle significantly alter the stability of a protein. The small marginal stability of the native state, and the fact that these forces are cooperative and highly dependent on environmental conditions, such as temperature and solvent exposure, make the accounting of the contributions of these different forces to the stability of a protein a highly difficult task. Partially because of the uncertainty in the magnitude of these different interactions, the free energy of stabilization for a protein cannot be calculated, even if high-resolution crystal structure for the protein is available (1). Furthermore, such calculations based on atomic coordinates from crystal structures do not consider the dynamics of protein structures, a prerequisite for their function (1). Biologically active proteins such as enzymes are dynamic molecules and need a certain degree of structural flexibility for performing their function as biocatalysts (13–15).

It appears that during the evolutionary adaptation of proteins to different environmental temperatures, preserving function through optimization of flexibility of critical regions of the protein molecules has been a priority. Thus, optimizing a function of an enzyme under given temperature conditions is expected to involve a compromise between two apparently opposing structural factors, dynamic flexibility and stability (1, 9, 15). Enzymes that perform the same catalytic function but are adapted to different habitat temperatures, appear to have about the same conformational flexibility at their respective temperature optima (1, 13, 15). This would suggest that temperature-adaptive changes of proteins would tend to conserve and optimize the functional state of the proteins, such that they are in “corresponding states,” with respect to functionally important motions, under the different physical conditions to which they have adapted (1, 9). This hypothesis suggests that in order to maintain such corresponding states for efficient biological function at low temperatures, cold-adapted enzymes must have adopted a higher degree of conformational flexibility (1, 15–18).

Enzymes from thermophiles, on the other hand, require very rigid and stable conformations that have to resist excessive thermal motions that lead to their denaturation, but that can maintain optimized flexibility (“corresponding states”) with respect to function at elevated temperatures. That the activity of enzymes

**Figure 1** Hydrogen-deuterium exchange of 3-isopropylmalate dehydrogenase (IPMDH) from *E. coli*, measured at pH 7.15 ( $\Delta$ ) and pH 8.15 ( $\square$ ), and from *T. thermophilus*, at pH 7.15 ( $\nabla$ ) and pH 8.15 ( $\circ$ ), plotted as relaxation spectra. For experimental details see (15). (A) Measurements at 25°C for both enzymes. Increasing values of  $X$  reflect increased rigidity. Curves therefore indicate a more rigid structure for the thermophilic enzyme. (B) Measurements at the temperature optima of the enzymes: at 48°C for the *E. coli*, and at 70°C for the *T. thermophilus* IPMDH. Curves for the two enzymes show very similar flexibilities. (From Ref. 15. Copyright 1998 National Academy of Sciences, U.S.A.)

from thermophiles is greatly diminished at lower temperatures at which their mesophilic counterparts have optimal activity is a manifestation of the flexibility/function relationship, as it would imply that cooling would freeze out the molecular fluctuations at or around the active site of the enzyme that are necessary for its activity (19, 20). The role of optimized flexibility in temperature adaptation and the inverse relationship between protein stability and function have recently been supported both by results obtained in experiments

where the temperature-dependent hydrogen-deuterium exchange kinetics of homologous mesophilic and thermophilic pairs of the enzymes 3-isopropylmalate dehydrogenase and glyceraldehyde phosphate dehydrogenase were compared (Fig. 1) (1, 15), and by theoretical model calculations (20). Hydrogen exchange experiments with the ultrathermostable protein rubredoxin, from the hyperthermophile *Pyrococcus furiosus*, however, did not lend support to the hypothesis that structural rigidity in the native state underlies the increased thermal stability of the protein (21). The reasons for the apparent contradictions in results obtained in these studies are not known, but have been commented on by Jaenicke (22).

On the basis of the proposed (and frequently observed) inverse correlation between enzyme stability and activity (14), much research effort has gone into explaining structural determinants of protein stability in order to gain insight into the molecular mechanisms that direct their temperature adaptation. While a global structural stabilization is essential for maintaining functional native states of thermophilic proteins at elevated temperatures, the fine adjustment of adaptive changes for activity may involve localized reversible conformational changes that would confer the necessary flexibility to critical parts of the protein molecules for function under given extreme conditions. Such local structural fluctuations within a protein structure have been defined as the microstability of proteins, as opposed to macrostability, that describes the ability of native confirmations of proteins to resist unfolding (denaturation) under given set of conditions (15). Making a distinction between micro- and macrostability of proteins may be necessary when attempting to explain the molecular origins of temperature adaptation. The noncooperative transitions that determine the microstability of a protein may occur on a different time scale and are not necessarily reflected in experiments that determine the cooperative unfolding/refolding transitions of protein molecules that define their macrostabilities.

In fact, Fields and Somero (18) found no correlation between denaturation rates and adaptation temperatures when comparing these parameters for cold-adapted orthologs of lactate dehydrogenase A4 from different fish species of Antarctic and South American origins. They suggested that increased cold activity in these orthologs involved increased flexibility in small areas of the molecule that affect mobility (hence microstability) of adjacent active site structures (18). Recent results for mutagenic studies have also shown that the stability of enzymes can be considerably increased con-

comitantly with significantly improved catalytic properties (23–25). This has not been observed, however, in enzymes from thermophiles, where lower catalytic efficiencies generally accompany higher thermal stabilities, as compared to the corresponding enzymes from mesophiles. Perhaps, the selective pressure set by the high-temperature environment imposes more restriction on the thermophilic enzymes to develop more stability at the expense of function, and are therefore not catalytically optimized enzymes, but are highly thermostable (19).

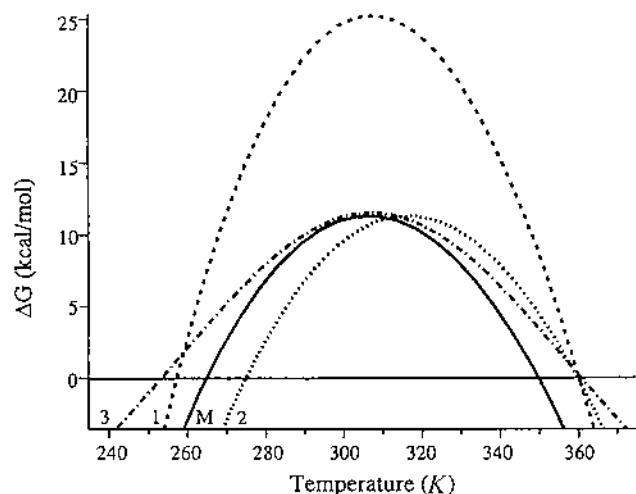

For enzymes from psychrophiles the selective pressure is probably more toward optimizing function which involves maintaining adequate molecular dynamics in spite of low thermal input from the cold habitat. This requires lowered microstability of the cold-adapted enzymes and may accompany, as is most often observed, decreased macrostability of the proteins, either as a structural consequence, or simply because it is not needed in the low-temperature environment (25).

### III. THERMODYNAMIC ASPECTS OF TEMPERATURE ADAPTATION

The thermodynamic stability of a protein (that denatures in a reversible, two-state manner) as a function of temperature can be described by the modified Gibbs-Helmholtz equation (26):

$$\Delta G = \Delta H^\circ - T\Delta S^\circ + \Delta C_p [T - T^\circ - T \ln(T/T^\circ)] \quad (1)$$

where  $\Delta C_p$ , the difference in heat capacity at constant pressure, is taken as a constant and is larger than zero.  $T^\circ$  is any reference temperature (most often the melting temperature,  $T_m$ ), and  $\Delta S^\circ$  and  $\Delta H^\circ$  are the changes in molar entropy and enthalpy evaluated at the reference temperature, respectively. The equation describes a parabolic curve for the temperature dependence of the free energy of unfolding ( $\Delta G_u$ ), defined by a slope,  $\delta\Delta G/\delta T = -\Delta S$ , and a curvature,  $\delta^2\Delta G/\delta T^2 = -\Delta C_p/T$  (26). The curve predicts that proteins have maximum stabilities ( $\Delta G_{max}$ ) at a temperature  $T_{max}$ , when  $\Delta S=0$ . The stability decreases on both sides of the maximum and intersects twice the x-axis (at  $\Delta G=0$ ), when the proteins undergo cold and heat denaturation, respectively (Fig. 2). Despite extensive research into the causes of thermal stability of (hyper-)thermophilic proteins, thermodynamic characterization in the form of protein stability curves are only available for relatively few thermophilic proteins. One major reason for this is that many thermophilic pro-

**Figure 2** Three possible mechanisms for the temperature dependence of free energy of unfolding ( $\Delta G_u$ ) for a thermophilic protein. Curve M (solid) depicts the relation of  $\Delta G_u$  and temperature ( $T$ ) for a typical mesophilic protein. In curve 1 (dashed), the thermophilic protein is stabilized across the temperature range and has a greater maximum stability (mechanism 1). In curve 2 (dotted), the  $\Delta G_u$  vs.  $T$  relationship is the same as for the mesophilic protein, but is shifted to a higher temperature (mechanism 2). In curve 3 (dash-dot-dash patterned), the  $\Delta G_u$  of thermophilic protein depends less on  $T$ , and thus leads to flattening of the stability curve, shifting the melting temperature to higher values ( $T = T_m$ , when  $\Delta G_u = 0$ ). (From Ref. 34. Copyright 1999 American Chemical Society.)

teins, especially multidomain proteins, do not undergo reversible, two-state thermal denaturation. Competing side reactions occur, such as aggregations, that prevent proper refolding at the high temperatures at which these experiments are carried out (1).

Recently, however, small, single-domain hyperthermostable proteins, which alleviate these experimental problems and fulfill the requirements for a two-state, reversible transition, have been used as models in such thermodynamic studies (27–35). More than two decades ago, Nojima et al. (36, 37) determined the thermodynamic parameters for denaturation of phosphoglycerate kinase and cytochrome c552 from the thermophile *Thermus thermophilus*, and compared them to those determined for their counterparts of mesophilic origin. From their studies they proposed three possible ways in which thermophilic proteins could thermodynamically adapt to increase their denaturation temperatures (Fig. 2). Compared to a mesophilic protein (curve M), the free energy of unfolding for the thermophilic protein could be increased over

the whole temperature range (curve 1); the stability curve ( $T_{\max}$ ) could be shifted to higher temperatures (curve 2); or the curve could be flattened (curve 3). In all cases the result would be to shift the melting temperature ( $T_m$ ) of the thermophilic protein to a higher temperature.

In mechanism 1 the higher stability acquired would require higher absolute values for  $\Delta H_u^\circ$  and  $\Delta S_u^\circ$  at  $T_m$  than for the mesophilic protein. In the second mechanism the maximal values for  $\Delta G_u^\circ$ ,  $\Delta H_u^\circ$ , and  $\Delta S_u^\circ$  would be of the same magnitude as for the mesophilic protein but would occur at different temperatures: i.e., at higher temperatures the thermophilic protein would be more stable, whereas the mesophilic protein would be more stable at lower temperatures (34). Mechanism 3 also predicts that the thermodynamic stability of the thermophilic protein would not be higher than of the mesophilic protein, but lower temperature dependence of  $\Delta G_u^\circ$  for the thermophilic protein, possibly because of lower entropy of unfolding, would lead to a flattened stability curve resulting in higher  $T_m$  values, as well as lower cold denaturation temperatures. From the relatively few cases available where the thermodynamic stability of thermophilic proteins has been characterized, it seems that mechanisms 1 and 3 most often prevail. For phosphoglycerate kinase, both from *Thermus thermophilus* and *Thermotoga maritima*, mechanisms 1 and 3 both seem to be at work in stabilizing the enzymes (36, 38), and the same seems to be the case for ribonuclease H from *T. thermophilus* (35) and ferredoxin from *T. maritima* (29).

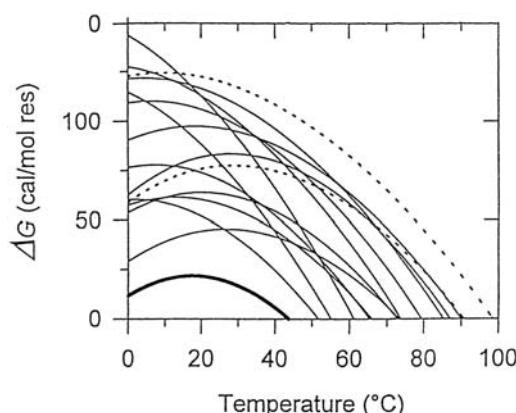

Greater thermodynamic stability according to mechanism 1 was found to stabilize the catalytic domain of cellulase E2 from *Thermomonospora fusca* when compared to the analogous domain of cellulase CenA from the mesophile *Cellulomonas fimi* (34). The thermostability of the small DNA binding proteins Sso7d (27, 31) and Sac7d (28) from *Sulfolobus* spp. appear on the other hand to be enhanced by flattened stability curves in accordance with mechanism 3 (although data on corresponding mesophilic proteins were not provided in these studies). A lateral shift in  $T_{\max}$  values to higher temperatures (mechanism 2), in concomitance with raised  $\Delta G_u$  values, has also been observed in studies on thermal unfolding of cytochrome c552 from *T. thermophilus* (37) and with archaeal histones (32).

When considering protein thermal stability, it is important to observe that depending on the absolute values for the thermodynamic parameters ( $\Delta H$ ,  $\Delta S$ , and  $\Delta C_p$ ), high  $T_m$  is not necessarily synonymous with larger maximum stability (39). This may be espe-

cially evident with small proteins that are unable to form a large hydrophobic core, and is reflected in low  $\Delta C_p$  values (40). The small DNA-binding protein Sso7d (64 residues) from the hyperthermophilic archaeon *Sulfolobus solfataricus* has its  $T_{\max}$  at 9°C with a stabilization free energy of only 7 kcal mol<sup>-1</sup>, but still has a  $T_m$  of 98.9°C (at pH 5.5) (27, 31). At 80°C, or close to the optimal growth temperature of *S. solfataricus*, the protein has a marginal stability of only 2.8 kcal mol<sup>-1</sup>. Similar stabilities have also been described for another related small DNA-binding protein, Sac7d from *S. acidocaldarius* (28). These proteins seem to be thermodynamically stabilized by mechanism 3 as discussed above. Since  $\Delta C_p$  determines the curvature of stability curves [Eq. (1)], the small size of these proteins and the correspondingly low  $\Delta C_p$ s (40), have the effect to create shallower protein stability curves, with broader  $\Delta G$  maxima, that extend the  $T_m$  values to higher temperatures.

Among cold-adapted proteins only an  $\alpha$ -amylase from the psychrophile *Alteromonas haloplanktis* has been characterized with respect to thermodynamic stability (41). The enzyme exhibits a reversible, two-state thermal unfolding with a melting temperature at 43.7°C, significantly lower than its mesophilic counterparts. The measured thermodynamic parameters were used to calculate a protein stability curve according to Eq. (1) for the enzyme, which is depicted in Figure 3, and compared to such curves for several small (< 18 kDa) proteins from meso- and thermophiles (including Sso7d and Sac7d). When the parameters were calculated and compared on per mol residue basis, to account for the different sizes of the proteins involved, it is clear that the cold-adapted enzyme is of much lower stability, characterized by lower absolute values for both enthalpy of unfolding and  $T_m$  (Fig. 3) (41).

The reverse of mechanism 1 above is apparently in effect in the cold adaptation of the enzyme, which is in line with the hypothesis that cold-adaptive mechanisms involve weakening of intramolecular interactions in order to increase flexibility (1). A most interesting feature of the stability curve for the psychrophilic enzyme, and what differs from meso- and thermophilic proteins, is that the physiological temperatures lie on different sides of  $T_{\max}$  on the parabolic curve (Fig. 3). As both  $\Delta S_u$  and  $\Delta H_u$  change sign and become negative at or within few degrees below  $T_{\max}$ , (26), low and high temperature adaptation may involve different adjustments in these thermodynamic parameters. As  $\Delta H_u$  becomes negative on the “cold side” of the stability curve maximum, destabilization of the native protein occurs for enthalpic reasons, whereas it is stabilized by

**Figure 3** Protein stability curves for  $\alpha$ -amylase from the Antarctic psychrophile *Alteromonas haloplanktis* (heavy lines), selected mesophilic proteins (continuous lines), and of the thermophilic proteins Sac7d and Sso7d (dashed lines). The Gibbs free energy of denaturation is presented in specific units (per mole residue) in order to account for the different sizes of the proteins compared. By increasing order of  $T_m$ , the curves are for the proteins: psychrophilic  $\alpha$ -amylase, T4 lysozyme, barnase, RNase T1, RNase A, spectrin SH3, barstar, phosphocarrier HPr, chymotrypsin inhibitor CI2, protein G IgG binding domain, ovomucoid third domain, thioredoxin, ubiquitin, and the thermophilic proteins Sac7d and Sso7d. (From Ref. 41. Copyright 1999 American Chemical Society.)

the negative  $T\Delta S$  contribution as the temperature is lowered. At higher temperatures, entropic dissipative forces increase faster than favorable enthalpic contributions, and hence heat denaturation occurs (11).

As a result of the different thermodynamic forces involved, it is apparent that at the molecular level the causes of destabilization of native proteins to cold and heat denaturation may be quite different (42). Probably the main cause of cold denaturation is the weakening of the collective water-apolar repulsions that provide the main driving force for maintaining the folded structure under physiological conditions (42). Indeed, cold denaturation has been found to occur most readily with the most hydrophobic proteins (43, 44). An additional cause of cold destabilization of proteins is more favorable energetics of interactions of water with polar and ionic groups at low temperatures (42). In this respect favorable interactions of water with the polar peptide groups, largely buried in the native structure, but that come into contact with water on unfolding, seem to play a pivotal role (44). Thus, the fact that water increasingly becomes a good solvent for buried polar and apolar residues at low temperatures appears to be a major driving force for cold denaturation (44).

#### IV. MOLECULAR BASIS OF EXTREMOPHILIC TEMPERATURE ADAPTATION

It is clear from several studies that proteins from psychro- or thermophilic organisms do not exhibit any peculiarities with respect to composition, size, or complexities as compared to their counterparts adapted to moderate temperatures. They are composed of the same 20 natural amino acids and usually show high degree of sequence and structural homology with mesophilic proteins (1, 3, 31). Extremophilic adaptation is therefore an intrinsic property of the proteins, and the reasons for the striking differences observed both in stability and function at different temperatures are encoded in their gene sequences. A number of studies have therefore been carried out attempting to correlate different structural factors, at all levels of the structural hierarchy of the proteins, to differences in temperature-adaptive properties (mainly thermal stability) in comparative studies of homologous proteins from organisms isolated from different temperature habitats. By far the greatest number of such comparative studies have focused on proteins from thermo- and hyperthermophiles relative to their mesophilic counterparts in attempts to elucidate the molecular causes for their high thermal stability. In the following discussion we will attempt to summarize some of the pertinent observations made in such comparative studies on proteins from different temperature habitats.

##### A. Proteins from (Hyper-)thermophiles

Thermophilic organisms are conventionally classified as those having optimum growth temperatures  $>60^\circ\text{C}$  and hyperthermophiles those with optimal growth  $>80^\circ\text{C}$  (1, 19). While thermophiles are either bacteria or Archaea, most hyperthermophiles are Archaea (45). In earlier comparative studies on thermostabilization, attempts were made to correlate structural factors based on the content of certain amino acids and derived parameters such as hydrophobic and aliphatic indices (see 4 and reference therein for review), to thermal stability of relatively small number of meso- and thermophilic proteins.

Argos and coworkers (46) carried out the first systematic study on sequence comparison of homologous proteins from meso- and thermophiles and identified certain amino acid exchanges that occurred more frequently in going from the meso- to thermophilic representative within the three protein families they compared. The objective of these and other subsequent

studies, which have included more proteins in their database (47), has been to identify certain “traffic rules” used for thermostabilization of proteins in nature. The effect of the thermostabilizing amino acid exchanges identified in these studies showed a tendency toward increasing surface hydrophilicity, decreased flexibility, and increased hydrophobicity, mainly in  $\alpha$ -helical regions of the proteins (46, 47). Critical evaluation of these early studies, however, showed that the data set used was too small to make predictions based on such compositional comparisons statistically significant (48).

Several recent studies, including extensive genomic comparisons of meso- and thermophiles, however, have pointed out certain trends in amino acid composition and exchanges that have correlated with temperature adaptation, some of which had also been observed in those earlier studies. These include higher content of charged amino acids, especially Arg and Glu in hyperthermophiles, often occurring concomitantly with lower content of polar uncharged amino acids (49–54). In a study where 115 protein sequences from the genome of the extreme thermophilic archaeon *Methanococcus jannaschii* were compared with their homologs from several mesophilic *Methanococcus* spp., the strongest correlation with thermophiles of observed amino acid exchanges was the decrease in the content of uncharged polar residues (Ser, Thr, Asn, and Gln), besides an increase in charged residues, increase in residue hydrophobicity, and increased residue volume (53). Nearly every other amino acid was preferred over polar uncharged amino acids in the thermophilic sequences.

A similar trend was observed in sequences deduced from the complete genome of the hyperthermophilic bacterium *Aquifex aeolicus* (50) and in a study where sequences of soluble proteins from complete genomes of eight thermophiles (including those of *M. jannaschii* and *A. aeolicus*) and 12 mesophiles (51). Moreover, Asn and Gln seem to be more discriminated against in proteins from hyperthermophiles, as compared to those from moderate thermophiles, while the decrease in Ser was apparently significant in moderate thermophiles (54). The trend to lower content of Asn and Gln likely reflects molecular adaptation in thermophilic proteins as it would tend to minimize deamidation, a reaction that may limit the thermal stability of the proteins as a result of irreversible denaturation (55, 56). A decrease in Cys, another thermolabile amino acid residue, has also been reported for thermophilic proteins when compared to their mesophilic counterparts, which may also be indicating an evolutionary

pressure to reduce the number of residues that can cause irreversible thermal denaturation of the proteins (19, 52).

Some of the most frequent amino acid replacements that lead to a decrease in polar uncharged residues in the proteins of *Methanococcus jannaschii* contribute significantly to increased hydrophobicity (Ser  $\rightarrow$  Ala, Thr  $\rightarrow$  Ile, Ser  $\rightarrow$  Pro, Thr  $\rightarrow$  Val) (53). Moreover, most frequent nonpolar to nonpolar replacements (e.g., Leu  $\rightarrow$  Ile, Gly  $\rightarrow$  Ala, and Met  $\rightarrow$  Leu) tended toward bulkier and more hydrophobic residues (53). The hydrophobic interaction has been emphasized as the major stabilizing force for the folded state of proteins (11, 12, 57). Strengthening of hydrophobic interactions and improved packing in the hydrophobic core have indeed been suggested to play an important stabilizing role in thermophilic proteins (31, 45, 49, 51, 53, 58, 59). In some other comparative studies, however, no significant correlations between hydrophobicity and thermophily have been observed (50, 52). Mutation studies have shown that increasing the bulkiness of buried nonpolar side chains, as discussed above, can significantly increase thermal stability of proteins (by  $\sim$ 1.3 kcal mol $^{-1}$  per  $-\text{CH}_2-$  residue buried), by a direct hydrophobic effect and by reducing the size of cavities, and hence optimized core packing through, e.g., more favorable van der Waals interactions (60–64). Indeed, increased residue volume (53) and smaller cavities (54) have been found to correlate well with hyperthermophilic adaptation (see below).

The increased number of high-resolution crystal structures has allowed more direct structural comparisons, where three-dimensional structures of thermophilic proteins are being compared to corresponding structures of one or more of its mesophilic counterparts (65–83). More detailed structural data have also facilitated systematic studies where various structural parameters have been calculated on the basis of known crystal structures or computer generated homology models from related sequences, and compared within or across protein families (46–54, 59, 84–89). Querol *et al.* (58) have also surveyed the literature on studies reporting thermostabilizing mutations in several different proteins and analyzed the structural consequences of those stabilizing single amino acid replacements. They created a database comprising 195 single amino acid exchanges in 164 different positions in the proteins which had been unambiguously related to thermostability enhancement (58). The most cited physicochemical reasons for thermostabilization as observed in this survey are summarized in Table 1.

**Table 1** Physicochemical Reasons for Enhanced Thermal Stability Resulting from Single Amino Acid Replacements in Several Different Enzymes as Cited in the Literature

Type	Number of citations
Better hydrogen bonding	18
Better hydrophobic internal packing	16
Enhanced secondary structure propensity	12
Helix dipole stabilization	10
Argos replacements	10
Removal of residues sensitive to oxidation or deamidation	10
Burying hydrophobic accessible area	7
Improved electrostatic interactions	6
Strengthening of intersubunit association	6
Decreased chain strain	5
Salt bridge optimization	4
Better van der Waals interactions	3
Better affinity for calcium	2
Improved $\Delta H$ upon substitution	1

In line with these observations, Argos and coworkers (49, 85) found, when comparing several structural factors of meso- and thermophilic proteins from 16 families, that the parameter that most consistently correlated with increased thermal stability was a higher number of hydrogen bonds in the thermophilic proteins. An increase in the fractional polar surface area, reflecting added hydrogen bonding density to water, was also found to increase with the thermostability of the proteins compared (49, 85). In other extensive comparative studies of meso- and thermophilic protein structures, an increase in the number of residues involved in hydrogen bonding (51) and an increase in side chain–side chain hydrogen bonds (88) were found to correlate with thermostability. Additional hydrogen bonds have also been pointed out as a major stabilizing factor from comparisons of known crystal structures of meso- and thermophiles (70, 72, 77).

In a detailed comparative study of high-quality three-dimensional structures of 64 mesophilic and 29 thermophilic proteins (of which five were hyperthermophilic) representing 25 protein families, however, practically no difference between mesophiles and thermophiles was observed in the number of hydrogen bonds (54). There was, however, a tendency to decrease the number of unsatisfied hydrogen bond acceptors and donors as the temperature of adaptation increased. The authors attributed the discrepancy observed in their

results as compared to those of Argos and coworkers (49, 85) to some bad-quality or incomplete crystal structures (five of which were mesophilic, but only one thermophilic) that had been included in the databases used in the former study that introduced a bias in the results. If these bad-quality structures had been omitted from the database used by Argos and coworkers, the observed difference in the number of hydrogen bonds between meso- and thermophilic proteins would have become insignificant (54).

Szilagyi and Zavodsky (54) calculated 13 properties in five categories (cavities, hydrogen bonds, ion pairs, secondary structure, and polarity of surfaces) from the coordinates for each of the proteins in the database, compared them using statistical methods, and correlated with optimal growth temperatures of organisms they originate from. On the basis of the optimal growth temperatures the proteins were divided into two groups; moderately thermophilic ( $T_{opt} = 45\text{--}80^\circ\text{C}$ ), and extremely thermophilic proteins ( $T_{opt} \sim 100^\circ\text{C}$ ). The findings of this comprehensive study are summarized in Table 2.

The most significant difference between mesophilic and thermophilic proteins was found in the number of ion pairs (salt bridges), a property that also correlated well with growth temperatures. In fact, several systematic comparative studies that have been described above (49, 51, 52, 59, 85, 88, 89), as well as comparisons of high-resolution three-dimensional structures of thermophilic and homologous proteins (69, 72, 73, 75–77, 79, 81, 90), have pointed to a prominent role of ion pairs in their stabilization, especially of hyperthermophilic proteins. The ion pairs often appear in the hyperthermophilic structures as clusters or networks at the surfaces or at interdomain interfaces in the proteins (Fig. 4). In some studies no correlation has been observed between the number of ion pairs, or ion pair networks, and stability of hyperthermophilic proteins (80, 88). Indeed, the role of ion pairs in protein stability has been controversial, as theoretical calculations have indicated that they may actually destabilize folded conformations of proteins, at least at room temperature (91).

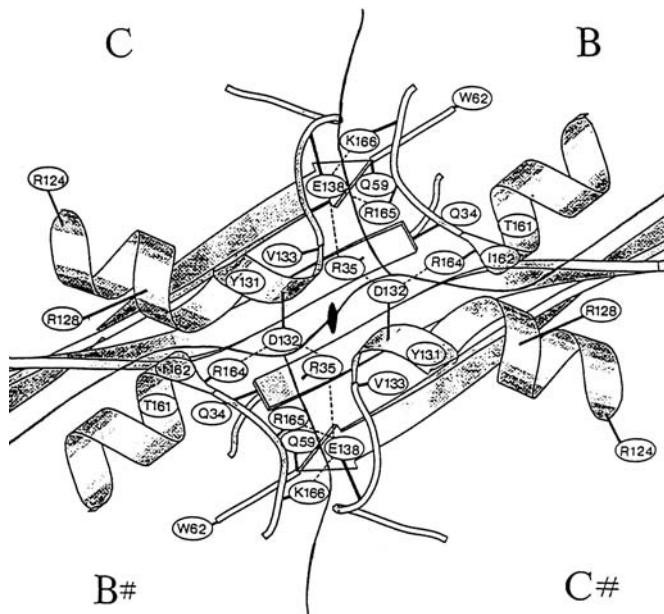

The destabilizing effect of ion pairs or salt bridges arises primarily from desolvation penalty associated with bringing separated charged groups of the unfolded protein together to form an ion pair in the fully folded protein (92). The desolvation penalties are especially high when burying charged groups in the low dielectric environment of the hydrophobic core of proteins (52, 88, 92). Despite the favorable coulombic interaction that incurs by bringing oppositely charged

**Table 2** A Summary of the Most Significant Differences Between Structural Parameters of Moderately Thermophilic and Extremely Thermophilic Proteins When Compared to Their Mesophilic Counterparts<sup>a</sup>

Property		Correlation with temperature	Change in moderately thermophilic proteins	Change in extremely thermophilic proteins
Cavities	Number	↓↓	0	↓↓↓
	Volume	↓	↑	↓
	Area	↓	↑	↓↓
Hydrogen bonds	Number	0	0	0
	Unsatisfied	↓	↓	↓
Ion pairs	< 4.0 Å	↑↑	↑	↑↑↑

Potential ion pair interactions are indicated by dashed lines. The backbone of the polypeptide chain is shown as a gray ribbon. The individual amino acids are indicated by their one letter code, followed by their sequence number. (From Ref. 79. Copyright 1998 Blackwell Science Ltd.)

groups together in the folded state, it may not outweigh the unfavorable desolvation (free energy of hydration) cost. Elcock (92) has recently shown that at higher temperatures, the desolvation effect becomes

less unfavorable, so ion pair formation would become increasingly favorable at higher temperatures and could provide a significant stabilization to hyperthermophilic proteins at elevated temperatures. It has also

been shown that the location of the ion pair within the protein structure, especially with respect to positioning of other ion pairs in its vicinity, is a critical determinant of the stability of these interactions, as they may in a cooperative manner facilitate the formation of ion pair networks (52, 88).

As mentioned earlier, extensive ion pair networks have been observed in three-dimensional structures of several hyperthermophilic proteins. Such cooperative electrostatic interactions offer simple means of enhancing stability without disrupting core residues, characteristics of different protein families (88). Such optimally located ion pair networks are therefore believed to be important stability determinants of proteins from hyperthermophiles.

A significant observation in the study of Szilágyi and Závodsky (54) was a decrease in the number of internal cavities in the structures of extremely thermophilic proteins, as compared to mesophilic and moderately thermophilic proteins (Table 2). A decrease in the number or the size of cavities leading to improved packing in the protein interior has also been observed in the structures of hyperthermophilic proteins (31, 67, 73, 93). However, in a study where the packing density of 80 nonhomologous proteins and 24 thermophilic ones was analyzed in context of their possible role in thermal stabilization, essentially no difference was observed in either partial specific volumes or cavity volumes in the two protein groups (86). Cavities created in the interior of proteins by use of site-directed mutagenesis have been shown to lead to significant destabilization (60–62). Creation of a cavity in barnase of the size of a  $-\text{CH}_2-$  group ( $\text{Ile}96 \rightarrow \text{Val}$ ) resulted in a destabilization of the enzyme of  $1.1 \text{ kcal mol}^{-1}$  and a cavity the size of three such groups ( $\text{Ile}96 \rightarrow \text{Ala}$ ) by  $4.0 \text{ kcal mol}^{-1}$  (60).

In a study of several cavity-creating mutants of T4 lysozyme, the destabilization of a  $\text{Leu} \rightarrow \text{Ala}$  substitution amounted to a constant term,  $\sim 2 \text{ kcal mol}^{-1}$ , plus a term that increased in proportion to the size of the cavity produced by the substitution (61). The constant term is approximately equal to the transfer free energy of leucine relative to alanine as determined from their partitioning between aqueous and organic solvents (61). These results point to ways to stabilizing proteins against high temperatures, i.e., by filling cavities in their core with bulkier, more hydrophobic amino acids, leading to enhanced hydrophobic driving force and improved van der Waals contacts in the protein core. As discussed previously, amino acid replacements of this type have frequently been observed in comparative studies of mesophilic and thermophilic proteins,

and optimized packing of side chains in the interiors, and the absence of cavities have been observed in crystal structures of hyperthermophilic citrate synthase (73) and lactate dehydrogenase (75).

Increasing structural compactness by decreasing cavities and increasing attractive interactions in the tightly packed protein core reflect a trend observed in structures of some hyperthermophilic proteins, i.e., to minimize their surface area-to-volume ratio (68, 72). Minimization of the ratio of surface area to volume can stabilize a protein by simultaneously reducing unfavorable surface energy and increasing the attractive interior packing interactions (68, 72, 75). Reduction of accessible surface area seems to be part of the molecular inventory that has been used in the high-temperature adaptation of hyperthermophilic proteins. At the quaternary structural level this is observed as higher states of subunit associations in oligomeric proteins from hyperthermophiles, e.g., triose phosphate isomerase (10, 71), phosphoribosyl anthranilate isomerase (76), ornithine carbamoyltransferase (78), enolase (10), and in the case of triose phosphate isomerase and phosphoglycerate kinase from *Thermotoga maritima* that are expressed as a “dimer of dimers” fusion protein (1, 10, 74). Minimizing hydrophobic surface area has also been suggested to be an important stabilizing principle in thermophilic lactate dehydrogenases (75).

Increased compactness of thermophilic proteins may also be accomplished through shortened surface loops (45, 70, 73, 74, 83, 87). Exposed surface loops and turns link successive core elements and are believed to be the regions of proteins where their unfolding begins (45, 87). Increasing the structural rigidity in such loops, either by shortening them or by stabilizing them by amino acid replacements (e.g., by increasing the number of prolines), could therefore significantly enhance protein stability (45, 87).

In some studies thermophilic proteins have also been found to be smaller than mesophilic counterparts (51, 87), reflecting truncation of loops, but also of N- and C-termini as has been observed for some thermophilic proteins (77, 80)). It has been pointed out that the apparently smaller size of thermophilic proteins may reflect a possible thermodynamical adaptive strategy of these proteins (51). As smaller proteins tend to have lower  $\Delta C_p$  values of unfolding (40), the shape of the stability curve could be affected, as its curvature is determined by  $\Delta C_p/T$  (see earlier). The net effect could therefore be to flatten the stability curve (Fig. 2), bringing the denaturation temperature to higher values (51).

## B. Proteins from Psychrophiles

Many microorganisms and ectothermic animals live under environmental temperatures that fluctuate in the range  $-2^{\circ}\text{C}$  to  $10^{\circ}\text{C}$  without the opportunity to regulate their cellular temperature (94–96). The term cold-adaptation refers to the chemical and physiological mechanisms that make this possible (97, 98). Without adaptation, the chemical enzyme systems of cold-blooded animals and psychrophilic microorganisms would work too slowly. Enzymes from psychrophilic organisms (max. growth temperature at  $20^{\circ}\text{C}$ ) or psychrotrophic organisms (max. growth temperature at  $40^{\circ}\text{C}$ ) (6) are generally less stable structures than comparable enzymes from warm-blooded or thermophilic organisms (96). This is true for enzymes from as diverse species as bacteria (16) or fish (7, 98, 100). The need for increased “flexibility” is envisioned to call for fewer noncovalent intramolecular interactions as temperatures are lowered (16, 98, 100). This led to the concept of “corresponding states” of enzymes at the temperatures in which they find themselves in the various living forms on earth (97, 98). In recent years the study of cold adaptation of enzymes has expanded greatly. As more examples accumulate, however, few generalizations can be made as several strategies are used differently in individual cases. Here we will summarize kinetic and stability characteristics of cold-active enzymes and then give the general concepts used in an attempt to explain temperature adaptations in molecular terms. Several reviews on psychrophilic enzymes have appeared recently (7, 16, 17, 96, 99, 101).

### 1. Enzyme Activity at Low Temperatures

As suggested earlier, the selective pressure for evolutionary adaptation of enzymes to low temperatures is probably geared more toward optimizing activity than stability, given that the kinetic properties are somehow related to the dynamic properties of the protein molecules. It is therefore of interest to examine how cold activity is expressed in terms of the kinetic parameters (Michaelis-Menten) for the enzymes. The final result of low temperature adaptation will surely be dependent on what properties the cold-adapted organism has to achieve from each enzyme; some extracellular enzymes presumably work at very low substrate concentrations and would benefit the organism by having low  $K_m$  values, whereas enzymes that work in abundant substrate could optimize the  $k_{\text{cat}}$  rate. Some restrictions may apply to lowering  $K_m$  values in order to increase

catalytic efficiency under nonsaturating substrate conditions ( $k_{\text{cat}}/K_m$ ), since for regulatory purposes most intracellular enzymes have  $K_m$  values approaching the physiological concentrations of their substrates (95). Then the rate of reaction will vary with oscillation in substrate concentration, which gives a way of controlling the reaction. Since temperature affects substrate affinity constants, cold-adapted enzymes are frequently found to have higher  $K_m$  values than mesophilic counterparts at common assay temperatures of  $25^{\circ}\text{C}$  or  $37^{\circ}\text{C}$ .

At first sight, one might therefore expect orthologous enzymes from organisms with different temperature optima for their existence to have some obvious amino acid substitutions in their active sites. However, active-site residues are usually strictly conserved in psychrophilic enzymes (18, 102–105). This has put the focus for cold adaptation at the molecular level on the rather loose concept of “flexibility” in protein structure as a critical factor for improving catalytic efficiency. Indeed, changes in the amino acid sequence distant from the active site often seem to determine the outcome of temperature adaptation, making rational design for altered kinetic properties a much more difficult proposition than initially hoped for. Higher flexibility of an enzyme molecule should increase the available number of conformational states, and therefore the best conformations for ligand binding would become rarer than in a more rigid structure. Consequently, ligand binding would become poorer, with higher  $K_m$  values for substrates and higher  $K_i$  values for competitive inhibitors. Early studies established an inverse relationship within a group of homologous enzymes between the  $K_m$  value and the working temperature of individual enzymes (95).  $K_m$  values for enzymes from cold-adapted organisms were higher than for mesophiles, when the  $K_m$  values were determined at one common standard temperature (98). This is to be expected, since the evolution of maximal catalytic rate (high  $k_{\text{cat}}$ ) can be predicted to be directed toward strong binding of the transition state and weak binding of the substrates in ground states—i.e., directing the trend toward higher  $K_m$  values (106).

As the goal is often to optimize  $k_{\text{cat}}/K_m$ ,  $k_{\text{cat}}$  values must increase in psychrophilic enzymes (98, 101). This would have to occur by improving the rate-limiting step of the enzyme-catalyzed reaction under consideration, be it binding of substrates, the chemical conversion steps, or the release of products. The most common situation is a two- to fivefold increase in  $k_{\text{cat}}$ , with less prominent changes in  $K_m$ . There are, however, notable exceptions, such as in the case of

trypsins from trout, Atlantic cod, Atlantic salmon, and krill (100, 107–109). In those cases one isozyme showed 10- to 25-fold improvement in  $k_{\text{cat}}/K_m$  in comparison with bovine trypsin, that was to a large extent due to lowering of the  $K_m$  value to one-tenth the value measured for trypsin from the warm-blooded animal. Although small synthetic substrates have mostly been used in studies of many enzymes with natural polymeric substrates, being the only choice for  $K_m$  determinations, at least twofold increase in catalytic rate is also seen with natural substrates such as polypeptides (7, 110), or starch (111).

In an early study, the relative importance of the enthalpic and entropic contributions to the activation free energy of catalysis ( $\Delta G^\ddagger$ ) was found to differ between enzymatic reactions of cold-adapted ectothermic enzymes and homologous enzymes of warm-blooded birds and mammals (112). The psychrophilic enzymes often have lower enthalpies of activation ( $\Delta H^\ddagger$ ) and reactions are consequently less temperature driven. Furthermore, the entropic terms ( $\Delta S^\ddagger$ ) with psychrophilic enzymes is less positive, which may indicate looser enzyme-substrate contacts, either to the ground-state  $ES$  complex and/or to the transition-state  $ES^*$  complex (101). As noted before, weaker net binding energy for substrate is one way to increase reaction rates in enzymes; i.e., most of the initial binding energy is offset against energetically costly preparative events, and this avoids a thermodynamic pit in front of the main energy transition curve (106). This includes events such as stopping the entropic movements of substrates present in solvent, removing hydration shells off substrates, and possibly juxtaposing charges of substrates against similar charges in the walls of the active site. Some of the catalytic power of enzymes is derived from their abilities to promote formation of reactive conformers of substrates that precede the transition state (113). Random thermal motions of the enzyme–substrate complex would eventually cause transformation of those conformers into transition states. These dynamic motions might be initiated at a distance from the active site. Although correlated motions appear to participate in catalysis, there is still little evidence as to how enzymes use such motions (113); therefore, the promotion of flexibility by amino acid substitutions in cold-adapted enzymes remains enigmatic.

$k_{\text{cat}}$  values are expected to be higher for an enzyme isolated from organisms classified as psychrophilic, although there are exceptions. For aspartate aminotransferase from an Antarctic bacterium,  $k_{\text{cat}}$  was significantly lower than determined for the *E. coli* enzyme

over a wide range of temperatures. The authors proposed that adaptation of this class of endocellular enzymes to cold environment might only have made them less stable and not more efficient (114), which is a rare outcome. Another interesting group of enzymes for consideration in the context of temperature adaptation are those which have reached the state of diffusion-controlled reaction rates, such as  $\beta$ -lactamase and triose phosphate isomerase (101). Such enzymes have optimized the activation energy hills throughout the reaction pathway to the extent that it is difficult to improve  $k_{\text{cat}}$  further when the organisms are challenged with low temperatures. The higher specific activity expected as a result of cold adaptation was not observed for beta-lactamase from the Antarctic psychrophilic *Psychrobacter immobilis*, although it was very thermolabile in comparison with a mesophile (115). As argued from directed evolution experiments (see below), there may be no evolutionary pressure for thermostability at low temperatures, and this last example would indicate that increasing global heat lability is not always sufficient for improving the catalytic efficiency at low temperatures (101, 115).

A kinetic comparison of three DNA ligases adapted to different temperatures (*Pseudoalteromonas haloplanktis*, *E. coli*, and *Thermus scotoductus*) indicated that an increase in  $k_{\text{cat}}$  is the most important adaptive parameter for enzymatic activity at low temperatures, whereas a decrease in  $K_m$  allowed *T. scotoductus* DNA ligase to work efficiently at high temperatures (116).  $K_m$  values of psychrophilic enzymes are indeed often higher compared with a matching mesophilic enzymes (101), although a number of exceptions exist. In the case of phosphoglycerate kinase from an Antarctic *Pseudomonas* sp., which notably is an intracellular metabolic enzyme, both an increase in  $k_{\text{cat}}$  and a decrease in  $K_m$  were observed. This double strategy, however, only increased catalytic efficiency twofold, compared with a mesophilic enzyme (117). For alkaline phosphatases from either a psychrophilic *Vibrio* bacterium or cold-adapted fish, faster product release (lower affinity for the phosphate reaction product) has been suggested as the underlying cause for greater catalytic rates (118, 119). The  $K_m$  values for the chosen substrate were identical in the former case and lower in the latter case, in comparisons with mesophilic enzymes. From these examples it becomes apparent that various strategies are employed in cold adaptation as reflected in  $K_m$  values, whereas  $k_{\text{cat}}$  is (nearly) always increased. The choice of substrates and/or reference mesophile may affect the outcome of such *in vitro* comparisons.

## 2. Relationship Between Cold Activity and Protein Stability

For cold-adapted enzymes, increased activity at low temperature is usually reflected in low thermal stabilities. This has been found by comparative studies of natural variants and further corroborated by site-directed mutagenesis experiments. However, it is very interesting that these two apparently interlinked phenomena can be decoupled (24, 120). Mutations have been produced that increase thermal stability while maintaining low-temperature activity (25). Although still rare, they bode well for possible development of biocatalysts for industrial applications having both of those often desirable properties: high specific activity and thermal stability. Studies have shown that active-site residues may not be optimally chosen for stability as demonstrated by mutagenesis of T4 lysozyme (14), but rather have individual needs for movement, as reflected in the observation that inactivation of many enzymes precedes global conformational changes of unfolding (121). Thus, functional amino acids are likely optimized for a degree of flexibility that is appropriate for optimal effectiveness, while the rest of the protein molecule could maintain stability.

As in the case of thermophilic adaptation, there apparently are no set of "traffic rules" used for all cold-adapted proteins that are responsible for their lower conformational stabilities. By sequence comparisons researchers have attempted to spot the crucial substitutions that differentiate psychrophilic proteins from their meso- and thermophilic relatives, and lately also by tertiary structure comparisons of selected proteins. Reduced-temperature stability may not always result in improved catalytic properties, as mentioned above for aspartate aminotransferase from a psychrophilic bacterium. In contrast to the observations made with many (extracellular) psychrophilic enzymes,  $k_{cat}$  and  $k_{cat}/K_m$  were significantly lower than those for the *E. coli* enzyme over the whole temperature range, although the enzyme showed much reduced thermal stability compared with a similar enzyme from *E. coli* (114). The reduction in stability points to the fact that stability considerations may be disconnected from functional necessities and only become important as the molecule becomes too unstable for the temperature range of its operation. However, increasing the stability of a psychrophilic phosphoglycerate kinase led to drastically reduced turnover number, an indication of some link between these two properties (117).

An extensive comparison of trypsin from cold-blooded and warm-blooded animals was recently pub-

lished (122). The digestive enzyme trypsin is among the most extensively studied proteins, and in this study 27 trypsin sequences were analyzed from a variety of organisms to find unique attributes. The amino acid compositions indicated a high number of charged (predominantly acidic groups) and polar residues, and fewer hydrophobic residues in the cold-adapted trypsins. All of the psychrophilic trypsins were anionic with calculated pIs of 5.5–6.6 (122). The main unique features of the cold-adapted trypsins attributable to low-temperature adaptation seemed to be: reduced hydrophobicity and packing density of the core, mainly because of a lower (Ile + Leu)/(Ile + Leu + Val) ratio; reduced stability of the C-terminal helix which cross-links to the other (N-terminal) domain; lack of one proline residue, which is conserved in temperature-stable trypsins; and a lack of one proline-plus-tyrosine stacking interaction. In addition, there was a difference in charge and flexibility of loops that extend from the substrate binding pocket, and a different conformation of the "autolysis" loop, which is likely to affect substrate binding (122).

Some of these factors have also been cited as possible structural determinants for cold adaptation in other studies. Thus, lower values of calculated hydrophobicity indices have repeatedly been observed in other studies for cold-adapted enzymes in comparison to mesophilic partners (100, 102, 111, 115, 123). For instance, the hydrophobicity index for psychrophilic bacterial  $\alpha$ -amylase in comparison with porcine  $\alpha$ -amylase was sharply decreased concomitantly with 25 substitutions out of the 84 residues that make up the central core in that enzyme (111). Exposure of nonpolar groups to the solvent may provide entropically driven destabilization of the protein, and hence increase the mobility within the structure. This was cited as a factor in  $\alpha$ -amylase cold-adaptation (124). As the strength of the hydrophobic effect decreases as the temperature is lowered the cold-adapted proteins may rely less on hydrophobic interactions for stability than proteins that are adapted to higher temperatures. Reduced hydrophobicity may also protect psychrophilic proteins against cold denaturations, which may be caused in part by the diminished strength of hydrophobic interactions at low temperatures (125).

Comparisons of the relative numbers of hydrogen-bond forming residues indicate a lower proportion in some psychrophilic enzymes (102, 126). As an example, trypsin from an Antarctic fish displayed 20% less potential for hydrogen bonds than corresponding bovine trypsin (123). In the case of triose phosphate isomerase from the psychrophilic bacterium *Vibrio mar-*

*in*us, a single amino acid substitution (Ser238→Ala), that eliminates two hydrogen bonds in a loop region of the molecule, could to a large extent account for the cold-adaptation of the enzyme with respect to catalytic activity and thermal stability (127).

Valuable information on the potential structural determinants of cold-adaptation has come from a few recent studies where three-dimensional crystal structures, or homology models for psychrophilic enzymes, have been compared to the corresponding structures from organisms adapted to higher temperatures. Based on such tertiary structural comparison, and corroborated with data from sequence comparisons, fewer salt bridges (111, 124, 128, 129), reduction in aromatic–aromatic interactions (11, 128, 129), extended surface loops (105, 128–130), fewer prolines in such loops (105, 115, 124, 129, 130), lower hydrophobicity (111, 115), weaker calcium bindings (104, 124, 128), improved solvent interactions through additional surface charges (105, 115, 128, 130), increased exposure of nonpolar groups to the solvent (105, 124), and reduced intersubunit ion pairs (105, 131) have all been cited as possible reasons for increased flexibility and/or decreased thermal stability of proteins from psychrophiles.

The first x-ray crystal structure of an enzyme from a cold-adapted ectothermic organism was that of salmon trypsin (102). It was followed by a structure of elastase from the same species (103) and other trypsin isozymes (132). Later, the structures of psychrophilic bacterial enzymes have been determined—those of  $\alpha$ -amylase from *Alternomonas haloplanktis* that lives in Antarctic seawater (104), and citrate synthase from another Antarctic bacterium (105). More recently, a structure was solved for a malate dehydrogenase from a psychrophilic bacterium isolate from an Arctic sediment that grows optimally at 4°C (131).

Superposition of the  $\alpha$ -amylase structure onto that of porcine pancreatic  $\alpha$ -amylase showed that the 24 residues that form the binding subsites for substrate were strictly conserved. Therefore, the cause for increased catalytic efficiency had to be sought outside the catalytic center. For this enzyme, it was suggested that reduced number of salt bridges, fewer proline residues in loops, fewer arginine-mediated hydrogen bonds, and lower hydrophobicity in the core were all contributing. Also, less interdomain interactions were proposed as a determining factor for the conformational flexibility that allows efficient enzyme catalysis in cold environments (104). Structural comparison suggested that the major factors for the efficient catalytic activity of *A. arcticum* malate dehydrogenase at low

temperatures were favorable surface charge distribution for substrate and cofactor binding, and reduced intersubunit ion pair interactions that increased relative flexibility of active site residues (131). The crystal structure of dimeric citrate synthase from an Antarctic bacterium revealed that the enzyme had much more accessible active site than thermophilic counterparts (105).

The surface electrostatic potential distribution was unusual, and an increased relative flexibility of the small domain compared to the large domain of the protein was noted within each monomer. Furthermore, reduced subunit interface interactions were found with no intersubunit ion pair networks, and loops were of increased length but carried fewer proline residues. Lastly, there was an increase in solvent-exposed hydrophobic residues and an increase in intramolecular ion pairs. In comparison, the thermal denaturation of hyperthermophilic dimeric citrate synthase appears to be resisted by complex networks of ion pairs at the dimer interface, a feature common to several other hyperthermophilic proteins as discussed previously. Catalytic efficiency of the cold-active citrate synthase appears to be achieved by a more accessible active site and by an increase in the relative flexibility of the small domain compared to the large domain in the enzyme (105).

Molecular modeling of various enzymes has given similar information as x-ray structures. Among features of a psychrophilic subtilisin S41 that might induce a more flexible and heat-labile conformation were four extended surface loops, a very hydrophilic surface (acidic pI of 5.3), and the lack of several salt bridges and aromatic interactions (128). The difference in the free energy of stabilization between subtilisin S41 and a mesophilic subtilisin was found to lie in the range 6–7 kJ/mol, suggesting that the balance of weak bonds is critical for the enzyme's flexibility.

Detailed model comparison of eight trypsin structures was made to seek explanations for the observed differences in properties seen with mesophilic and cold-adapted variants (132). Increased substrate affinity of the psychrophilic enzymes was traced to a lower electrostatic potential of the S1 substrate binding pocket, and the lack of five hydrogen bonds adjacent to the catalytic triad. Reduced stability of the cold-adapted trypsins might result from fewer interdomain bonds, including hydrogen bonds and salt bridges, as well as poorer packing in the core regions of the two domains.

A dimeric 3-isopropylmalate dehydrogenase that catalyzes the penultimate step in leucine biosynthesis was cloned from a psychrotrophic *Vibrio* sp., living in

Arctic seawater (129). The elements that were found to be destabilizing in this case were a smaller number of salt bridges, a reduction in aromatic interactions, fewer proline residues, and longer surface loops (129). The structural model of a psychrophilic phosphoglycerate kinase indicated the same key determinants of its low stability (117).

Some of the examples described above are of dimeric enzymes, where psychrophilic variants have reduced links between monomers. The formation of dimers, and higher multimers, has often the sole purpose of increasing stability (133), without linked effects on kinetic properties. This seems to be the case for several oligomeric enzymes from thermophiles, as we discussed earlier. Alkaline phosphatase from cold-adapted *Vibrio* bacteria is apparently monomeric (118, 134) and may thus be an example of the opposite trend, since the well-known enzyme from *E. coli*, another Gram-negative species, has a very heat-stable dimeric structure. This may be an example where pressure to form dimers was not present. Phosphoglycerate kinase is a monomeric enzyme, except in extremophilic archaea, where the enzyme has been found as a dimer or a tetramer (135, 136).

Subtle alterations in structure at dimer interfaces can produce enzymes with characteristics of being psychrophilic rather than mesophilic or thermophilic. Horse liver alcohol dehydrogenase contains two tryptophan residues per subunit, one on the surface of the catalytic domain and the second buried in the interface between the subunits of the dimer. After substituting the tryptophan at the interface with a leucine, and making two compensatory mutations that were required to obtain a stable protein, the turnover numbers for ethanol oxidation, acetaldehyde reduction, and the dissociation constants of the coenzymes increased by two- to sixfold (137). The three substitutions at the dimer interface apparently activated the enzyme by allowing more rapid conformational changes that accompany coenzyme binding, probably owing to movement of a loop. A subunit interface was also the site of a single amino acid substitution that brought different stabilities of temperature- $K_m$  relationships to a related group of lactate dehydrogenases (95). Furthermore, many enzymes, although monomeric, can be viewed as aggregates of folding domains. Interdomain interactions could contribute to greater movement in cold-active enzymes, allowing more efficient enzyme catalysis in cold environments. In fact, fewer interdomain interactions were found in  $\alpha$ -amylase from a psychrophilic bacterium than in porcine pancreatic amylase, which was likely a con-

tributing factor to efficient catalysis in cold environments (124). Also, this type of adaptation has been given consideration in the case of Atlantic salmon trypsin, where the active site is divided on both sides of two relatively rigid  $\beta$  barrels (102). In contact regions near the catalytic residues, fewer hydrogen bonds were found in the salmon trypsin, and ion pairs might be important in the relative orientation of the two domains of the molecule, as well as contributing to greater stability of the bovine variant (102).

## V. TEMPERATURE ADAPTATION BY SITE-DIRECTED MUTAGENESIS AND DIRECTED EVOLUTION

Evolution of a particular trait necessitates that a single base change can at times lead to a single amino acid substitution that brings about alterations in a protein's properties, which is beneficial to the host. Site-directed mutagenesis is therefore often employed in tandem with rational design ideas in order to understand the functioning of enzymes. Theories derived from the study of a three-dimensional model of a particular enzyme are utilized to select particular residues for mutation and predict the possible outcome. Thus, experiments with T4 lysozyme showed that even a single mutation in the hydrophobic core of an enzyme can have dramatic effects on stability (138). This may be informative, but it does not necessarily cover all the parts of the molecule that can affect its properties. Attention is often directed at the active-site region and at internal residues, whereas more distant residues may cause functional alterations, even those that reside on the outside surface of the molecule.

Studies using site-directed mutagenesis, however, have uncovered the fact that thermostability is not systematically inversely related to specific activity, one example being subtilisin excreted by an Antarctic *Bacillus* TA39 (139). The enzyme displays the usual characteristics of cold-active enzymes—i.e., a high catalytic efficiency at low temperatures and an increased thermosensitivity. The affinity for calcium is also almost 3 orders of magnitude lower than that of mesophilic subtilisins. An important stabilization of the molecular structure was achieved through a modification of one residue acting as a calcium ligand. The thermostability of the mutated product expressed in a mesophilic *Bacillus* reached that of mesophilic subtilisin, and this mutation further enhanced the specific

activity by a factor close to 2 when compared to the wild-type enzyme.

Single-base mutations do not cover a large fraction of protein sequence space since they often produce conservative substitutions. Another approach that increases nonconservative substitutions is that of directed evolution, where rapid screening procedures are combined with random mutagenesis and *in vitro* recombination. Structural analysis of selected mutants can then bring about understanding of the observed phenotype, be it stability or catalytic activity, in terms of chemical function. The vast majority of possible evolutionary paths lead to poorer enzymes, so for successful directed evolution, the strategic challenge is to choose the right path that will eventually improve the desired features (140).

Recent examples can be found where the stability of enzymes from psychrophiles or mesophiles has been increased without effects on activity. A moderately stable thermolysin-like metalloprotease from *Bacillus stearothermophilus* was made hyperstable by a limited number of mutations. An eightfold mutant enzyme had a half-life of 2.8h at 100°C, but still displayed wild-type-like activity at 37°C (24, 141). Subtilisin E from a mesophilic *Bacillus subtilis* was converted into an enzyme functionally equivalent to its thermophilic counterparts by directed evolution (142). Subtilisin E differs from thermitase at 157 amino acid positions. However, only eight amino acid substitutions were sufficient to convert subtilisin E into an enzyme equally thermostable, a result from five generations of DNA alterations. Interestingly, the eight substitutions were distributed over the surface of the enzyme. Only two of those are found in thermitase. Also, thermostability could be increased without compromising enzyme activity (142).

In another study, thermoresistance was engineered into bacterial  $\beta$ -glucosidase by a directed-evolution strategy (143), whereas no significant alterations in kinetic parameters were observed. The main factors for increasing the thermostability were a combination of one extra salt bridge, replacement of a solvent-exposed asparagine residue, stabilization of the hydrophobic core, and stabilization of the quaternary structure. An earlier study used *in vitro* evolution to probe the relationship between stability and activity in a mesophilic esterase. Six generations of random mutagenesis, recombination, and screening, stabilized *Bacillus subtilis* *p*-nitrobenzyl esterase significantly without compromising its catalytic activity at lower temperatures. It was also found that mutations that increased thermostability, while maintaining low-tem-

perature activity, were very rare. The results suggested that stability at high temperatures was not incompatible with high catalytic activity at low temperatures because of perceived mutually exclusive demands on enzyme flexibility (144).

Low-temperature activity can also be generated by mutations. It was possible to improve catalytic activity at 37°C of a thermophilic enzyme with a single or double amino acid substitution. DNA shuffling was used to mutate indoleglycerol phosphate synthase from the hyperthermophile *Sulfolobus solfataricus* (145). The parental enzyme's turnover number at room temperature was limited by the dissociation of the enzyme–product complex, apparently because the loops that obstruct the active site were not flexible enough at low temperatures. In the variants, the binding and release of product was much more rapid, and this shifted the rate-determining step to a preceding chemical step (145). Similarly, multiple random mutants of  $\beta$ -glucosidase from the hyperthermophile *Pyrococcus furiosus* were screened for increased activity at room temperature (146). Multiple variants were identified with up to threefold increased rates of substrate hydrolysis. Amino acid substitutions were widespread, occurring in the active-site region, at the enzyme surface, buried in the interior of the monomers, and at subunits interfaces. Interestingly, low-temperature activity was achieved in different ways, by altering substrate specificity or by overall destabilization of the enzyme. Single amino acid substitutions were sufficient to drastically alter the kinetic properties, as would be expected, if evolutionary processes are to work. The enzyme was able to accommodate in its interior amino acids with larger or smaller side chains, and with different properties without affecting thermostability. Substrate specificity was also determined by substitutions distant to the active site.

The stability of enzymes from psychrophiles can also be increased without reducing activity (25). The psychrophilic protease subtilisin S41 was subjected to two different selection pressures. The evolved subtilisin S41 retained its psychrophilic character as a catalyst in spite of its dramatically increased thermostability. These results demonstrated that it is possible to increase activity at low temperatures and stability at high temperatures simultaneously. It was concluded that the fact that enzymes displaying both properties are not found in nature, most likely reflects the effects of evolution rather than any intrinsic physico-chemical limitations on proteins (25). However, the dependence of slower thermal inactivation on calcium concentration indicated that enhanced calcium

binding was largely responsible for the increased stability.

Few studies are to be found where the kinetic characteristics of a psychrophilic enzyme have been produced by directed evolutionary methodology. A cold-adapted subtilisin has been generated by evolutionary based sequential methodology. Cold-adaptation was achieved with three mutations, and it was found that an increase in substrate affinity (i.e., decreased  $K_m$  value) was mostly responsible for the observed doubling in catalytic efficiency at 10°C (147).

This section has shown that single-residue substitutions can affect stability of enzymes considerably and influence kinetic properties. However, it may be generally a fact that more than one substitution is required to realize the full potential for temperature adaptation in an enzyme.

## VI. TEMPERATURE EXTREMOPHILES AS SOURCES FOR BIOCATALYSTS FOR THE FOOD INDUSTRY

### A. Thermophilic Enzymes

As mentioned earlier, it is generally advantageous to run industrial processes at elevated temperatures, as long as sensitive components in the reaction are not damaged under such conditions. It is therefore not surprising that many of the biotechnological processes involving enzymes are carried out at relatively high temperatures, and most of the enzymes used are quite thermostable, despite them being usually of mesophilic origin (148). A useful industrial enzyme must have several specific properties depending on the particular application, but thermostability is usually an absolute necessity (148). Despite the potential benefits that may be achieved by using more thermostable enzymes in several of these processes, the industrial uses of thermophilic enzymes are still very limited (19). In some industrial sectors (including the food industry), which use "bulk" industrial enzymes, cost is the major issue, as introducing a new enzyme is worthwhile only if the cost improvement provided by the new enzyme justifies the research and development costs as well as the required changes to production equipment (19).

Some successful biotechnological applications of thermophilic enzymes have already been developed and implemented. At present, by far the most important large-scale application of thermophilic enzymes is in the use of DNA polymerases in the polymerase chain reaction (PCR). The most commonly used

enzyme in these applications is the so-called *Taq* polymerase from *Thermus aquaticus*, but several other DNA polymerases from other thermo- or hyperthermophilic bacteria and Archaea have been characterized and are commercially available (6, 149).

Improved thermal stability is a highly desirable property for the enzymes ( $\alpha$ -amylase, glucoamylase, pullulanase, glucose isomerase) that are used in the commercial processing of starch to glucose and fructose in the production of high-fructose corn syrup. In this process the starch is typically gelatinized at 105°C for 5 min and then  $\alpha$ -amylase is used at 95°C and pH 6–6.5 to partially cleave the  $\alpha$ 1-4-glycosidic linkages in the interior of the polymer, leading to liquefaction of the starch. For the second (saccharification) step, the temperature must be lowered to 60–62°C and the pH to 4.5, to adjust to the stability and the pH optimum of the exo-acting glucoamylase and pullulanase that further cleave the chain to smaller saccharides (95–96% glucose in glucose syrups) (6, 19, 150). In the final step the concentrated glucose syrup is again pH adjusted to 7–8.5, and is passed through a column with immobilized glucose isomerase (xylose isomerase) at 55–65°C, which converts it preferably to 55% fructose (150). The limited thermal stability of the currently used glucose isomerases determines the moderate temperatures used in this process (19).

The use of more thermostable enzymes which are active under similar temperature and pH conditions could significantly improve the starch conversion process, as it would be possible to run the liquefaction and saccharification process in one step (19, 31). Finding thermostable enzymes with similar pH characteristics (activity and stability) would also reduce costs in the process as the use of ion exchanger step could be avoided, but that is necessary to carry out to remove salts that accumulate as a result of the pH adjustments between different steps. In this respect hyperthermophilic  $\alpha$ -amylases with lower pH optima are promising candidates (6, 151).

Studies have also shown that isomerization of glucose to fructose can be improved considerably by running this step at elevated temperatures (150). A search for more thermostable glucoamylases (or  $\alpha$ -glucosidases), pullulanases, and glucose isomerases from hyperthermophilic Archaea and bacteria is now actively being pursued with the goal of finding enzymes with more desirable properties in the starch conversion process (see 6, 19, 31, for review). Furthermore, protein engineering has increasingly been used to improve thermal stability (152, 153), or catalytic properties (154) of glucose isomerases.

Mutant enzymes obtained with protein engineering techniques may prove to be important candidates for future industrial applications, in these and other processes.

Cyclodextrins are useful in the food industry in specific separation processes, in flavor stabilization, and in controlled release and exclusion of unwanted compounds from the bulk phase (155). They are nonreducing cyclic products of six to eight glucose units. At the industrial level they are made from starch that first is liquefied at high temperature by a thermostable  $\alpha$ -amylase, followed by transglycosylation reaction leading to the cyclized product, a reaction catalyzed by cyclodextrin glycosyl transferase (CGTase) (6, 19). The mesophilic CTGases that are conventionally used in the process are heat-labile and the second step in the process must be run at lower temperatures. Using a thermostable CGTase would greatly improve the process, as liquefaction and cyclization could be carried out in one step (6, 19).

Several proteases from thermophiles and hyperthermophiles have been characterized (19, 48). The major large-scale use of proteases as industrial enzymes is in the detergent industry, as additives in household detergents, with alkaline serine proteinases from mesophilic *Bacillus* species (subtilisins) as the main enzymes. These enzymes are generally quite stable at moderately high temperatures (60–65°C) and under alkaline conditions (pH 9–11) (148). A number of subtilisin-like serine proteinases from extreme thermophiles have been characterized (see, e.g., 156–158) that would be expected to have properties more optimized for detergent applications, but that have not been used for that purpose. A major reason is that changing the large bulk production lines for the present detergent proteases for the more thermophilic enzymes may not be cost-effective at present.

An advantage of doing proteolysis at high temperatures is that the protein substrates are denatured, which makes them generally more accessible to proteolytic attack than when in their native states. This may be particularly important when hydrolyzing difficult proteinaceous waste materials (148). Because of their high thermal activity and stability under conditions that denature most other proteins, thermophilic proteases are good candidates for applications aimed at utilizing different protein waste materials for making protein hydrolysates for different purposes. High-temperature treatment of such waste materials would also contribute to maintaining aseptic conditions and to prevent the growth of spoilage bacteria and pathogens during processing.

Proteases have increasingly been used in peptide synthesis, where advantage is taken of their reverse reaction under modified solvent conditions. Studies have shown that peptide synthesis is favored under controlled conditions at higher temperatures. It has therefore been suggested that, owing to their optimal activity at high temperatures and higher resistance to organic solvents than their mesophilic counterparts, thermophilic proteases should prove excellent candidates for enzymatic peptide synthesis (19). Indeed, the use of the thermophilic neutral metalloprotease thermolysin for the synthesis of the artificial sweetener aspartame (a dipeptide) has been developed into a large-scale application, and is currently the only industrial application that uses a thermophilic protease (19, 148).

## B. Psychrophilic Enzymes

Despite the fact that stability is a major criterion for the industrial application of enzymes, the use of psychrophilic enzymes in selected instances may offer advantages. Examples of the real usage of such enzymes in an industrial setting are very rare, although ideas as to the potential application of cold-active enzymes have been around for the past two decades (5, 8, 99, 159). The main advantages seen for cold-active enzymes are twofold: high activity at low temperatures, which may reduce energy consumption, and easy inactivation through moderate heating or low-pH treatment. Low processing temperatures might also work toward reducing bacterial contamination (5). Potential uses range from the use of cold-active enzymes in the detergent industry for washing or disinfecting at low temperatures (amylases, lipases, and proteinases), to various applications in food industries. Examples relating to milk processing include lactose hydrolysis by  $\beta$ -galactosidase, or the use of proteases to coagulate milk and accelerate cheese maturing. Also, cold-active enzymes may become useful in specific biotransformations, such as the production of oils with high polyunsaturated fatty acid content, and in whole organisms for environmental cleaning, where temperatures are generally low (e.g., removal of heavy metals or toxic materials from aqueous effluents). More specialized uses include addition to contact lens cleaning fluids, and the potential use of ice-nucleating proteins in the manufacture of ice cream or artificial snow (5, 99).

Some other examples relating to food production have been considered in the fishing industries of North Atlantic coastal nations, but large-scale use is still in its infancy (159–162). Examples where cold-

active enzymes have found use as processing aids include caviar productions (i.e., releasing roe from roe sacks), the deskinning of fish fillets or squid mantle, and the removal of membranes from cod liver or swim bladder. In some instances the task has proven virtually impossible by manual or mechanical means, thus augmenting the value of the enzymatic process. Development of several other technical processes has been a success at a laboratory scale, but not found widespread use in demanding industrial environments. Also, a dependable source of speciality enzymes (i.e., cold-active enzymes) in bulk has not been there and they are still costly. Large-scale fish processing that will depend on biotechnology may still be a long way in the future.

Besides being useful for industrial application, enzymes from extremophiles have applications as fine chemicals for research laboratories. Cold-active alkaline phosphatase from shrimp (163), for example, is preferred to more heat-stable variants in DNA work, and DNA ligase from *P. haloplanktis*, which is very efficient at low temperatures, may offer a novel tool for biotechnology (116). As mentioned for thermophilic enzymes, the psychrophilic enzymes may also be well suited for biocatalysis in organic media, an emerging field of possible application (164).

## Nitrogen Fixation and the Enzyme Nitrogenase

**William E. Newton**

*The Virginia Polytechnic Institute and State University, Blacksburg, Virginia, U.S.A.*

### I. INTRODUCTION

Only a very small proportion of the nitrogen present on earth is in a usable form at any one time. More than 99.9% of the nitrogen is present as the dinitrogen molecule ( $N_2$ ). Most organisms cannot metabolize this abundant, but relatively inert  $N_2$  and so they must assimilate nitrogen in a “fixed” form, such as ammonia ( $NH_3$ ) or nitrate ( $NO_3^-$ ). As part of the geochemical nitrogen cycle, nitrogen fixation drives the conversion of atmospheric  $N_2$  to ammonia. However, the complementary processes of nitrification and denitrification convert ammonia back to dinitrogen, which is returned to the atmosphere. This constant cycling means that the pool of fixed nitrogen within the biosphere must be constantly replenished because ammonia is necessary for the formation of biologically essential, nitrogen-containing compounds, such as amino acids and nucleic acids. Dinitrogen is fixed naturally by both nonbiological processes, like lightning and combustion, and by biological processes. Natural nonbiological processes contribute  $\sim 10\%$  and biological processes contribute about 65% of the total annual fixation rate. Industrial ammonia synthesis contributes the other 25% (1, 2). Thus, biological nitrogen fixation is a pivotal life-supporting process that provides the majority of the fixed nitrogen source necessary to sustain life on earth.

Animals, including man, are directly dependent on plants to supply much of the energy and many of the nitrogenous compounds required to survive. Plants, in their turn, are dependent on the availability of nitro-

genous compounds produced from atmospheric  $N_2$  either commercially or biologically by microbes. In this way, nitrogen fixation assumes significant importance in agriculture because the availability of fixed nitrogen is most often the limiting factor in crop production. Consequently, efforts to grow sufficient crops to feed the global population have led to increases in the application of commercial nitrogen fertilizers. However, applying nitrogen fertilizers has its costs. These costs, which are directly associated with the Haber-Bosch process, include: (a) consumption of non-renewable fossil fuel resources as both feedstock and energy source; (b) significant storage costs for product manufactured year-round but applied seasonally and significant transportation costs due to the production site usually being remote from the site of use; and (c) contamination of local water systems through runoff. In fact, only about one-third of the applied nitrogen is assimilated by plants, whereas one-third is leached away (after conversion to nitrate) and one-third is denitrified and lost to the atmosphere as  $N_2$ (1). An alternative approach to using the Haber-Bosch process for producing commercial nitrogen fertilizer is to exploit the biological process and considerable effort is currently being directed at understanding the molecular mechanism of biological nitrogen fixation.

### II. NITROGEN-FIXING ORGANISMS AND CROP PLANTS

Only prokaryotes, i.e., those living things without an organized nucleus (Eubacteria, Archaea, and actino-

mycetes), can perform biological nitrogen fixation. The ability to fix N<sub>2</sub> is widely spread among bacterial genera (3, 4) and, despite a number of claims, no eukaryote has been clearly established to fix N<sub>2</sub>. Although farmers recognized the benefits of crop rotations centuries ago, the source of much of that benefit was unknown to them. The first report of nitrogen fixation in 1838 involved a comparison of the growth and nitrogen content of cereals with leguminous plants (mainly clover in rotations with wheat and tuber crops) in both greenhouse and field experiments. The result "that azote (nitrogen) may enter the living frame of the plants directly" (5, 6) was received with much skepticism. It was not until almost 50 years later that Boussingault's work was convincingly confirmed by Hellriegel and Wilfarth (7), who also solved the perplexing question of the source of the fixed nitrogen by localizing the activity to the bacteria-filled nodules on the roots of their pea plants (6, 8).

Most nitrogen-fixing microbes are free living and fix nitrogen for their own benefit. Except for the cyanobacteria, the free-living bacteria are generally not agriculturally important, contributing only ~ 0.1% of the fixed nitrogen of a leguminous association. The most extensively studied free-living bacterial species are *Azotobacter vinelandii* (an obligate aerobe), *Clostridium pasteurianum* (an obligate anaerobe), *Klebsiella pneumoniae* (a facultative anaerobe), *Rhodobacter capsulatus* (a photosynthetic bacterium), and *Anabaena* sp. 7120 (a heterocyst-forming cyanobacterium). However, some nitrogen-fixing microbes enter into a mutually beneficial interaction with other organisms. The most agriculturally important symbiotic relationship involves leguminous plants and rhizobial microsymbionts, but many other nitrogen-fixing, symbiotic relationships are known. These include examples with lichens, bryophytes (mosses and liverworts), pteridophytes (ferns), cycads, and other nonleguminous angiosperms, such as small shrubs and trees, like *Myrica* and alder, and larger trees, like *Casuarina* (3).

The leguminous association ensures that the plant receives fixed nitrogen directly from the rhizobia bacteria, which are harbored in nodules on its roots. In return, the bacterium receives a protected environment and a supply of energy from the plant. Another benefit arising from this association is the provision of an environment with a low O<sub>2</sub> tension within the root nodules. This function is vital because the enzyme, which catalyzes biological nitrogen fixation and is called nitrogenase, is extremely sensitive to the presence of O<sub>2</sub>. Most often, the first level of protection

against O<sub>2</sub> occurs through a physical barrier to free O<sub>2</sub> diffusion provided by the plant-derived, outer cortex layer of the nodule. This structure prevents O<sub>2</sub> from flooding the central core of the nodule where the nitrogen-fixing bacteria are located. However, some O<sub>2</sub> is required for bacterial respiration to provide the energy and reducing equivalents to drive its nitrogen fixation, and this low, but sufficient, concentration is delivered by an oxygen-transporting protein, called leghemoglobin.

Establishment of a symbiotic relationship is a complicated process, which most often involves specificity between the host plant and its microsymbiont (9). In the legume symbiosis, initiation of the infection process occurs when bacteria induce curling of the tip of root hairs (10, 11). These structures then envelop the bacteria and form an "infection thread," which penetrates the root cortex and along which the invading bacteria enter the host plant cells (12). As infection thread formation occurs, cell division is induced within the root cortex, resulting in formation of a nodule primordium (13). When the infection thread contacts a newly divided primordial cell, bacteria are released and they enter the cytoplasm of the primordial cell through an endocytotic process, which results in a plant-derived peribacteroid membrane that surrounds the bacteria (14). Following multiple bacterial-cell division and peribacteroid membrane proliferation, the host cell becomes filled with bacteria, which then differentiate into bacteroids that are specialized for fixing nitrogen.

The symbiotic interaction requires coordination among the partners at both the developmental and metabolic levels. This cooperation is accomplished through reciprocal communication and control of gene expression. Signaling between the partners starts when the regulatory nodulation (*nod*) genes of the rhizobia detect plant signals present in root exudates. These plant signals are usually flavonoids (15). These flavonoids specifically induce rhizobial *nodD* gene expression (16), which produces a regulatory protein (a transcriptional activator) that controls the expression of all other *nod* (and *nol*) genes. The concerted action of the products of other *nod* genes results in the synthesis and release of the bacterial signals, called Nod factors (17). Each rhizobial Nod factor is species specific. It is chitinlike, being composed of  $\beta$ (1-4)-linked *N*-acetylglucosamine residues. The specificity of a particular Nod factor depends on both the extent of oligomerization (usually up to five residues) and the range of chemical modification of the chitin core, such as O-acylation or N-acylation at the nonreducing end

and sulfation at the reducing end. The *nodABC* genes are called the “common” *nod* genes because their products are required for catalyzing formation of the oligosaccharide core for all Nod factors. The other *nod* genes are “host specific” and their products are responsible for oligomerization and modification of the oligosaccharide core. In some plant strains, isolated Nod factors can initiate root hair curling, infection thread development, and nodule formation.

Root nodules are the usual result of N<sub>2</sub>-fixing symbioses involving *Rhizobium*; however, some tropical legumes, like *Sesbania*, produce stem nodules in association with *Azorhizobium caulinodans* (18). In addition, some stem nodules retain the ability for photosynthesis and contain, in the case of *Aeschynomene indica*, rhizobia themselves capable of photosynthesis (19). This close relationship of photosynthesis to nitrogen fixation may ease some of the energy demand of nodules.

Although this tight, nodule-based, symbiotic arrangement is very successful, it does not extend to most of the important food crops, like the cereal grains (rice, wheat, and corn) and root and tuber crops. None of these harbor symbiotic partners in nodules. Hence, for the productivity of these crops to reach commercially acceptable levels, extensive augmentation by commercially fixed nitrogen is usually necessary. However, other, less formal associations occur regularly in which some interdependence exists among some grasses (family Gramineae) and bacteria. The associations of tropical grasses *Paspalum* and *Digitaria* with the bacteria *Azotobacter paspali* and *Azospirillum brasiliense*, respectively, are good examples of such a relationship (20). With *Paspalum*, a mucilaginous sheath forms around the root within which the bacteria live and fix N<sub>2</sub>. The bacteria do not invade the plant tissue. In contrast, the *Digitaria–Azospirillum* association does involve root invasion but no nodule develops. The extent to which the plants benefit from these associations is uncertain. *Azospirillum lipoferum*, which occurs in temperate zones, associates with certain corn and sorghum cultivars, but the effect on the plants appears to be small (21, 22). The more formalized endophytic associations of both *Acetobacter diazotrophicus* and *Herbaspirillum* spp. with sugar cane (23) and of *Azoarcus* spp. with Kallar grass and possibly rice (24) may supply up to 100% of the fixed nitrogen required for the host plant’s growth, indicating a significant agronomic and economic potential.

Nitrogen-fixing associations involving animals also exist (25). In the case of higher animals, like either man

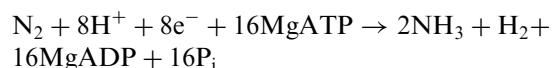

with *Klebsiella* or ruminants with *Clostridium*, it is unlikely that much is contributed to the nitrogen status of the animal because its diet likely contains sufficient fixed nitrogen, which will repress any N<sub>2</sub>-fixing activity by the bacteria. However, with termites and shipworms, the associations are significant. *Citrobacter* infects the intestinal tract of termites and can fix N<sub>2</sub> there with the amount fixed and the benefit gained depending on the insect’s diet (26, 27). The N<sub>2</sub>-fixing, cellulose-decomposing bacterium that inhabits the Deshayes gland of woodboring shipworms contributes significantly to the mollusk’s well-being by providing up to 35% of its fixed nitrogen requirement (28). The whole area of animal symbioses is under-researched.

### III. NITROGENASES

#### A. Molybdenum Nitrogenase

With one exception (29), all known diazotrophs contain a nitrogenase (or nitrogenases) that is a complex of two metalloproteins (30–33). The individual nitrogenase component proteins of the most commonly occurring nitrogenase, usually referred to as Mo-nitrogenase, have been designated as the Fe protein (or component 2 or dinitrogenase reductase) and the MoFe protein (or component 1 or dinitrogenase). The trivial names for these proteins are derived from the composition of their associated metal centers. The Fe protein is a homodimer ( $M_r = 64,000$ ), which contains two MgATP binding sites and a single [4Fe–4S] cluster. The MoFe protein is an  $\alpha_2\beta_2$  heterotetramer ( $M_r = 230,000$ ), which contains two pairs of two different metalloclusters, called P-clusters and iron-molybdenum cofactors (or FeMo cofactors). The three-dimensional structures of the Fe protein (34) and MoFe protein (35, 36) have been solved, as have the structures of their associated metal clusters (34, 37, 38). The Fe protein serves as a specific reductant for the MoFe protein, which contains the site(s) of substrate binding and reduction.

Wild-type nitrogenase catalyzes the biological nitrogen-fixation reaction, which is usually described as:

In addition, nitrogenase catalyzes the reduction of many other small molecule substrates, all of which have the same requirements for catalytic activity, namely MgATP, a low-potential reductant and an anaerobic environment (39, 40). The optimal stoichiometry for nitrogenase function is four molecules of

MgATP hydrolyzed for each pair of electrons transferred to substrate; this ratio is independent of the substrate reduced. The so-called *alternative substrates* include, for example, acetylene, which is only reduced by two electrons to ethylene, HCN, which is reduced by six electrons to methane and ammonia and by four electrons to methylamine, and azide, which is reduced by two electrons to nitrogen gas and ammonia. Carbon monoxide (CO) is a potent inhibitor of all nitrogenase-catalyzed substrate reductions with the exception of H<sup>+</sup> reduction (41). H<sub>2</sub> has a unique involvement with Mo-nitrogenase and with N<sub>2</sub> reduction in particular. It can play any one of four well-documented roles both *in vivo* and *in vitro*. H<sub>2</sub>, *via* the action of hydrogenase, can be the source of reducing equivalents for nitrogenase; it is the sole product in the absence of other reducible substrates in an ATP-dependent, CO-insensitive reaction (42); it is a specific competitive inhibitor of N<sub>2</sub> reduction, affecting neither the reduction of any other substrate nor its own evolution (43); and, under an N<sub>2</sub>/D<sub>2</sub> atmosphere, HD is formed in a CO-sensitive, MgATP-requiring reaction (44–47). These Mo-nitrogenases, from a variety of genera, exhibit a high level of primary sequence identity. The sequence conservation is particularly high in the regions of the MgATP- and metallocluster-binding sites (48). With the notable exception of *C. pasteurianum*, the component proteins from all Mo-based nitrogenases interact as heterologous crosses to form catalytically active enzymes (49).

## B. Alternative Nitrogenases

With the single exception noted above and described in Section III.C below, all nitrogen-fixing organisms that have been studied at the level of the enzyme have the Mo-containing nitrogenase. There are, however, two other types of nitrogenases, which are closely related to the Mo-nitrogenase, but neither contains Mo. These so-called alternative nitrogenases (50–52) consist of two protein components, including a Fe-protein component specific for each alternative nitrogenase. The larger of the two component proteins of the first alternative nitrogenase contains a cofactor with a vanadium (V) atom substituting for the Mo atom. This replacement results in a VFe protein containing a FeV cofactor. The second type contains a cofactor where the Mo atom is substituted by Fe to produce a FeFe protein containing a FeFe cofactor. The high level of primary sequence identity recognized among the Mo-dependent nitrogenases also extends to the alternative nitrogenases. This identity strongly suggests that all nitro-

genases are likely to have common structural features and mechanistic similarities. However, the larger component of these alternative nitrogenases is hexameric with three types of subunits, which are encoded by either *vnfDGK* (51, 53, 54) or *anfDGK* (52, 55), rather than the tetrameric form of the MoFe protein.

There appears to be no logic to the way in which these nitrogenases are distributed among microorganisms. For example, *Klebsiella pneumoniae* has only Mo-nitrogenase, whereas *Azotobacter chroococcum* has both Mo- and V-nitrogenase, and *Rhodobacter capsulatus* has Mo- and Fe-nitrogenase. Moreover, all three nitrogenase types are found in *A. vinelandii*. The expression of each nitrogenase is under hierarchical control through the availability of either Mo or V in the growth medium (56, 57). Whenever Mo is available, expression of the Mo-dependent nitrogenase is stimulated and the expression of the others is repressed. Similarly, when V is available and Mo is absent, expression of the V-nitrogenase only occurs. If both metals are absent, then only the Fe-nitrogenase is expressed. Such control by metal availability is physiologically reasonable because Mo-nitrogenase is the most efficient catalyst for nitrogen reduction, followed by V-nitrogenase, with the Fe-nitrogenase being the least efficient with a large majority of reducing equivalents being used to evolve H<sub>2</sub> rather than to produce ammonia (58, 59). Active heterologous nitrogenase results from crosses among the two-component proteins from Mo-nitrogenase and V-nitrogenase, but crosses involving either component protein from the Fe-nitrogenase are ineffective with the complementary protein from both Mo- and V-nitrogenases (59).

## C. *Streptomyces thermoautotrophicus* Nitrogenase

Although this recently discovered (29), unique nitrogenase system consists of two component proteins, the larger of which contains Mo, Fe, and sulfide, that is where the similarities to the classical Mo-nitrogenase stop. The Fe-protein component of the classical nitrogenase is replaced by a manganese-containing superoxide oxidoreductase, which oxidizes superoxide to dioxygen and then transfers the electron to a MoFeS-containing protein at which each dinitrogen molecule is reduced by eight electrons to two molecules of ammonium and one molecule of dihydrogen. This reaction appears to require less MgATP per dinitrogen reduced than that required by the classical Mo-nitrogenase. In place of flavodoxin or ferredoxin as the electron donor to the Fe protein, a Mo-containing

CO dehydrogenase operates by coupling the oxidation of CO to the reduction of dioxygen to produce superoxide. The MoFeS-containing protein is a  $\alpha\beta\gamma$  heterotrimer quite different from the  $\alpha_2\beta_2$  composition of the classical Mo-nitrogenase. Other unique features of this nitrogenase include the insensitivity of its nitrogen fixation toward dioxygen, CO, and dihydrogen, all of which are potent inhibitors of nitrogen fixation in the classical system. Finally, this nitrogenase does not catalyze the reduction of acetylene to ethylene.

#### D. Mechanism of Nitrogenase Action

During catalysis, the Fe protein delivers electrons, one at a time, to the MoFe protein in a process that couples MgATP binding and hydrolysis to the association and dissociation of the two component proteins and concomitant electron transfer (33, 60). Both component proteins are required for MgATP hydrolysis, and neither component protein alone will reduce substrate.

Based on a substantial amount of kinetic data, a numerical model has been developed to describe the process by which electrons are sequentially delivered to the MoFe protein and then to substrate (60). This model treats the MoFe protein as a dimer of dimers with each  $\alpha\beta$ -dimer operating independently and being serviced by Fe protein. This approach involves two interconnecting processes, which are called the Fe-protein cycle and the MoFe-protein cycle. The Fe-protein cycle describes how the Fe protein's [4Fe–4S] cluster cycles between its reduced 1<sup>+</sup> and its oxidized 2<sup>+</sup> redox states as it delivers an electron to the MoFe protein, coupled with MgATP hydrolysis, and is then reduced by another electron transfer protein, usually either a ferredoxin or a flavodoxin.

The MoFe-protein cycle is necessarily more complex because it involves the progressive reduction of the MoFe protein by up to eight electrons for N<sub>2</sub> binding and reduction, which therefore requires eight turns of the Fe-protein cycle. This model is consistent with N<sub>2</sub> becoming bound to the active site only after three electrons have been accumulated within the MoFe protein. How and where these electrons are stored prior to the binding and reduction of substrate is unknown. However, current biochemical data suggest that intra-MoFe-protein cluster-to-cluster electron transfer occurs (61, 62). In addition, structural data supporting this thesis come from the crystallographic model for the docked complex of two Fe proteins with one MoFe protein (63) (**Fig. 1**). Docking occurs along the Fe protein's twofold symmetric axis, which bisects the single [4Fe–4S] cluster, and the pseudosymmetric  $\alpha\beta$

interface of the MoFe protein. This arrangement places the Fe protein's [4Fe–4S] cluster in close proximity to the P-cluster of the MoFe protein and also situates the P-cluster between the Fe protein's [4Fe–4S] cluster and the FeMo cofactor. This arrangement suggests that electron transfer occurs from the [4Fe–4S] cluster through the P-cluster to the FeMo cofactor, where substrate reduction occurs.

One P-cluster is located at each  $\alpha\beta$ -interface of the MoFe protein. In its as-isolated form, which is believed to represent its fully reduced, all-Fe<sup>2+</sup> state, the [8Fe–7S] P-cluster consists of two [4Fe–4S] sub-clusters that share a single, six-coordinated sulfide (P<sup>N</sup> in **Fig. 2**). Upon oxidation by redox-active dyes, the P-cluster structurally rearranges through movement of two of its eight Fe atoms to P<sup>OX</sup>, both of which also undergo a change in their ligand environment. This redox-dependent structural change of the P-cluster is likely to be mechanistically related to its role in accepting electrons from the Fe-protein and coupling their delivery, along with the required protons, to the FeMo cofactor and substrate (38).

The FeMo cofactor is composed of a [Mo–7Fe–9S] core plus one molecule of (R)-homocitrate (**Fig. 3**). This basic framework consists of two partial clusters, [Mo–3Fe–3S] and [4Fe–3S], bridged by three sulfides. Homocitrate is coordinated to the Mo atom through its 2-hydroxyl and 2-carboxyl groups. Substrate binding and reduction at the FeMo cofactor is supported by several lines of evidence. First, mutant strains, which are unable to biosynthesize FeMo cofactor, are also unable to catalyze nitrogen fixation (64) but, when isolated FeMo cofactor is added to crude extracts prepared from such mutant strains, the ability to fix nitrogen *in vitro* is restored. Second, when citrate replaces homocitrate as the organic constituent of an altered FeMo cofactor, the resulting MoFe-protein exhibits altered catalytic properties (64–66). Third, altered MoFe proteins, which have amino acid substitutions within the FeMo cofactor's polypeptide environment, also exhibit altered catalytic properties (67, 68). Although how substrates interact with FeMo cofactor during turnover is not known, both the presence of six coordinately unsaturated Fe atoms (69–73) and the homocitrate bound to Mo (74) have been suggested to be involved in substrate and inhibitor binding. For example, multiple distinct and possibly overlapping sites have been proposed involving the Fe–S framework (75). In contrast, the carboxylate group, which is coordinated to the Mo atom, has been suggested to serve as a leaving group in a mechanism that activates Mo to provide a substrate coordination site (76).

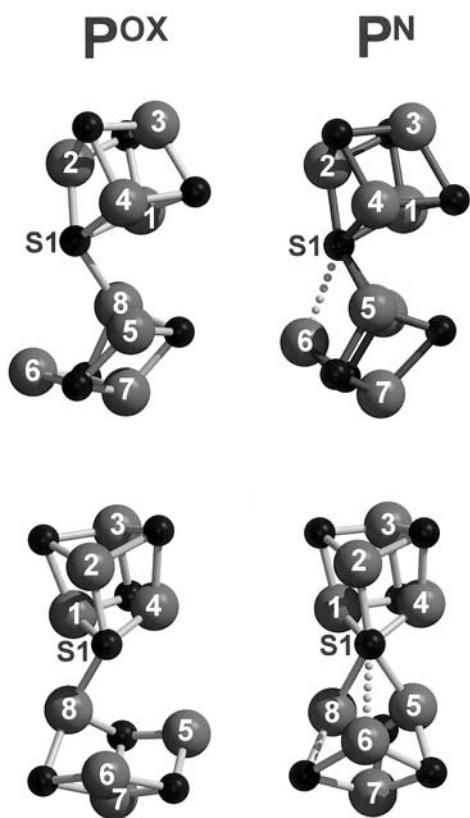

**Figure 1** Ribbon diagram of the three-dimensional structure of the *A. vinelandii* Mo-nitrogenase complex, which is stabilized by using ADP-A1F<sub>4</sub><sup>-</sup> as an ATP analog. The complex consists of two molecules of the Fe-protein (lightest shading), one at each end of one molecule of the MoFe-protein  $\alpha_2\beta_2$  tetramer. The twofold symmetry axis of the Fe-protein aligns with the pseudo-twofold symmetry axis, which bisects the  $\alpha\beta$ -subunit interface of the MoFe-protein. Each half of the MoFe-protein molecule (which may be visualized by drawing a line through the center from the 1 o'clock to the 7 o'clock position) represents an  $\alpha\beta$ -subunit dimer, each encompassing one P-cluster and one FeMo-cofactor. The  $\beta$ -subunits (darkest shading) make all contacts among the two  $\alpha\beta$ -dimers. The  $\alpha$ -subunits (medium shading), which do not contact one another, are located in the lower left and upper right (with the FeMo cofactor clearly visible in both). (Courtesy of Dr. D. C. Rees, California Institute of Technology.)

### E. Role of MgATP in Nitrogenase Catalysis

The overall reduction of N<sub>2</sub> to yield 2NH<sub>3</sub> is thermodynamically favorable, although the formation of two-electron-reduced intermediates, if they exist, is not. It appears, then, that MgATP binding and hydrolysis during nitrogenase catalysis is not a thermodynamic requirement but rather it is used to drive electron transfer toward substrate reduction and to prevent the back flow of electrons to the Fe-protein. This situation may be envisioned as the “gating” of electron flow in which MgATP binding and hydrolysis causes con-

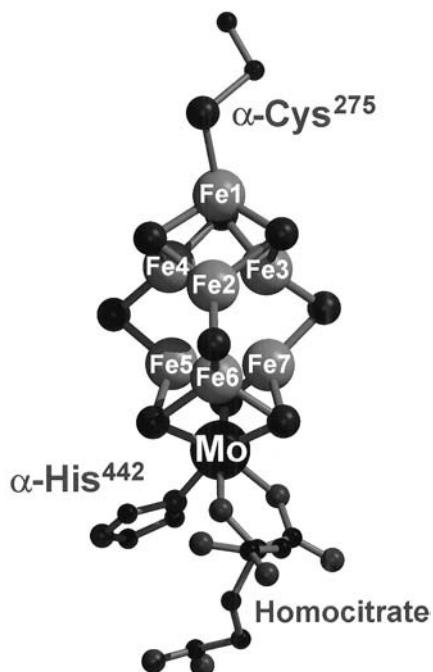

formational changes in both nitrogenase proteins that ensure delivery to and accumulation within the MoFe-protein of multiple electrons prior to their delivery to substrate. In support of this concept, primary amino acid sequence and structural comparisons show that the Fe-protein is a member of a large class of signal transduction proteins that undergo conformational changes upon MgATP binding and hydrolysis.

The following sequence of events, which occur during a single turn of the Fe-protein cycle and which account for the role of MgATP in nitrogenase catalysis, is widely accepted (77). First, the reduced Fe-pro-

**Figure 2** Ball-and-stick structural models of the two forms,  $P^{OX}$  and  $P^N$ , of the P-cluster of the nitrogenase MoFe-protein. Each form is shown in two orientations, which are related by a  $90^\circ$  rotation. The iron atoms are gray and labeled 1–8; and the S atoms are black with the S atom that is labeled as S1 being shared among the two subclusters. The length of the Fe6–S1 bond is longer than the normal Fe–S bond and is shown as a dotted line. (Figure courtesy of Dr. J.W. Peters, Utah State University.)

tein binds two MgATP molecules, which produces a conformational change in the Fe-protein that makes it competent for interaction with the MoFe-protein. Second, the two proteins form a complex, which induces changes in the midpoint potentials of the metal–sulfur clusters such that electron flow toward FeMo cofactor is energetically favored. In the nitrogenase complex, the redox potential of the Fe-protein’s [4Fe–4S] cluster is  $-620$  mV, that of the P-cluster is  $-390$  mV, and the redox potential of the FeMo cofactor is  $-40$  mV (78). Third, in addition to electron transfer, the docking of the component proteins triggers MgATP hydrolysis, although it is not clear whether this occurs shortly before, concomitantly with, or shortly after electron transfer or whether the timing varies depending on other factors. It is clear,

**Figure 3** Ball-and-stick structural model of the FeMo cofactor of the nitrogenase MoFe-protein. Its iron atoms are gray and labeled Fe1–Fe7; the Mo atom is large and black; the S atoms are medium-size and black; and all C, N, and O atoms are small and black. Also shown are the directly bonded entities, which are R-homocitrate and the two  $\alpha$ -subunit residues, histidinyl-442 and cysteinyl-275. (Figure courtesy of Dr. J.W. Peters, Utah State University.)

however, that phosphate release (which is usually when energy transduction occurs) from the complex follows electron transfer and that phosphate release does not drive the dissociation of this complex into its component proteins (79). Fourth, the conversion of the Fe-protein from the MgATP-bound state to the MgADP-bound state causes complex dissociation and this process is the rate-limiting step in nitrogenase catalysis (60). This complex intercommunication between the two proteins results in the accumulation of electrons within the MoFe-protein, and the whole process appears to be synchronized by sequential conformational changes induced by MgATP binding, component protein interaction, and MgATP hydrolysis.

#### F. Electron Transport to Nitrogenase

A source of reducing equivalents of sufficiently low potential is required for regeneration of reduced Fe-protein after it has donated one electron to the MoFe-protein. Both flavodoxins and ferredoxins are

capable of serving this function *in vitro*. The ultimate donor of low-potential electrons has not been identified for most nitrogenases. In some bacteria, *e.g.*, *A. vinelandii*, redundancy is apparent with several flavodoxins and ferredoxins capable of supporting nitrogenase turnover. However, for *K. pneumoniae*, two genes, *nifF* and *nifJ*, are involved in coupling the reduction of Fe-protein to intermediary metabolism (80, 81). The *nifF* gene product is a flavodoxin that can donate an electron to the oxidized Fe-protein. In this process, the reduced hydroquinone form of its flavin is oxidized to a semiquinone form. The re-reduction of flavodoxin is accomplished through the catalytic activity of the *nifJ* gene product, which is a pyruvate-flavodoxin oxidoreductase. It couples the oxidation of pyruvate, yielding acetyl-CoA and CO<sub>2</sub>, to the reduction of the semiquinone form of the flavin to its hydroquinone form. The *nifJ* gene has not been found in other nitrogen-fixing genera, so other means of providing reducing equivalents to nitrogenase must be operating.

#### IV. *nif* GENES

In addition to the products of the *nif* genes discussed above, other genes and their products are required for the maturation of the nitrogenase component proteins and for the regulation of the expression of the nitrogenase genes. The organism that appears to have the simplest organization of nitrogen fixation-specific (*nif*) genes, and which is the one best studied at the molecular genetic level, is the facultative anaerobe, *Klebsiella pneumoniae*. This organism has 20 *nif* genes organized into seven transcriptional units. The specific designations for individual *K. pneumoniae nif* genes are also used to denote genes whose products have homologous functions in other organisms. For example, the *nif* structural genes from all diazotrophs are designated *nifH*, *nifD*, and *nifK* and they encode the Fe-protein and the MoFe-protein  $\alpha$ - and  $\beta$ -subunits, respectively. Complications occur, however, in the genetic nomenclature of *nif* genes in that some organisms do not have homologues of all *K. pneumoniae nif* genes and others have nitrogen fixation-related genes that are not present in *K. pneumoniae*. A general convention is that the *nif* designation is reserved for only those genes that have functional counterparts in *K. pneumoniae*, whereas nitrogen fixation-related genes present in other organisms without functional counterparts in *K. pneumoniae* are given other designations. For example, the "fix" designation is used for such genes occurring in the rhizobia. A number of nitrogen fixation

genes associated with both of the genetically distinct, Mo-independent "alternative" enzymes have also been identified, including the structural genes for both the V-nitrogenase (*vnfHDGK*) and the Fe-nitrogenase (*anfHDGK*) (82, 83), two *nifA*-like genes (84), and one *nifEN*-like sequence (85). The functions of the products of these last three genes is described in the next two sections.

#### V. MATURATION OF NITROGENASE

The primary translation products of the nitrogenase structural genes are not active. Many other *nif*-specific genes are required to activate these immature structural components. The function of the products of these *nif*-specific maturation genes is to catalyze the formation and then insertion of the individual metalloclusters into apo-forms of the Fe-protein and MoFe-protein. In the case of the Fe-protein, only the *nifM* gene product is specifically required for its maturation (86). The *nifM* gene product has not yet been isolated in an active form, but it appears to be a member of a family of peptidyl-prolyl isomerases (87), which assist protein folding by catalyzing the *cis/trans* isomerization of certain peptidyl-prolyl bonds. It is not obvious why such a requirement exists for the maturation of the Fe-protein, but it could be involved with the formation of a transient state of the immature Fe-protein necessary for insertion of the [4Fe-4S] cluster.

Maturation of the MoFe-protein, particularly the formation and insertion of the FeMo cofactor into an immature form of the MoFe-protein, is much more complicated. This process involves the products of, at least, the *nifH*, *nifE*, *nifN*, *nifB*, *nifV*, and *nifQ* genes. The nitrogenase Fe-protein, whose subunits are the product of *nifH*, is required for both formation and insertion of the FeMo cofactor (88, 89). The Fe-protein's specific function in these processes is unknown but neither its MgATP-binding and -hydrolysis properties nor its electron transfer capability are involved (90, 91). Biochemical complementation experiments show that the FeMo cofactor is initially synthesized elsewhere and then inserted into a FeMo cofactor-deficient MoFe-protein that contains intact P-clusters (92).

A portion of the biosynthetic process occurs within a complex of the products of the *nifEN* genes. The *nifEN* gene products bear primary sequence similarity to the products of the *nifDK* structural genes (93) and a heterotetrameric complex of the *nifEN* products likely

serves as a molecular scaffold for FeMo cofactor assembly (93, 94). In *A. vinelandii*, a second *nifEN*-like set of genes, which are called *vnfEN*, have been detected and they appear to have a common function in both the *vnf* and *anf* systems. The *vnfEN* gene products probably work similarly for both the FeV cofactor and the putative Anf cofactor (FeFe cofactor) (85). The product of the *nifB* gene catalyzes the formation of a FeMo cofactor precursor called NifB cofactor (95). NifB cofactor appears to provide the basic Fe–S framework necessary for FeMo cofactor construction and becomes accommodated within the NifEN complex (96).

The *nifV* gene product catalyzes the condensation of acetyl-CoA and  $\alpha$ -ketoglutarate to form homocitrate, the organic constituent of FeMo cofactor (97, 98). The *nifQ* gene product has a role in providing the Mo atom for the FeMo cofactor, especially under Mo-deficient conditions, but its exact role is unknown (99). The products of the *nifX*, *nifW*, and *nifZ* genes might also have some role in FeMo cofactor biosynthesis (100, 101). With *K. pneumoniae*, a low-molecular-weight protein, encoded by *nifY*, appears to be associated with the apo-MoFe-protein produced in strains lacking either *nifB* or *nifEN* activity. The *nifY* gene product may stabilize an apo-MoFe-protein conformation that is amenable to FeMo cofactor insertion (102, 103). A different low-molecular-weight protein, which is called gamma and is not encoded by *nifY*, appears to serve the same function in *A. vinelandii* (104).

Two other *nif* gene products, those of *nifS* and *nifU*, catalyze reactions that are involved in the general mobilization of Fe and S for metallocluster assembly (98, 105, 106). The *nifS* gene product is a cysteine desulfurase that activates S for Fe–S cluster formation. The *nifU* gene product might have a role in providing Fe. Homologs to *nifU* and *nifS*, whose expression is not under *nif*-specific control, are present in many organisms and these may function in general Fe–S cluster formation and repair (107).

When the alternative nitrogenases are considered, the situation becomes complicated because the products of the *nifMBVUS* genes are essential for functional activity of the V-nitrogenase and Fe-nitrogenase as well as the Mo-nitrogenase (59, 108, 109). The *nifM* requirement indicates that all three Fe-proteins are so similar that a single NifM-protein can process them all. Because the *nifBV* gene products are involved with the biosynthesis of the FeMo cofactor of Mo-nitrogenase, their common requirement suggests similar cofactors in all three systems. Further, the *nifB* requirement supports the suggestion that its function cannot be Mo

specific. The requirement for *nifB*, but not *nifEN*, is surprising because *nifB* and *nifN* are fused in *Clostridium pasteurianum* (110), which expresses a Mo-independent nitrogenase (111). Moreover, the *nifV* requirement shows that homocitrate is a constituent of all three cofactors as are S<sup>2-</sup> and Fe, which would be provided through the requirement for the products of the *nifUS* genes.

## VI. REGULATION OF NITROGENASE EXPRESSION

Because both nitrogenase proteins are denatured by dioxygen and because nitrogenase turnover requires consumption of considerable metabolic energy, it would make no sense to express the *nif* genes when dioxygen is present, when a fixed nitrogen source is available, or when cellular growth is limited by the availability of a carbon source. All three factors regulate *nif* gene expression. Moreover, many free-living nitrogen fixers have alternative nitrogenases and so the expression of the *nif* genes is also controlled by the availability of Mo or V.

*K. pneumoniae* has been most thoroughly studied in terms of the regulation of *nif* gene expression. Two of its 20 *nif*-specific genes are the regulatory genes, *nifL* and *nifA* (112), and they are contained in one of the seven transcriptional units in *K. pneumoniae*. Expression of the *nifLA* genes is controlled by the global nitrogen regulatory elements consisting of the products of the *ntrA*, *ntrB*, and *ntrC* genes. The expression of the other six *nif* transcriptional units is controlled by the products of *nifL*, *nifA*, and *ntrA*. The *ntrA* gene product, which is known as either NtrA or  $\sigma^{54}$ , is an alternative sigma factor that controls the expression of not only the *nif* and *ntr* genes but also that of a wide variety of gene families (113). The presence of NtrA imparts a specificity to RNA polymerase and allows it to recognize a consensus promoter sequence, CTGG-N<sub>8</sub>-TTGCA, which is located –24 to –12 bp before the transcription initiation site. Generally, the normal RNA polymerase, which contains the abundant sigma factor called  $\sigma^{70}$ , recognizes a typical prokaryotic promoter sequence, TTGACA-N<sub>17</sub>-TATACA, at –35 to –10 bp before the transcription initiation site. Expression of *ntrA* does not appear to be tightly controlled, and the omnipresence of NtrA apparently reserves a portion of the RNA polymerase for specialized functions like nitrogen fixation.

The specific regulation of the expression of the *nifLA* genes is controlled by the products NtrB and

NtrC of the global nitrogen regulatory genes, *ntrB* and *ntrC*. NtrB and NtrC form a two-component regulatory system in which NtrB is the phosphatase/kinase sensor protein that controls the phosphorylation state of NtrC in response to the ratio of  $\alpha$ -ketoglutarate to ammonia in the cell (114). When this ratio is high, a condition that signals fixed-nitrogen limitation and high energy charge, NtrC is phosphorylated and, when the ratio is low, NtrC is dephosphorylated. Under the former condition, phosphorylated NtrC initiates a two-tiered regulatory cascade that first leads to activation of the *nifLA* promoter, which then results in activation of the other *nif* promoters. Phosphorylated NtrC recognizes and binds to a consensus DNA sequence that is located upstream from the  $\sigma^{54}$ -RNA polymerase-binding site of *nifLA*. Bound, phosphorylated NtrC catalyzes an ATP-dependent conformational isomerization at the promoter site, which ultimately results in the initiation of transcription of the *nifLA* transcriptional unit (115). Accumulation of the products of the *nifL* and *nifA* genes then specifically controls the other *nif* promoters.

NifA is structurally and functionally similar to NtrC (116, 117). It also binds to an upstream activator sequence, but one with a consensus sequence motif, TGT-N<sub>10</sub>-ACA, that is different from the NtrC-binding site. This sequence is located  $\sim$  100 bp before each *nif* promoter except that for *nifLA* (118). However, unlike NtrC, NifA activity is not controlled by phosphorylation/dephosphorylation; rather, its ability to activate *nif* gene expression is controlled by NifL, which acts as an antiactivator. Although just how NifL complexes with NifA is not known, this complexation occurs when either the dioxygen level or the fixed-nitrogen level is sufficiently high and the *nif* promoters are not activated. NifL is a flavoprotein that senses the redox status of the cell by conformational changes that are controlled by the oxidation state of its FAD moiety (119, 120). In *A. vinelandii*, each of the alternative nitrogenase enzyme systems has its own specific NifA-like protein (either VnfA or AnfA), which acts as a positive regulator of *nif* gene expression (84).

The mechanism by which *K. pneumoniae* controls *nif* gene expression is not universal. Many other strategies are used. Very little is known about the regulation of *nif* gene expression in the Archaea or clostridia, for example, except that it is different from that described above. Other control mechanisms, in addition to transcriptional control, include posttranslational modifications. For example, the reversible modification of the

nitrogenase Fe-protein occurs in *Rhodospirillum rubrum* and *Azospirillum brasiliense*. These organisms regulate nitrogenase activity by ADP-ribosylation of a specific arginine residue on the docking surface of the Fe-protein in response to changes in environmental conditions (121, 122). In strict aerobes, nitrogenase can undergo “conformational protection” to guard against O<sub>2</sub> damage by forming a protein aggregate, which dissociates to resume fixation when the O<sub>2</sub> stress is relieved (123).

Very different examples of the control of the expression of nitrogenase activity involve the formation of specialized structures. In many cyanobacteria, for example *Anabaena* 7120, nitrogen fixation is restricted to specialized cells called heterocysts (124). The formation of heterocysts, as well as nitrogenase expression, is both temporally and spatially controlled through terminal differentiation events involving genomic rearrangements. The root nodule was discussed earlier, but here another specialized case of the control of nitrogenase gene expression occurs. Because the function of the root nodule bacteria (rhizobia) is to produce and export fixed nitrogen to its host plant, it would defeat its purpose to retain a regulatory mechanism that is sensitive to the presence of fixed nitrogen. However, control of *nif* gene expression in response to the cellular dioxygen concentration is still absolutely required. Similar to the two-component NtrB/NtrC system, dioxygen control of *nif* gene expression in rhizobia occurs through another sensor-regulator pair (125). The sensor protein, FixL, is a hemoprotein located within the cell membrane and, like NtrB, it has phosphatase/kinase activities. Under microaerobic conditions, FixL catalyzes the phosphorylation of FixJ, which then activates the expression of *nifA* similarly to NtrC activation in *K. pneumoniae*. Rhizobia do not contain a NifL analog. Therefore, control of *nif* gene expression involves no antiactivator; rather, the activity of rhizobial NifA proteins appears to be directly sensitive to the presence of dioxygen (126).

## VII. SUMMARY AND OUTLOOK

Considerable progress has been made in understanding the mechanism of action of nitrogenase, particularly since 1970. In the early 1960s, only crude, cell-free preparations were available for investigating the nitrogen fixation phenomenon, whereas highly purified, crystalline preparations of the nitrogenase component proteins are now available for study. The x-ray derived structures of both protein components and a docked

complex (35, 63) have clearly defined the structural goals to add to the obvious reactivity goal for effective model building. However, there is still no detailed mechanism that describes biological nitrogen reduction in structural terms, although a very useful numerical model is available (60). Even so, purely chemical systems have been devised that bind N<sub>2</sub> and, in some cases, activate it sufficiently that reduced nitrogen compounds, ammonia, and/or hydrazine are produced on protonation (127–129). These chemical N<sub>2</sub> fixation systems, which work under ambient conditions, may in the future form the basis of a simple, low-temperature and low-pressure system, possibly operated electrochemically and driven by a renewable resource, such as solar, wind, or water power or off-peak electrical power, located near or in irrigation streams. However, they are unlikely to compete directly with commercial nitrogen fertilizer production by the Haber-Bosch process or profoundly impact our understanding of the biological system.

In the near term, exploitation of the benefits of biological nitrogen fixation will depend on an increased use of legumes and other symbiotic systems in agriculture with care to match the most effective rhizobial strains with the appropriate cultivar. If these associations could be manipulated either to start fixation earlier or to continue it longer, substantial yield, nutritional and economic benefits could accrue. Similarly, benefits would accrue if the ability to fix N<sub>2</sub> in the presence of fixed-nitrogen sources were conferred on bacteria. The ongoing discovery of new nonleguminous, associative symbioses indicates new avenues through which N<sub>2</sub> fixation and the delivery of fixed nitrogen to crop plants may be enhanced. Close scrutiny of these systems may yield information on how to engineer new associations, possibly with the principal food crops that at present do not enter into N<sub>2</sub>-fixing symbioses. These associations could have dramatic effects on both fertilizer usage and food production.

Genetic manipulation of N<sub>2</sub> fixation is the ultimate solution for providing fixed nitrogen input to crop plants and for increasing global food supplies. In doing so, decreased reliance on fossil fuel energy inputs to fertilizer production will result. Recent genetic manipulation of the recognition and infection processes could result in both new and enhanced symbiotic associations because many plants appear to already have most genes necessary to produce a nodulelike structure. In addition, the success of transferring the *nif* genes from one bacterial genus to another has opened up the possibility of their transfer to crop plants (130). However, genetic transfer is not enough.

If it were, nature would probably have many N<sub>2</sub>-fixing plants already in place. Protection from dioxygen and a sufficient energy supply are also required. These needs could be satisfied if nitrogenase were relocated to the chloroplasts of leaves where, if properly protected from the O<sub>2</sub> evolved by photosynthesis, it could take advantage of directly available reducing equivalents produced from sunlight. Finally, at no time soon does it appear likely that the many known associations involving animals will be exploited. Therefore, man appears destined to remain dependent on plants for a supply of fixed nitrogen.

## Enzymes in Amylose and Amylopectin Biosynthesis

Bruce P. Wasserman<sup>†</sup> and Ying Yu

Rutgers University, New Brunswick, New Jersey, U.S.A.

### I. INTRODUCTION

Starch is the major storage carbohydrate of higher plants. In wild-type maize, starch consists of 25% amylose and 75% amylopectin. Starch and its chemically modified derivatives are of great importance to the world's food supply and economy. Starch-based products have long been used as sources for sweeteners and numerous other food and industrial ingredients, including pharmaceuticals, fat substitutes, textiles, packaging materials, and adhesives. The increasing agricultural and industrial importance of starch and its derivatives has raised interest in the possibility of producing bioengineered starches with improved functional properties.

Bioengineering of the genes encoding the major starch biosynthetic enzymes has the potential to modify starch yield and starch structure. In theory, gene alteration can be used to modify structural features such as the ratio of amylose to amylopectin, chain length and polymer size, degree of branching, the spacing between branch points, and the subsequent attachment of phosphate or sulfate groups. A detailed understanding of the enzymes that function within the starch biosynthetic pathway in higher plants is therefore vital.

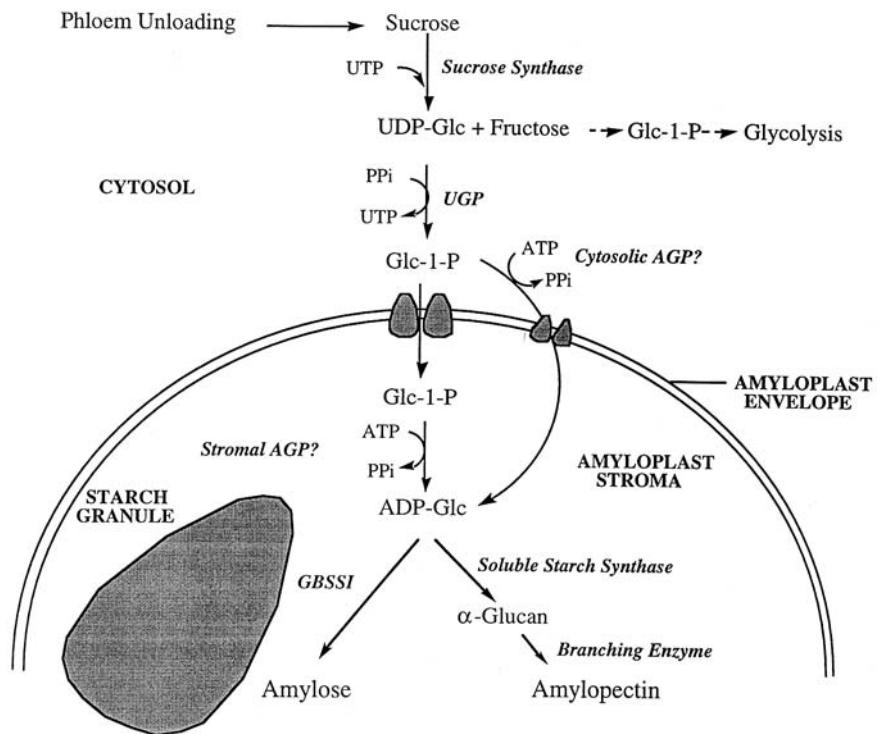

### II. THE STARCH BIOSYNTHETIC PATHWAY

A current view of the starch biosynthetic pathway in maize endosperm is diagrammed in Fig. 1. The immediate precursor of endosperm starch is sucrose. Sucrose is synthesized by photosynthesis in the leaf, and transported through the phloem. By the process of photoassimilate partitioning, sucrose is taken into the sink or storage tissue, which in this case is the endosperm of the kernel. Sucrose is converted into starch by a series of enzymatic steps (Fig. 1). In the cytosol, sucrose synthase and UDP-glucose pyrophosphorylase convert sucrose into Glc-1-P.\*

The final three committed steps of starch biosynthesis consist of substrate formation, chain elongation, and branch point insertion. AGP catalyzes the formation of ADP-Glc from Glc-1-P and ATP. AGP is widely believed to be the major regulatory enzyme of the synthetic pathway (1, 2). One reason for this is that AGP is tetrameric and subject to allosteric regulation. A second reason is that plants carrying mutations in the AGP large or small subunits produce markedly decreased levels of starch (3, 4).

<sup>†</sup>Deceased.

\*Abbreviations: ADP-Glc, adenosine diphosphoglucose; AGP, adenosine diphosphoglucose pyrophosphorylase; ATP, adenosine triphosphate; ae, amylose extender mutant; BT2, brittle-2; GBSS, granule-bound starch synthase; Glc-1-P, glucose-1-phosphate; SBE, starch branching enzyme; SDBE, starch debranching enzyme; SH2, shrunken-2; SS, starch synthase; su-1, *sugary-1* mutant.

**Figure 1** Starch biosynthetic pathway in maize endosperm.

Chain elongation reactions use ADP-Glc as substrate. Starch synthases are glycosyltransferases that elongate oligosaccharide chains by successive addition of (1,4)- $\alpha$ -linked glucose units to the nonreducing end of growing  $\alpha$ -glucan chains. There are at least two classes of starch synthase. The GBSSI, also known as the Waxy protein, is responsible for the synthesis of amylose. The soluble starch synthases are believed to be involved in chain elongation of amylopectins. Starch chain length is thought to be controlled by specific starch synthase isoforms.

The (1,6)- $\alpha$ -linked branch linkages are introduced by isoforms of SBE, which are believed to operate by a cut-and-paste type mechanism (5). SBE is thought to bind to the sites where adjacent starch chains are juxtaposed. The enzyme then cleaves at a (1,4)- $\alpha$ -linkage, and the newly generated reducing end is then attached at another site to form a (1,6)- $\alpha$ -branch point. Spacing between branch points may be controlled by specific SBE isoforms.

### III. STARCH BIOSYNTHETIC ENZYMES AND THEIR ISOFORMS

Many isoforms of AGP, SS, and SBE have been purified, characterized, and cloned from a variety of plants. The occurrence of having multiple isoforms encoded by distinct genes may be significant for several reasons. First, each specific isoform may possess distinct catalytic properties and therefore determine parameters such as chain length or the spacing of branch points. For example, GBSSI is specifically responsible for the synthesis of amylose, and waxy mutant maize which lacks GBSSI is deficient in amylose. In addition, the isoforms of SBEI and SBEII transfer chains of different length. Second, the occurrence of multiple isoforms enables differential expression with regard to both tissue distribution, and plant growth and differentiation. Therefore, the identification and characterization of these isoforms is essential to the use of genetic engineering to improve starch yield and starch quality.

## A. Adenosine Diphosphoglucose Pyrophosphorylase

AGP is a tetrameric protein composed of two large and small subunits known as SH2 and BT2, respectively. In maize, the SH2 and BT2 subunits have molecular masses of 54 and 51 kDa, respectively (Table 1) (3, 6). AGP is the only known tetrameric protein within the starch biosynthetic pathway. Most plant AGPs are subject to allosteric regulation by the activator 3-phosphoglycerate and the inhibitor inorganic phosphate (1). The AGP-catalyzed reaction is widely regarded as the rate-limiting step in the pathway. One body of evidence was obtained by expressing a regulatory variant, containing the *E. coli* AGP gene in tobacco, tomato, and potato. Since the bacterial AGP is relatively insensitive to regulatory inhibition by Pi, each of the transgenic plants exhibited significant increases in starch content (2).

The SH2 and BT2 subunits of AGP have both been purified from a variety of plants (3, 7–11). cDNA (12–16) and genomic (17) clones have been isolated and sequenced, and subunit function has been probed by site-directed mutagenesis (18).

## B. Starch Synthase

Classification of starch synthases has not been straightforward because the literature groups classified the various isoforms according to three different criteria. Particular groupings may be based on solubility considerations, biochemical and catalytic properties, and deduced amino acid sequences derived from cDNA clones.

### 1. Granule-Bound Starch Synthase

Based on solubility, the predominant granule-bound starch synthase is referred to as GBSSI. GBSSI was identified by studies with the *waxy* mutant. This mutant lacks amylose, and is also deficient in a 60-kDa polypeptide known as the Waxy protein. *Waxy* mutants from numerous plant species are deficient in both the Waxy protein and amylose. In *waxy* mutants, the starch is exclusively amylopectin. On this basis, it has become widely accepted that the 60-kDa Waxy protein is the starch synthase responsible for chain elongation in amylose (19). Thus, the terms GBSSI and Waxy protein are now used interchangeably. The Waxy protein is solubilized by gelatinization of starch granules in the presence of a detergent such as SDS (19, 20).

GBSSI was the first maize starch synthase to be cloned (23). Mutations in the *waxy* locus result in low GBSS activities, absence of the Waxy protein, and virtually no amylose in the sink tissue of higher plants (19, 21–23). When potato plants were transformed to produce antisense RNA so that the expression of the *waxy* gene was transcriptionally inhibited, GBSS activity was greatly reduced and the tubers contained amylose-free starch (24).

### 2. Soluble Starch Synthases

The second major starch synthase class, based on solubility, is synthases which are partially soluble and partially granule bound (Table 1). These starch synthases have been grouped according to the order by which activity peaks from soluble extracts elute from ion exchange columns. Several soluble starch synthase iso-

**Table 1** Starch Biosynthetic Isoforms from Maize

Process	Isoforms/subunits	Apparent mass (kDa)	Reference(s)
Substrate formation	AGP large subunit (SH2)	54	(12, 13, 63)
	AGP small subunit (BT2)	51	
Chain elongation	GBSSI	60	(19, 23)
	SSI	76	
	SSII	> 180	
Branch insertion	SBEI	90	(30, 31)
	SBEIIa	89	
	SBEIIb	85	
Processing/trimming	SDBE (SU1)	79	(58,61)

forms have now been partially purified, characterized, and cloned from a diverse range of plants.

Ion exchange chromatography of soluble extracts from whole endosperm revealed the presence of multiple starch synthase isoforms (25–28). In maize, two soluble starch synthase isoforms have been documented. Starch synthase I exhibits maximal activity in the presence of citrate (primer independent). On the other hand, starch synthase isoform II is active in the presence of glycogen (primer dependent). The separation of the two isoforms was also achieved by size exclusion chromatography (28). Following additional purification using MonoQ and hydrophobic interaction chromatography, starch synthase I activity was correlated with a 76-kDa polypeptide (28).

A cDNA clone encoding the 76-kDa starch synthase I was subsequently obtained (29). This cDNA bears homology to a soluble starch synthase cloned from rice (25). Three isoforms of the rice synthase were isolated by anion exchange chromatography, and their N-terminal amino acid sequences were obtained. From this information, the rice cDNA phage clone was isolated using oligonucleotide probes prepared according to direct sequences. The predicted amino acid sequence of the clone contained the KXGG motif which represents the putative ADP-Glc binding domain existing in virtually all starch and glycogen synthases.

The apparent size of SSII is 180 kDa. SSII activity has not been aligned with any specific polypeptide from maize endosperm. However, isolation of a gene encoding a putative polypeptide correlating with SSII activity has been reported (30).

Moreover, two other starch synthase cDNA clones, designated *zSSIIa* and *zSSIIb*, have been isolated from a maize endosperm cDNA library (31). The deduced amino acid sequences of both clones contain the KXGGL consensus sequence. The identity of *zSSIIa* and *zSSIIb* as starch synthases has been confirmed by expression of their activities in *E. coli*. *zSSIIa* was shown to be predominantly expressed in the endosperm, while *zSSIIb* transcripts were mainly detected in the leaf at low abundance.

In potato, a third kind of soluble starch synthase, known as SSIII, has been identified. Its cDNA clone was obtained by using an antibody directed against a domain conserved in starch synthases to screen a tuber-specific expression library. The deduced amino acid sequence showed that it is a novel type of starch synthase. The immature enzyme with its transit peptide has a mass of 139 kDa (32).

### 3. Four Classes of Starch Synthase Genes

Based on the deduced amino acid sequences derived from cDNA clones, starch synthase genes have been divided into four classes (33). The extensively characterized GBSSI genes belong to the first class. The genes of the second class encode soluble starch synthases localized in the endosperms of monocots. Thus far, the cDNA clones of two members from this class have been isolated and characterized. These include a soluble starch synthase from rice (25) and the citrate-stimulated starch synthase I from maize (29). A third group of genes, the SSII class, bears sequence similarity to the primer-dependent SSII from pea (34) and potato (35). In addition to these three classes, starch synthases of the SSIII class, represented by a gene encoding a 139-kDa soluble starch synthase III in potato, are believed to significantly contribute to starch biosynthesis in some species (32, 33). SSIII activity is believed to account for approximately 80% of the soluble starch synthase activity present in potato tuber. The cDNA of potato SSIII exhibits greater similarity to bacterial glycogen synthases than to members of the other three classes.

The deduced amino acid sequences of starch synthase clones share several common structural features. First, they all contain the Lys-X-Gly-Gly-Leu (KXGGL) consensus sequence, which is suggested to be the putative ADP-Glc-binding site. This conserved region was first identified in *E. coli* glycogen synthase (36). The lysine residue binds to the phosphate moiety adjacent to the glycosidic linkage of ADP-Glc (37). Moreover, starch synthase genes encode transit peptides ending with a consensus cleavage site motif. It is believed that starch synthases are synthesized in the cytosol and are targeted to the amyloplast by the transit peptides, which are then proteolytically cleaved upon translocation through the amyloplast envelope into the stroma (38, 39). Finally, several conserved regions between the KXGGL site and the 3' terminus of the coding sequence exist in most of the clones (25).

### C. Starch Branching Enzymes

The functionality and economic value of starches are largely determined by the relative ratio of amylose and amylopectin. Since SBE is the enzyme which introduces  $\alpha$ -1,6-linked branch points into the  $\alpha$ -1,4-linked glucan chains of amylopectin, it plays an essential role in determining starch fine structure. Multiple isoforms of SBE have been identified, purified, and character-

ized from many plants including maize endosperm (40–43), wheat endosperm (44, 45), pea seed (46), and rice endosperm (47, 48).

Different SBE isoforms differ in their specificity for substrate with respect to both chain length and degree of branching. The SBE isoforms and their clones can be categorized into two groups as initially defined by the Commission on Plant Gene Nomenclature (1994) and as later suggested by Burton et al. (49). One family (SBEI or class B) includes maize SBEI, rice SBEI, pea SBEII, and potato SBE. The second family (SBEII or class A) includes maize SBEII, pea SBEI, and rice SBEIII. The establishment of the two groups was based on immunological reactivity, chromatographic and enzyme kinetic properties, and amino acid composition (46–48, 50). In vitro, maize SBEI preferentially transfers longer chains than SBEII (42). Moreover, maize SBEI preferentially adds branch points to amylose, and its activity toward amylopectin is < 10% relative to amylose (41). Conversely, maize SBEII exhibits a sixfold higher preference for amylopectin than SBEI, but lower rates in branching amylose (~ 9–12% of that SBEI) (41).

In maize, cDNA clones for SBEI (51), SBEIIa (52), and SBEIIb (53) have been isolated and their expression patterns characterized (54). Maize SBEI elutes from ion exchange columns in the pass-through fraction, whereas SBEIIa and SBEIIb require salt for eluting from the column (40). SBEIIa and SBEIIb are very similar in their immunological reactivities, enzyme kinetic properties, substrate specificity, and amino acid sequence (1, 41, 42).

For quite some time, there was a controversy as to whether or not SBEIIa and SBEIIb are encoded by a single gene. However, the isolation of SBEIIa cDNA from *ae* mutants lacking SBEIIb has clarified this question (55). Using an *ae* mutant in which SBEIIb was absent, Fisher et al. observed significant SBEIIa enzyme activity and polypeptide levels (53), suggesting that SBEIIa is encoded by an independent gene distinct from the *Sbe2b* locus. The localization of the two mRNA transcripts in maize tissues also differed. *Sbe2b* is expressed in endosperm, developing embryo and tassels (53). *Sbe2b* mRNA levels were 10-fold higher in embryo than in endosperm tissue, and were much lower than *Sbe2b* in both tissues (55).

In hexaploid wheat, the situation is more complex. Wheat is believed to contain similar classes of SBE as those found in maize and rice. Moreover, each of the three genomes of wheat may contain a unique set of SBE isoforms. The isoforms contained within each unique set are referred to as allozymes (44).

Immunological evidence and substrate specificity studies indicated that wheat BEIA and BEIB are related to the SBEI class of maize and rice, while wheat BEII (45) is related to SBEII class (44).

## D. Starch Debranching Enzyme

An additional putative enzyme of the starch biosynthetic pathway, SDBE, has attracted great recent interest. Ball and others have proposed an additional set of steps in the biosynthesis of amylopectin consisting of formation of a “preamylopectin” and its subsequent trimming to a “mature amylopectin” (56). SDBE is believed by some researchers to be involved in converting preamylopectin into mature amylopectin. These researchers propose that SBE and SDBE work in a concerted fashion to determine the fine structure of amylopectin (57).

Two classes of SDBE have been studied in plant systems, termed pullulanases and isoamylases. Both types can directly hydrolyze  $\alpha$ -(1,6)-branch point linkages. Each class differs in its specificity toward distinct substrates. Pullulanases, also referred as R-enzyme, hydrolyze pullulan at a much higher rate than amylopectin, and do not act on glycogen. In contrast, isoamylases act on both amylopectin and glycogen, but do not hydrolyze pullulan or, if so, at a very low rate. Pullulanases have been characterized in maize (58), rice (59), and many other plants. Isoamylases, however, have only been reported and studied in potato tuber (60) and maize endosperm (58, 61).

In maize endosperm, the identification and characterization of SDBE, an isoamylase, was achieved using a *su1* mutant which carries mutations on the SDBE gene (61). In maize kernels, these mutations lead to increased sucrose levels, reduced amylopectin, and accumulation of the highly branched glucopolysaccharide phytoglycogen (62). The correlation between the *su* mutation and the deficiency of SDBE was first reported by Pan and Nelson (58). This study showed that SDBE activities from wild-type maize endosperm could be separated into three peaks on a hydroxyapatite chromatography column. Their key observation was that the *su1* endosperm lacked one of the three activities while the other two were greatly reduced. They also observed that SDBE activity was proportional to the number of copies of the *Su* allele, suggesting that the *Su* allele was the structural gene for SDBE. This publication classified SDBE as an R-enzyme or pullulanase, and assumed that the biochemical lesion in the *su1* mutant of maize was induced by mutations at the structural gene for the R-enzyme. Recently,

James et al. isolated part of the *su1* gene locus and a cDNA copy of the *su1* transcript using transposon tagging (61). Five new *su1* mutations were isolated. The cDNA sequence specified a polypeptide of at least 742 amino acids bearing high similarity to bacterial isoamylase. This emerging area is further discussed in a recent review paper (57).

#### IV. CONCLUSION

A complete understanding of amylose and amylopectin synthesis in higher plants requires full knowledge of individual enzymes catalyzing substrate formation, chain elongation, and branch point insertion. The heightened research efforts have been focused on basic biochemistry and molecular biology along the following lines:

1. Enzyme purification, characterization and polypeptide identification.
2. Isolation and characterization of cDNA and genomic clones.
3. Expression of starch biosynthetic enzymes in bacteria and transgenic plants.

These efforts will eventually lead to a complete elucidation of the molecular mechanisms underlying starch biosynthesis and thus enable the bioengineering of starch biosynthetic process in cereal plants.

#### DEDICATION

This chapter is dedicated to the memory of my mentor, Bruce P. Wasserman, who passed away on August 26, 1998.

#### ACKNOWLEDGMENTS

Funding for this research was provided by the U.S. Department of Agriculture National Research Initiative (95-02531 and 98-01235), and by the New Jersey Agricultural Experiment Station.

### I. INTRODUCTION

Vegetable oil is an economically important agricultural product with an annual production of some 90 million metric tons. It is used both as food and in a wide range of industrial applications. By using both traditional plant breeding methods and genetic engineering techniques, vegetable oils can today be modified for particular end uses. The production of so-called designer oils to suit requirements is an ever-increasing prospect, and hence it is anticipated that the world output of such commodities will increase accordingly (1).

The end use and hence value of an oil are largely dependent on the fatty acid quality and content. The wide range of fatty acids and their relative concentrations, found in oils from many plant species, have made them particularly suited for food production (e.g., confections, ice cream, mayonnaise, margarines, animal foodstuffs, etc.), cooking oils, nutraceuticals, and pharmaceuticals. Besides being used for human consumption they have many applications in the chemical industries and particularly for the manufacture of detergents and surfactants, polymers, coatings, and specialized lubricants. In the kingdom Plantae perhaps well over 800 different fatty acids have been identified (2). Many of these are uncommon and are found in only a few species. However, this enormous genetic resource is of immense commercial value as it becomes feasible to transfer the capacity to synthesize unusual

and desirable fatty acids to oil-crop species such as oil-seed rape, sunflower, and soy. The scientific base for the production of genetically modified oil-seeds is well established (3) and it is therefore anticipated that an ever-increasing level of oil and oil products from such sources will enter the human diet. Here we describe, therefore, the current understanding of fatty acid biosynthesis in plants, oil assembly, and the role of fatty acid oxidation in flavor generation. Where appropriate the biotechnological applications of such knowledge will be discussed.

### II. FATTY ACIDS AND COMPLEX LIPIDS

Most fatty acids are monocarboxylic and consist of an unbranched chain containing an even number of carbon atoms (Table 1). The homologous series of saturated fatty acids is represented by the general structure  $\text{CH}_3(\text{CH}_2)_n\text{COOH}$  with the carboxy carbon designated carbon 1. The number of carbon atoms in the fatty acid can vary considerably from medium chain (C8–C10) to long and very long chain (C12 and up) although it is the long-chain ones that tend to predominate. The methyl and carboxy termini of the molecule are termed the omega ( $\omega$ ) and delta ( $\Delta$ ) ends, respectively. These fatty acids can be saturated or unsaturated and in some cases may have additional functional groups. A notable characteristic of plants

**Table 1** Fatty Acid Structures

Essential fatty acids are polyunsaturated fatty acids of the omega-6 (n-6) and omega-3 (n-3) families that are essential for life and good health, and are not produced in man and must be obtained from plants as part of the diet.

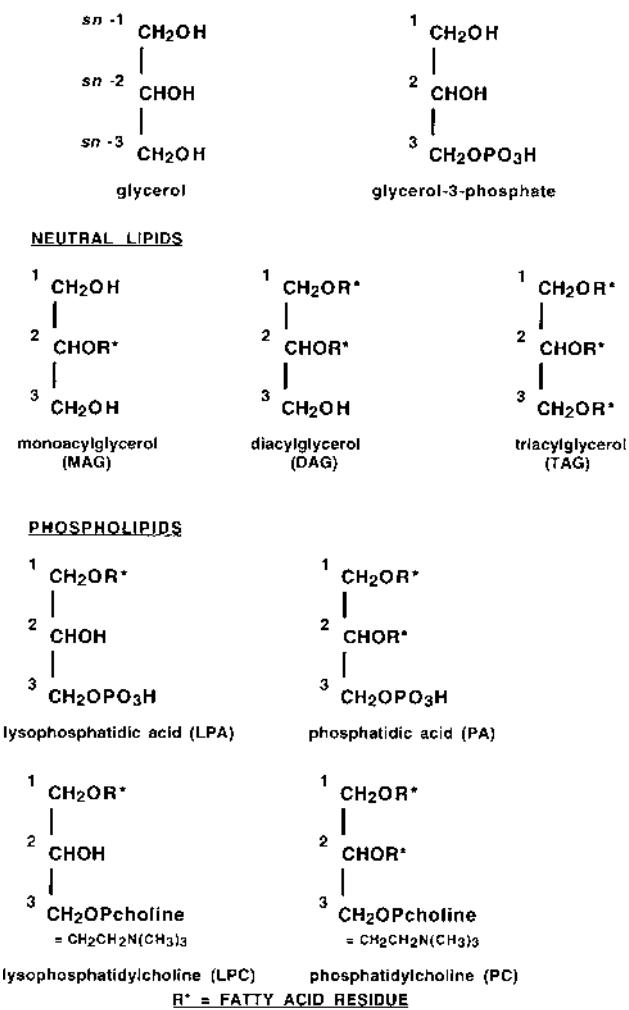

is the high incidence of unsaturated and polyunsaturated fatty acids and particularly those of 18 carbon atoms.

Unsaturation generally describes a four-electron (double bond/olefinic) linkage between carbon atoms. Polyunsaturated fatty acids (the so-called PUFAs) are polyenoic acids having more than one olefinic center, the double bonds generally of a *cis* configuration and methylene interrupted. By convention PUFAs are described as being *n*3 or *n*6 fatty acids depending on whether the first double bond is three or six carbon atoms from the methyl end (omega carbon), respectively. Further double bonds are separated from each other by a methylene group. Such fatty acids are also termed omega-3 and omega-6 acids. The omega-3 series are derived from  $\alpha$ -linolenic acid (C18:3 *n*3) by chain elongation and further desaturation and include eicosapentaenoic acid (EPA; C20:5 *n*3) and docosahexaenoic acid (DHA); C22:6 *n*3). On the other hand, the omega-6 acids are derived from linoleic acid (C18:2 *n*6) and include  $\gamma$ -linolenic acid (GLA; C18:3 *n*6) and arachidonic acid (AA; C20:4 *n*6). Linoleic acid and linolenic acid are substances which cannot be synthesized de novo in the human body and so, like vitamins, must be provided in the diet from

plant sources for the synthesis of the other *n*6 and *n*3 metabolites. Hence, these are the so-called essential fatty acids (EFAs) and are required for the normal structure of all membranes, for cholesterol transport, for the maintenance of normal permeability barriers and as precursors of eicosanoids (prostaglandins, thromboxanes, leukotrienes).

A further unsaturated fatty acid terminology, of particular value to biochemists, defines the position of the double bonds from carbon atom 1 (i.e., the  $\Delta$  end of the molecule). The delta system is convenient for denoting all double bonds, their position in the carbon chain, and the specific desaturase enzymes which catalyze their introduction into the molecule. Hence, linoleic acid and  $\alpha$ -linolenic acid become C18:2 $^{\Delta}9,12$  and C18:3 $^{\Delta}9,12,15$ , respectively. Fatty acid structures and trivial and systemic nomenclatures are given in Table 1. Desaturases, which abstract hydrogen atoms from adjacent CH<sub>2</sub> groups to produce double bonds, can be specifically defined. For example, a  $\Delta$ 12 desaturase or a  $\Delta$ 5 desaturase would introduce double bonds at the  $\Delta$ 12 and  $\Delta$ 5 carbon atom in the acyl chain, respectively.

Triacylglycerols, the major constituents of the oil, consist of a glycerol backbone to which a fatty acid

**Figure 1** Glycerolipid structures.

acyl group is esterified to each of the three hydroxy groups. Each carbon atom in the glycerol molecule is defined by the stereoscopic numbering system and *sn*1, *sn*2, and *sn*3 describes each carbon, respectively (Fig. 1). The glycerol carbons of the phospholipids (membrane polar lipids), important in understanding triacylglycerol biosynthesis, are similarly defined (Fig. 1). The quality of the oil, and hence its end use, is determined by the fatty acids esterified to each of the glycerol carbon atoms. Most commercial annual oil crops have seed oils largely composed of the five major fatty acids, palmitic (C16:0), stearic (C18:0), oleic (C18:1<sup>Δ9</sup>), linoleic (C18:2<sup>Δ9,12</sup>) and α-linolenic (C18:3<sup>Δ9,12,15</sup>) acids. These are the “housekeeping” fatty acids, so called because they are also found in the membrane lipids of all plants cells. The fatty acid

composition of membrane lipid in leaves and roots, however, is under strict control and differs little among plant species whereas the relative abundance of a fatty acid in the storage triacylglycerol can show distinct variations among different oil crop species.

### III. FATTY ACID BIOSYNTHESIS

#### A. Carbon Source

Acetyl-CoA is regarded as the direct carbon source for fatty acid synthesis and can be generated by the pyruvate dehydrogenase (PDC) complex. Despite the fundamentally crucial requirements for acetyl-CoA, its biogenesis in plants is poorly understood. Both chloroplast (cPDC) and mitochondrial (mPDC) forms (4, 5) have been characterized. There has been speculation about the supply of pyruvate for acetyl-CoA formation from cPDC and whether there is sufficient activity of the glycolytic enzymes to provide pyruvate within this organelle. In mustard, for example, there appears to be a sufficient supply of pyruvate to satisfy this requirement, although in other tissues important cytosolic pyruvate may be required to support fatty acid biosynthesis (6). Studies with plastids from heterotrophic tissues indicate that the metabolites utilized for fatty acid synthesis include glucose, fructose, glucose-6-phosphate, triose phosphate, malate, pyruvate, and acetate (7). Of these only acetate has been shown to be freely permeable to the selective barrier of the plastid envelope. There is considerable variation in the efficiency with which these substrates are utilized by plastids, and the basis for this may be determined by the presence of highly selective transporter proteins on the plastid envelope.

It has recently been shown that during oil deposition in oil seed rape, fatty acid synthesis is initially supported by glucose-6-phosphate and then by pyruvate through the corresponding activities of the transporters for these metabolites (7, 8). In isolated leucoplasts from developing castor seed endosperm, however, the rate of malate-dependent fatty acid synthesis was threefold higher than that from pyruvate and evidence was presented for a malate/Pi translocator (9). Whether the expression of selective transporters on the plastid envelope determines the ability of these organelles to accumulate oils or starch requires further research. In this regard it is interesting to note the isolation of a novel *Arabidopsis* mutant producing wrinkled, incompletely filled seeds with an 80% reduction in triacylglycerols. Wild-type and homozygous *wrl* mutant plantlets or mature plants were indistin-

guishable. However, developing homozygous *wri1* seeds were impaired in the incorporation of sucrose and glucose into triacylglycerols but incorporated pyruvate and acetate at an increased rate (10). Because the activities of several glycolytic enzymes, in particular the hexokinase and pyrophosphate-dependent phosphofructokinase, are reduced in developing homozygous *wri1* seeds, it was suggested that *wri1* is involved in the developmental regulation of carbohydrate metabolism during seed filling.

### B. Acetyl-CoA Carboxylase

Acetyl-CoA carboxylase (ACCase) catalyzes the formation of malonyl-CoA from acetyl-CoA and bicarbonate. Plants have two types of acetyl-CoA carboxylases; one is the multisubunit complex located in plastids, and the other a large multifunctional polypeptide localized in the cytosol (11). The plastidic form consists of four subunits, and in *Arabidopsis* these are encoded by three single copy nuclear genes (*cac1*, *cac2*, and *cac3*) and one plastidic gene (*accD*) (12, 13). The cytosolic ACCase generates malonyl-CoA for the biosynthesis of a variety of secondary metabolites and for the elongation of fatty acids. The enzyme is a dimer of a 260-kDa subunit and in *Arabidopsis* is encoded by two genes (*acc1* and *acc2*) which are in a tandem array within a 25-kb segment of the genome. In photosynthetic tissue the chloroplast ACCase is modulated by light/dark. Plants have a light-signal transduction pathway in chloroplasts which operates when electrons from photosystem 1 are shuttled through the electron transport chain to thioredoxins via ferredoxin and then by reducing the disulfide bonds of target enzymes (14). Enzyme activities of the reductive pentose phosphate pathway cycle in chloroplasts are regulated via this redox cascade. Recent results suggested that a redox cascade may be responsible for coordination of fatty acid synthesis with photosynthesis (14).

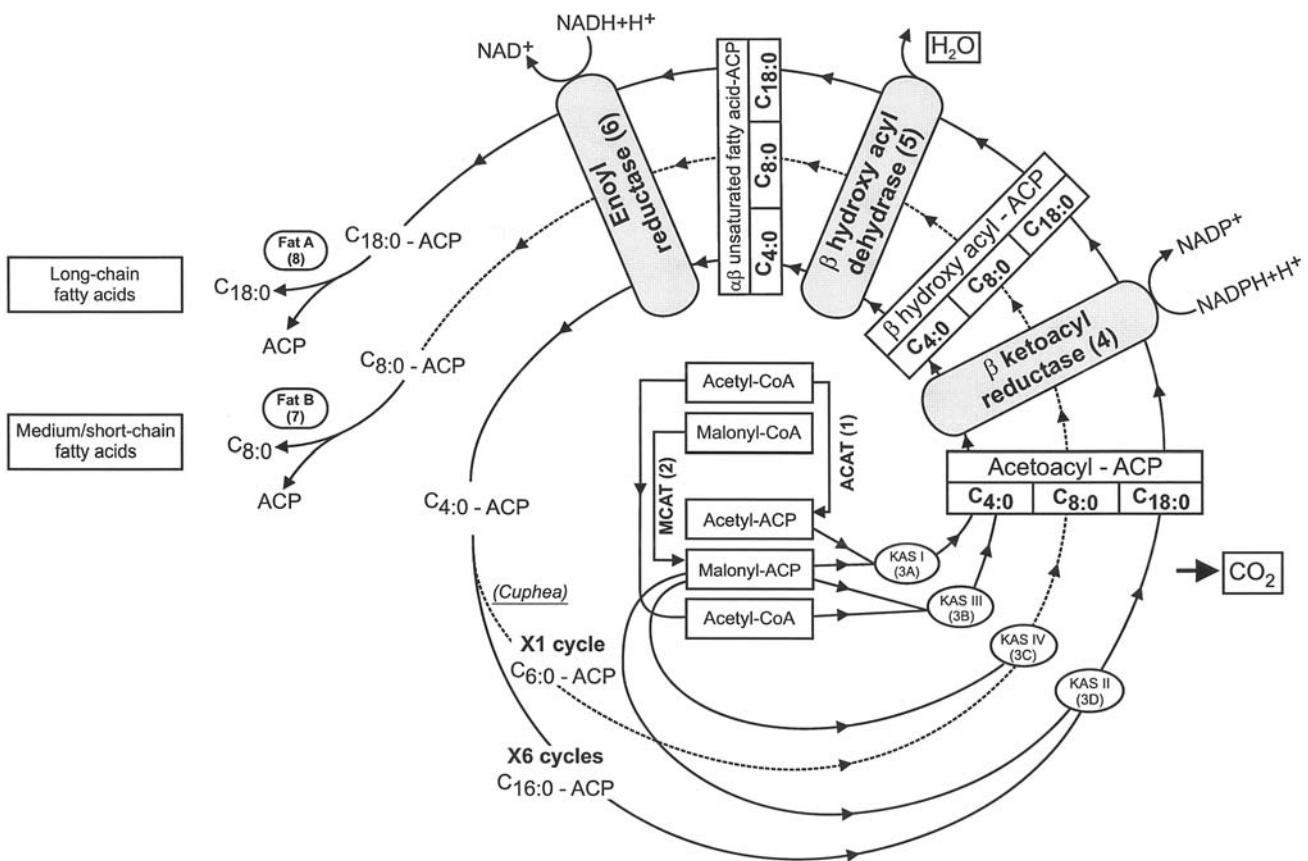

In mammals the ACCase consists of a single polypeptide chain containing three functional domains, while in *E. coli* the enzyme consists of four separable proteins: biotin carboxyl carrier protein (BCCP), biotin carboxylase (BC), and carboxyl transferase (CT<sub>a</sub> and CT<sub>b</sub>). Initial attempts to purify the plant ACCase generated widely differing apparent molecular weights (15, 16). These discrepancies were originally interpreted as being due to differential rates of proteolysis in different tissue extracts, and it was therefore considered that the plant acetyl-CoA carboxylase, like that from mammals, was a multifunctional protein.

It has now been established, however, that there are two forms of ACCase in plants (11, 17). In dicotyledonous species there is a low-molecular-weight (LMW) form present in the plastid and high-molecular-weight (HMW) one in the cytosol whereas in the Graminaceae the LMW form has not been detected and HMW forms are present in both the plastid and cytosol. This provides an explanation for the differential action of the monocotyledon-specific acyloxyphenoxy-prionate and cyclohexenediose group of herbicides, whose main target is the HMW ACCase in the plastid. It is currently believed that the HMW ACCase in the plastid is responsible for de novo fatty acid biosynthesis which is herbicide sensitive and a further HMW ACCase in the cytoplasm responsible for fatty acid elongation (see later) which is insensitive (11). Despite the molecular characterization of ACCases, little progress has been made on the metabolic regulation of the enzyme in plants. Unlike the mammalian enzyme where regulation by phosphorylation and intermediates of the tricarboxylic acid cycle, particularly citrate, have been shown to be involved, no evidence exists for such regulatory mechanisms in plants.

### C. Fatty Acid Synthase

The molecular organization of the plant fatty acid synthase is composed of dissociable enzyme activities, similar to *E. coli* and termed type II FAS, has been recognized since the early 1980s (Fig. 2). The initial reactions of FAS are catalyzed by transacylases which transfer the acetyl and malonyl units from their CoA esters to the corresponding ACP derivatives (18). The initial condensation reaction in plant fatty acid biosynthesis takes place between acetyl (C2) ACP and malonyl (C3) ACP, resulting in the formation of acetoacetyl (C4) ACP and carbon dioxide. This reaction is catalyzed by ketoacyl ACP synthase (KAS). In the next step the acetoacetyl-ACP is reduced to hydroxybutyryl-ACP by  $\beta$ -ketoacyl-ACP reductase using NAD(P)H. The hydroxybutyryl-ACP is then dehydrated by hydroxyacyl-ACP dehydratase, and the crotonyl-ACP form is converted to butyryl-ACP by enoyl-ACP reductase using NAD(P)H. This completes the first round of fatty acid synthesis.

In the next round the butyryl (C4) ACP is condensed with malonyl (C3) ACP resulting in the formation of C6 ACP and carbon dioxide which then undergoes a further two reductions and dehydration step as described earlier to complete the second cycle. Subsequent additions of C2 units from malonyl-ACP results in the formation of long-chain fatty acids of

**Figure 2** The fatty acid synthetase complex. Acetyl-CoA:ACP transacylase (ACAT; reaction 1) and malonyl-CoA:ACP transacylase (MCAT; reaction 2) convert acetyl-CoA and malonyl-CoA to ACP derivatives, respectively. Condensation of these products by  $\beta$ -ketoacyl ACP synthase (KAS I; cerulenin sensitive; reaction 3A) results in the formation of acetoacetyl-ACP (C4 on the figure) and the generation of  $\text{CO}_2$ . Acetyl-CoA can also be condensed directly with malonyl-ACP in a KAS III mediated reaction (cerulenin insensitive; reaction 3B). Acetoacetyl ACPS are reduced by  $\beta$ -ketoacyl reductase (reaction 4) to yield the  $\beta$ -hydroxyacyl-ACP derivatives, which undergo dehydration, catalyzed by a  $\beta$ -hydroxyacyl-ACP dehydratase (reaction 5). The generated  $\alpha$ , $\beta$ -unsaturated fatty acid-ACPs are further reduced by an NADH-specific enoyl reductase (reaction 6), resulting in the formation of the acyl-ACP product. In subsequent rounds of condensation, malonyl-ACP is used as the primer which again is followed by reduction (reaction 4), dehydration (reaction 5), and further reduction (reaction 6). In species accumulating short- to medium-chain fatty acids (e.g., *Cuphea*), a short chain-specific condensing enzyme has been identified (KAS IV; reaction 3C). In species not accumulating short-chain fatty acids, KAS I (and/or KAS III up to C6) supports these condensation reactions. A further three and four rounds of the cycle result in the formation of C8:0 and C10:0 chain length products, respectively. In species accumulating short-chain fatty acids, these products are hydrolyzed from the ACP by the action of a specific thioesterase (reaction 7; only C8 illustrated), resulting in the formation of unesterified fatty acids which are subsequently utilized for storage lipid formation. All species synthesize C16 and C18 chain length fatty acids both for membrane lipid and oil synthesis. C16:0 is elongated to C18:0 by a specific  $\beta$ -ketoacyl-ACP synthetase (KAS II; reaction 3D). These fatty acids are released from the ACP by thioesterase activity to yield unesterified fatty acid for use in oil assembly.

which palmitate (C16:0) and stearate (C18:0) are the principal end products. The enzyme responsible for the formation of stearate from palmitate has been shown to be an isoform of the KAS I and has been designated KAS II based on reconstitution experiments and on selective inhibitor studies using arsenite and cerulenin (19).

The transfer of acetyl groups from the CoA track to the ACP track, catalyzed by the acetyl:ACP transacylase, was considered to be the possible rate-limiting step in fatty acid synthesis (18). However, in the late 1980s studies with *E. coli* indicated the presence of a short-chain condensing enzyme whose activity was not blocked by cerulenin, and short-chain ACPS accumulated. A similar activity was subsequently reported in plants and it appeared that conversion of acetyl-CoA to acetyl-ACP could be bypassed and the acetyl-CoA and malonyl-ACP condensed directly (20). This activity has been referred to as KAS III. This has subsequently brought into question the earlier suggestion that the transacylase played a regulatory role and was the rate-limiting step in fatty acid biosynthesis. There are, however, indications that acetyl ACP:CoA transacylase is a partial activity of KAS III, but this awaits confirmation by characterization of the purified enzyme. Metabolic plasticity has been observed in many pathways, and the role of the KAS III and/or transacylase may yet be another example of this phenomenon.

Malonyl-CoA:ACP transacylases (MCAT) have been purified from a number of plant species. The enzymes usually have molecular weights determined from standard curves (MW) or by mass spectrometry (molecular mass)  $\sim 40$  kDa, and tissue-specific isoforms have been reported (15). The gene has recently been cloned from *Brassica napus* using a complementation approach (21); the protein showed a 47% homology to the *E. coli* MCAT amino acid sequence in the coding region for the mature protein. The  $\beta$ -hydroxyacyl dehydratase has also been purified and partially characterized from a number of sources (see 11) and, although the plant enzyme has received little further molecular characterization, the bacterial dehydratase has recently been cloned (22).

The enzymes for the two reductive steps required in each round of fatty acid biosynthesis have been purified and shown to have a preference for the ACP-linked esters over the corresponding CoA derivatives (16). The first reductive step is catalyzed by  $\beta$ -ketoacyl ACP reductase, an NADPH-dependent reaction that produces hydroxyacyl-ACP. Hydroxyacyl-ACP is dehydrated by a dehydratase and then further reduced

by enoylacyl-ACP reductase (ENR) to form acyl-ACP, which in developing oilseed rape, is an NADH-dependent enzyme. The *Brassica napus* ENR is tetrameric (23) and has been cloned and overexpressed in *E. coli* (24) and crystallized (25). Interestingly, the ENR is the target for antibacterial diazaborines and the front-line antituberculosis drug isoniazid. Recent structural studies have revealed the chemical basis for its molecular binding of drugs which, based on its similarity to other oxidoreductases, may have generic applications in other areas of medicinal chemistry (26).

## D. Chain Termination

The principal-product of fatty acid biosynthesis in most plant tissues is palmitoyl-CoA, which can then be elongated by a specific  $\beta$ -ketoacyl-ACP synthase type II (KAS II) to generate stearoyl-ACP. However, since storage lipid accumulation is not under the same functional constraints imposed on membrane lipids, several plant families have evolved mechanisms for terminating fatty acid synthesis at the C8–C14 chain length stage for incorporation into triacylglycerols during seed development. The potential applications of these fatty acids has been a major driving force in the search to elucidate the mechanisms by which they are synthesized. A number of potential chain-terminating mechanisms were hypothesized (see 15) and included the presence of a medium chain-specific acyl-ACP thioesterase, specific acyl-ACP transferases,  $\beta$ -fatty acid synthetases, and  $\beta$ -ketoacyl-ACP synthetases. Other possibilities include the availability of the fatty acid metabolites malonyl-CoA and acetyl-CoA, and cofactor levels of ACP.

An important role for the medium-chain acyl-ACP thioesterase was firmly established following the expression of the Californian bay 12:0-ACP thioesterase in *Arabidopsis* resulting in the formation of laurate and the first genetically engineered rapeseed (27). Thioesterases with the potential to confer different medium-chain length phenotypes have now been isolated from a number of species, especially from the genus *Cuphea* (28–30). Although acyl-ACP thioesterases with specificities toward medium-chain substrates are requisite enzymes in plants which produce C8–C14 seed oils, they do not appear to be the sole chain length determinants. It has recently emerged that  $\beta$ -ketoacyl-ACP synthase also plays an important role in the production of medium-chain fatty acids and that it is the cooperation of the synthase and thioesterase which determines the phenotype, at least in *Cuphea* (28).

cDNA clones encoding the 3-ketoacyl-ACP synthase have been isolated from *Cuphea* and overexpressed in *Brassica* (29). Expression of this enzyme in transgenic *Brassica* seeds which normally do not produce medium-chain fatty acids did not result in any detectable modification of the fatty acid profile. However, coexpression of the *Cuphea* KAS with the medium chain-specific thioesterase strongly enhanced the level of C8:0–C12:0 fatty acids in the seed oil as compared with seeds expressing the thioesterase alone. By contrast, coexpression of the *Cuphea* KAS along with the 18:0/18:1-ACP thioesterase did not result in a modified fatty acid profile. These data indicated that the *Cuphea* KAS had different acyl chain specificities to the previously characterized KAS I, II, and III and was therefore designated KAS IV, a medium chain-specific condensing enzyme (29). Knowledge of this enzyme activity and its relationship with the short-chain thioesterase may be exploited in the future engineering of oilseeds to increase yields and medium-chain fatty acids or extend the range of medium-chain phenotypes.

A few plant species have been identified that accumulate significant amounts of stearate in their seed oils; these include cocoa (*Theobroma cacao*), shea (*Butyrospermum parkii*), sal (*Shorea robusta*), and kokum (*Garcinia indica*), the oils of which are valuable as cocoa butter or cocoa butter substitutes in many confectionary applications. The level of stearate available for triacylglycerol assembly is likely controlled by the combined regulation of the plastid localized enzymes  $\beta$ -ketoacyl-acyl carrier protein synthase II (which generates stearoyl-ACP) and stearoyl-ACP desaturase, acyl-ACP thioesterase, and acyl-ACP acyltransferases, all of which use stearoyl-ACP as substrate (31). Downregulation of stearoyl-ACP desaturase resulted in the significant accumulation of stearate in the storage oil of non-stearate-accumulating species such as *Brassica rapa* and *B. napus* (32).

It should be pointed out that plant acyl-ACP thioesterases fall into two distinct but related classes known as FatA and FatB (27, 33). The FatA class includes the palmitoyl-, stearoyl-, and oleoyl-ACP thioesterases and these are regarded as ubiquitous. The fatB class contains all the specialized thioesterases (including the medium-chain thioesterases described above) as well as an apparently ubiquitous thioesterase with a broader specificity for longer-chain saturated and unsaturated substrates. Recently, Hawkins and Kridl (31) have reported the cloning and characterization of three different acyl-ACP thioesterase cDNAs from mangosteen (*Garcinia mangostana*) seed RNA—two from the fatA

class, and one from the fatB class. Expression of *Garm* FatA1 in *Brassica* seeds led to the accumulation of stearate up to 22% in the seed oil. These results suggest that *Garm* FatA1 is at least partially responsible for determining the high stearate composition of mangosteen oil and that fatA, as well as fatB, thioesterases have evolved for specialized roles.

## E. Unsaturated and Polyunsaturated Fatty Acids

In many oleaceous species the products of fatty acid synthesis in the plastid are palmitic (C16:0), stearic (C18:0), and oleic (C18:1) acids (see above). These are made available to the endoplasmic reticulum for triacylglycerol assembly (see below) and the formation of other fatty acids, particularly polyunsaturated fatty acids. Unsaturated fatty acids, therefore, are synthesized by the sequential insertion of double bonds into a more saturated precursor. The first double bond in the production of C18 unsaturated fatty acids is inserted at the  $\Delta$ 9 position of stearic acid (C18:0) and yields oleic acid (C18:1 $\Delta$ 9). The  $\Delta$ 9 desaturase catalyzing this reaction is a soluble plastidic protein utilizing C18:0ACP as substrate. To date the  $\Delta$ 9–18:0ACP desaturase is the only desaturase to have its structure and mode of action fully characterized. A cDNA encoding this desaturase, isolated from castor bean endosperm and overexpressed in *E. coli*, generated sufficient protein for biophysical characterization (34). The desaturase contained a di-iron cluster at the active site and in this respect was similar to methane mono-oxygenase hydroxylase (35). The protein has been crystallized and its structure determined (36). A mechanism of action for the desaturase proposes that the removal of two hydrogens results in the formation of a transient di-radical that spontaneously recombines to form the  $\Delta$ 9 double bond (37).

Antisense constructs of the  $\Delta$ 9 stearoyl-ACP desaturase, with seed-specific promoters inserted into oilseed rape, brought about a dramatic increase in stearate in the rape oil from the normal < 2% to 40% and with a corresponding decrease in oleate (32). Triacylglycerols with high stearate are of commercial interest as cocoa butter substitutes in confectionary fat.

Oleate, from the plastid, is channeled into phospholipid, mainly phosphatidylcholine of the endoplasmic reticulum and there, depending on the plant species, sequentially desaturated by a  $\Delta$ 12 and  $\Delta$ 15 desaturase into linoleate and  $\alpha$ -linolenate (38, 39). Similar desaturation steps occur in the plastid galactolipids and are catalyzed by desaturases encoded by genes which are separate from those encoding the endoplasmic reticu-

lum proteins (40). It is only the endoplasmic reticulum desaturases, however, that appear to be responsible for the production of the polyunsaturated fatty acids in the storage triacylglycerols. The  $\Delta 12$  desaturation in oil seeds occurs with oleate at both the *sn1* and *sn2* positions of *sn*-phosphatidylcholine, whereas  $\Delta 15$  desaturation in linseed exhibits a strong preference for substrate at position *sn2*. The oil seed endoplasmic reticulum  $\Delta 12$  desaturase is cyanide sensitive and requires NAD(P)H and molecular oxygen. Spectrophotometric evidence shows that the safflower microsomal  $\Delta 12$ -desaturation is mediated through the cytochrome b5-cytochrome b5 reductase system (41); this was confirmed with antibodies to cytochrome b5, which inhibited desaturase activity (42). Seed microsomal cytochrome b5 has been molecularly characterized for studies on desaturation and polyunsaturated fatty acid synthesis (43–46).

Mutagenesis and conventional plant-breeding programs have produced several oil seed varieties with blocks in both oleate and linoleate desaturase activity, resulting in dramatic changes in the unsaturation level of the seed triacylglycerols (47, 48). The seeds develop normally and are viable. There were no fatty acid lesions in other parts of the plant, indicating tissue-specific  $\Delta 12$  and  $\Delta 15$  desaturase genes (48–50). Such observations bode well for manipulating the polyunsaturation in oil seeds by genetic engineering. The endoplasmic reticulum desaturases are integral membrane proteins and highly hydrophobic, and hence little progress has been made in their solubilization and purification. Much of our understanding of this class of desaturases has come from *Arabidopsis* mutants (40, 51). These mutants, termed FAD mutants, are each defective in a particular desaturase. For example, FAD2 and FAD3 genes have been cloned and shown to be responsible for  $\Delta 12$  and  $\Delta 15$  desaturation in the endoplasmic reticulum, respectively (52, 53). Examination of deduced amino acid sequences show that membrane bound desaturases from a number of sources are characterized by the presence of three regions of conserved histidine residues and that these are responsible for catalytic activity (37, 54).

Desaturation reactions involved in the synthesis of a number of other, less common polyunsaturated fatty acids are also endoplasmic reticulum-bound enzymes. Only  $\gamma$ -linolenic acid ( $18:3^{\Delta 6,9,12}$ ), however, has been studied in detail. Polyunsaturated fatty acids with a  $\Delta 6$  double bond are prevalent in the Boraginaceae. Here, the dominating  $\Delta 6$  fatty acid in leaf tissue is an octadecatetraenoic acid (stearidonic acid,  $18:4^{\Delta 6,9,12,15}$ ), and this is particularly enriched in the galactolipids

(55). In seed oil, however,  $\gamma$ -linolenate predominates and in borage accounts for some 25% of the triacylglycerol fatty acids. The seed  $\gamma$ -linolenic acid is synthesized by a  $\Delta 6$  NADH-dependent desaturation of linoleate esterified to largely microsomal phosphatidylcholine (56). The  $\Delta 6$  desaturase has a strong preference for linoleate at position *sn2* of phosphatidylcholine.  $\alpha$ -Linolenic acid acts as a substrate for the  $\Delta 6$  desaturase and the formation of  $18:4^{\Delta 6,9,12,15}$  (55).

$\gamma$ -Linolenic acid is considered of therapeutic value in alleviating a wide range of clinical and atopic disorders (57), and  $\gamma$ -linolenate-rich oil from a number of species (borage, evening primrose, black currant, and some fungi) (58) is available for this purpose. The inclusion of a  $\Delta 6$  desaturase gene in a high linoleate oil crop could yield  $\gamma$ -linolenate oil for medical and dietary use and at a competitive price. In borage the membrane lipids are also enriched in  $\gamma$ -linolenate, and the  $\Delta 6$  desaturase gene appears to be expressed in the whole plant. It can be assumed, therefore, that its expression in a transgenic plant would not adversely affect membrane function and this appears to be the case.

Recently a cDNA has been isolated that encodes the  $\Delta 6$  desaturase from the developing seeds of borage (59). Its function has been confirmed by ectopic expression in transgenic tobacco plants. The transformants grew well and contained appreciable quantities of  $\gamma$ -linolenic acid (13%) and stearidonic acid (10%). The polypeptide encoded by the  $\Delta 6$  desaturase cDNA is unusual and contains diagnostic sequences related to cytochrome b5 at the N-terminus. The microsomal form of borage cytochrome b5 is 32% identical to the N-terminal extension of the  $\Delta 6$  desaturase. Microsomal desaturases ( $\Delta 12$ ,  $\Delta 15$ ) that have been cloned from higher plants do not contain this cytochrome b5 domain (53), even though the requirement for cytochrome b5 has been demonstrated *in vitro* (41). The borage  $\Delta 6$  desaturase therefore appears to represent a new class of fatty acid desaturases in higher plants existing as cytochrome b5 fusion proteins.

It is interesting that none of the other plant desaturases ( $\Delta 12$ ,  $\Delta 15$ ) (53) or the closely related hydroxylase from castor (60) have a cytochrome b5 domain and use the “free” microsomal form of the protein. It is possible that desaturation is more efficient with an endogenous heme binding domain in the protein. It may be significant that the  $\Delta 6$  desaturase from borage differs from the  $\Delta 12$  and  $\Delta 15$  desaturases in that it introduces a center of unsaturation between an existing double bond and the carboxy carbon—i.e., a front-end desaturase (61), as opposed to double-bond formation

toward the methyl end of the carbon chain. Other front end desaturases have now been cloned and functionally identified and include the  $\Delta 5$  from the filamentous fungus, *Mortierella alpina* (62) and the nematode worm, *Caenorhabditis elegans* (63); again, these contain cytochrome b5 domains.

## F. Fatty Acid Elongation

Very long chain fatty acids (VLCFAs) have chain lengths from 20 to 30 carbons or greater. For a detailed review of the biochemical and molecular characterization of elongase activity, see Postbeittenmiller (64) and Domergue et al. (65). Here we will summarize the current understanding and the recent advances in the molecular characterization of the process. The major site of VLCFA synthesis is the epidermal cells where they are used for the formation of waxes including suberin, cutin, and the epicuticular waxes which cover the aerial parts of the plant (66). The VLCFAs are either directly incorporated into waxes or else act as precursors for other aliphatic hydrocarbons which include alkanes, primary and secondary alcohols, ketones, aldehydes, and acyl esters. VLCFAs also accumulate to high levels in the seed oils of some species; they are mostly monounsaturated, belonging chiefly to the *cis* (n-9) series, i.e., higher homologs of oleic acid, e.g., erucic acid, as found in the older varieties of oilseed rape.

VLCFAs are of particular importance for the oleochemical industries, and the need for renewable raw materials has led to a significant interest in this area of research, particularly for the characterization of the so-called fatty acid elongases. The elongase activity is composed of four activities analogous to those found in de novo fatty acid synthesis and involves the sequential additions of C2 moieties from malonyl-CoA to preexisting C18 fatty acids exported from the plastid to the membranes of the endoplasmic reticulum. It is thought that each cycle of elongation comprises: (a) condensation of malonyl-CoA with a long chain acyl-CoA; (b) reduction to  $\beta$ -hydroxyacyl-CoA; (c) dehydration to an enoyl CoA; and (d) reduction of the enoyl-CoA, resulting in an elongated acyl-CoA. Recent work with *Arabidopsis*, which contains  $\sim 21\%$  (w/w of total fatty acids) as eicosanoic acid (20:1), has shown that a fatty acid elongation (*FAE1*) gene encodes a putative seed-specific condensing enzyme and catalyzes the first step in the cycle outlined above (67).

Introduction of the *FAE1* gene into yeast and tobacco and the vegetative tissues of *Arabidopsis*

where significant quantities of VLCFAs are not found conferred the ability to accumulate these fatty acids. *FAE1* thus appears to be the rate-limiting step in *Arabidopsis* seed, and the introduction of extra copies resulted in higher levels of VLCFAs. Furthermore, it was suggested that the condensing enzyme is the activity of the elongase that determines the acyl chain length of the VLCFAs produced. In contrast, the other three enzyme activities are found ubiquitously throughout the plant and are not rate limiting and play little if any role in the control of VLCFA synthesis.

Because condensing enzymes are pivotal in the synthesis of VLCFAs, they may be useful for biotechnology. For example, the accumulation of VLCFAs in *p35S-FAE1* tobacco raises the possibility of producing VLCFAs in plant species that do not normally have them. The availability of expressed sequence tags (ESTs) may allow identification of enzyme activities that could synthesize VLCFAs up to C34 in length. Targeting of these fatty acids to seeds may eventually lead to the production of new, agronomically important VLCFAs. In a broader application, the availability of condensing enzymes with different acyl chain specificities, together with an ability to manipulate their expression in epidermal cells, could result in the generation of plant crops with enhanced performance physical barriers (waxes) and thereby show increased tolerance to environmental stresses and/or resistance to pathogens.

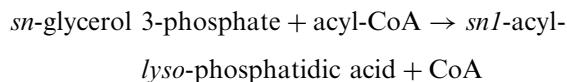

## IV. TRIACYLGLYCEROL BIOSYNTHESIS

### A. Assembly

Saturated fatty acids up to the levels of palmitic acid (C16:0), stearic acid (C18:0), and oleic acid (18:1 $^{\Delta 9}$ ) are synthesized in the plastid (see above). All further modifications of the acyl-chain and the assembly of triacylglycerols are accomplished by membrane-bound enzymes localized in the endoplasmic reticulum (ER). The oil is released from the endoplasmic reticulum membranes and stored as discrete oil bodies in the cytoplasm. Maximum oil deposition in the seed usually occurs over a narrow time window after pollination. In species such as sunflower and safflower,  $> 60\%$  of the oil is laid down over a period of a few days  $\sim 15$  days after flowering and when the cells of the cotyledons are undergoing cell expansion. At the close of oil accumulation, the triacylglycerols constitute  $> 90\%$  of the total lipid, with the remainder being phospholipids and glycolipids (68). Seed cotyledons in the active

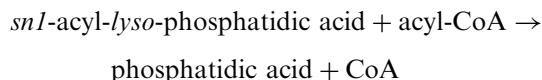

phase of oil deposition yield microsomal membrane preparations capable of massive oil assembly in vitro. Given suitable substrates, microsomal preparations produce triacylglycerols in mass and these accumulate as visible oil droplets in the incubation medium (69).

The major pathway for triacylglycerol biosynthesis in plants is via the so-called Kennedy, or glycerol-3-phosphate, pathway (70, 71) and is catalyzed by enzymes in the endoplasmic reticulum. The assembly of the triacylglycerols proceeds through three sequential acylation steps each catalyzed by a specific acyltransferase (AT; Fig. 3). In the first reaction, the acyl moiety from acyl-CoA is transferred to the *sn*1 position of *sn*-glycerol-3-phosphate to yield lysophosphatidic acid:

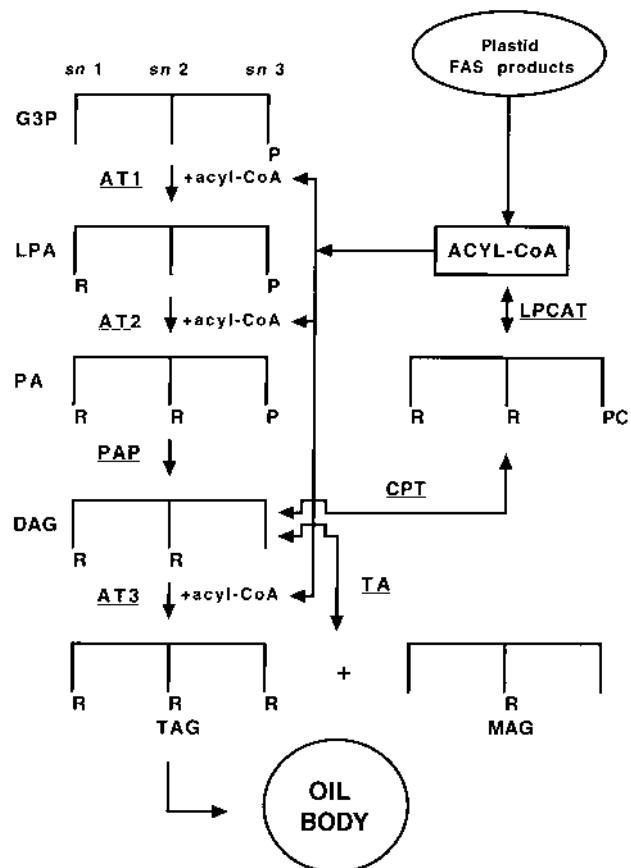

The glycerol-3-phosphate acyltransferase (AT1) catalyzing this reaction generally has a broad acyl specificity and will accept both saturated and unsaturated fatty acids (72, 73). In some species, however, which produce an unusual seed-specific fatty acid, the AT1 may exhibit a greater specificity for the acid than the enzyme from plants that lack it (74, 75).

The enzyme lysophosphatidic acid acyl transferase (AT2) catalyzes the acylation of lysophosphatidic acid at the *sn*2 position to yield phosphatidic acid:

In most oil seeds, AT2 exhibits a strong selectivity for unsaturated 18-carbon fatty acids (76, 77), and this results in a nonrandom distribution of the acyl groups at the *sn*1 and *sn*2 positions of phosphatidic acid and in other lipids derived from this such as phospholipids, diacylglycerols, and triacylglycerols (78). As a general rule, therefore, plant triacylglycerols have mainly unsaturated fatty acids at position *sn*2. Interesting exceptions are plants with triacylglycerols rich in medium-chain fatty acids (C8–C14) and especially in the genus *Cuphea* (79). The acyl specificities of the AT2 from three different *Cuphea* spp. have been investigated and have similar properties. Medium-chain acyl-CoA substrates are readily utilized. Long-chain acyl-CoA esters, however, were only used if the acyl acceptor, lysophosphatidic acid, contained a long-chain acyl group (75, 80). The AT2s from oil seed species which accumulate triacylglycerols with only long-chain fatty acids lack these properties. These enzymes poorly utilize medium-chain lysophosphatides and acylate

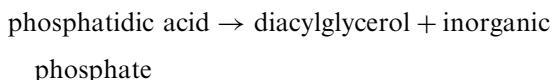

**Figure 3** Glycerol-3-phosphate (G3P) undergoes acylation to yield lysophosphatidic acid (LPA) and phosphatidic acid (PA) through the action of glycerol phosphate acyltransferase (AT1) and lysophosphatidic acid acyltransferase (AT2), respectively. A phosphatidic acid phosphohydrolase (PAP) gives rise to diacylglycerol (DAG) which undergoes acylation, catalyzed by diacylglycerol acyltransferase (AT3), to form triacylglycerol (TAG). Oleic acid (18:1) from the plastid enters the acyl-CoA pool and can be transferred to the *sn*2 position of *sn*-phosphatidylcholine (PC), through the activity of lysophosphatidylcholine acyltransferase (LPCAT), for desaturation to C-18 polyunsaturated fatty acids. The desaturated fatty acid products in PC enter the acyl-CoA pool by the reverse reaction of LPCAT. During the movement of glycerol backbone towards TAG through the so-called Kennedy pathway DAG can freely interconvert with PC through the forward and reverse reactions of a cholinophosphotransferase (CPT). During oil formation DAGs also give rise to TAG and monoacylglycerol (MAG) through a transacylation (TA) reaction, which is freely reversible.

them at a considerably higher rate with long-chain acyl-CoA than medium-chain acyl-CoA (81). The rather special properties of the *Cuphea* AT2 enables the cell to synthesize phosphatidic acid in two major

molecular species consisting of medium-chain and long-chain acyl groups, respectively, and with little of the mixed acyl species. This feature is probably a necessity in *Cuphea* in order to maintain correct membrane lipid assembly and function (see below).

In vitro assays have shown that the AT2 in rape seed has a poor capacity to acylate unusual fatty acids in the *sn*2 position (81, 82). In line with these observations it was found that rape seed–accumulating erucic acid (C22:1) (82) and transgenic rape seed engineered to accumulate laurate (C12:0) (83, 84) nearly totally exclude these fatty acids from the *sn*2 position of triacylglycerols. However, this exclusion of unusual fatty acids from the *sn*2 position in rape can be surpassed by introducing other AT2s from other species. For example, transgenic laurate-producing rape transformed with a cDNA encoding coconut AT2 (which acylates medium-chain fatty acids at the *sn*2 position) resulted in rape seeds with 30 mol% of laurate in the *sn*2 position of triacylglycerols (85). When a cDNA encoding a *Limnanthes* AT2 was introduced into an erucate acid–producing rape, it resulted in transgenic seeds with significant erucic acid at the *sn*2 position of the triacylglycerols (86). A thorough review of the molecular biology of AT1 and AT2 has been presented by Frentzen and Wolter (87). It is evident that particular cloned AT2 genes can be successfully used to manipulate fatty acid composition in transgenic seeds. It also appears that the expression of a yeast AT2 gene in transgenic rape seed improves oil yield (88, 89).

In the further reactions of triacylglycerol assembly the phosphatidic acid is converted to diacylglycerols and inorganic phosphate through the action of the enzyme, phosphatidate phosphohydrolase (PAP):

In oil seeds, the enzyme appears to be present in both soluble and membrane-bound forms and these may have a regulatory function in lipid synthesis (90). Good purification of this enzyme has recently been achieved and it is currently under investigation (91).

Diacylglycerols are the precursors for the membrane lipids, phosphatidylcholine, and phosphatidylethanolamine as well as storage triacylglycerols. Consequently, diacylglycerol utilization constitutes a branch point between membrane and storage lipid synthesis. The final step in triacylglycerol biosynthesis is the acylation of the diacylglycerols at the *sn*3 position catalyzed by diacylglycerol acyltransferase (AT3):

The acylation of diacylglycerol is the only unique step in triacylglycerol assembly. There are many plant species with unusual fatty acids in their seed oil. These are often major constituents in the triacylglycerols and are almost absent in the seed membrane lipid. It is probable that the presence of many of these unusual acids in membrane lipids would severely impair proper membrane function. How particular acyl species of diacylglycerols are channeled almost exclusively to triacylglycerols is not fully understood. Although experimental data suggest that the mechanisms might differ depending on the type of “triacylglycerol-specific” fatty acid, it appears that the AT3 must play an important role in this regulation. It has been shown that AT3 in plants accumulating unusual fatty acids can exhibit acyl specificity and selectivity which enables the preferential channeling of these fatty acids into triacylglycerols (92, 93). As yet little progress has been made on the molecular biology of AT3 in plants. Recently, however, a mouse cDNA-encoding AT3 has been isolated and characterized (94). This appears to be the first successful identification of an AT3 gene and hopefully bodes well for the identification of genes with a similar function in plants.

## B. Desaturation and Its Relationship to Oil Assembly

Since phospholipids are the prime substrates for the production of linoleic and linolenic acids that are designed for plant triacylglycerol assembly (see above), there must be efficient mechanisms by which the oleate is channeled into phospholipids for desaturation and the desaturated acyl groups made available for triacylglycerol biosynthesis. Among the phospholipids present in the endoplasmic reticulum, it is only phosphatidylcholine that undergoes rapid turnover and it is this lipid that is important in providing polyunsaturated fatty acids for triacylglycerol formation. An equilibration reaction between acyl groups in phosphatidylcholine and the acyl-CoA pool occurs in oil seeds and by this reaction oleate from oleoyl-CoA enters position *sn*2 of phosphatidylcholine for desaturation. Concomitantly, the products from that position enter the acyl-CoA pool for the acylation of all three positions of the glycerol backbone. The reaction can be catalyzed by the combined forward and reverse reactions of an acyl-CoA:lysophosphatidylcholine acyltransferase (LPCAT) (95).

Diacylglycerol may be utilized for phosphatidylcholine synthesis by a CDP-choline:diacylglycerol choline-phosphotransferase (CPT) catalyzed reaction. In oil seeds, this appears to be reversible and thus the phosphatidylcholine can also reconvert with diacylglycerols (96). In the combined forward and reverse reactions of the cholinephosphotransferase, the oleate at both positions of diacylglycerols can enter phosphatidylcholine for desaturation and the polyunsaturated products transferred to the diacylglycerol pool for triacylglycerol synthesis (97). The relative importance of the two reactions, the acyl exchange between acyl-CoA and phosphatidylcholine and the phosphatidylcholine-diacylglycerol interconversion, in providing polyunsaturated fatty acids for triacylglycerol assembly is unclear and might differ among plant species (98, 99). The cholinephosphotransferase has recently been cloned from soybean (100), which should lead to a better understanding of the role of this enzyme in influencing oil quality.

### C. Transacylation

Observations suggest that events other than those described above may also occur during oil assembly. In previous experiments with safflower microsomal membranes, triacylglycerols appeared to form from diacylglycerols, but in the absence of acyl-CoA, and hence not by the direct acylation through diacylglycerol acyltransferase activity (97). At that time no explanation was offered for this. Also it has recently been shown that preformed triacylglycerols in the embryos of sunflower at an early stage of development can become further enriched with linoleate (101), suggesting that fatty acids esterified to triacylglycerols, and presumably before stabilization in the oil body, are available to the  $\Delta 12$ -desaturase of the endoplasmic reticulum. Further, it has been demonstrated that there is considerable remodeling of *in situ*-synthesized triacylglycerol involving acyl groups from polar lipids in microsomal preparations from the developing castor bean endosperm (102).

In attempts to reconcile these observations with our present understanding of oil assembly, the utilization by microsomal membranes of radiolabeled neutral lipid substrates has been investigated. Safflower microsomes were found to catalyze the interconversion of mono-, di-, and triacylglycerols (103). From these studies it was clear that diacylglycerols gave rise to triacylglycerols and monoacylglycerols as well as phosphatidylcholine. Radioactivity was transferred from triacylglycerols to diacylglycerols and monoacyl-

glycerols were rapidly converted to di- and triacylglycerols. These interconversions occur in the absence of acyl-CoA and hence do not involve diacylglycerol acyltransferase activity. The evidence is consistent with the operation of a diacylglycerol-diacylglycerol transacylation yielding monoacylglycerols and triacylglycerols; the reaction is freely reversible. A similar transacylase reaction has been characterized in rat intestinal microsomes where it is involved in the net synthesis of monoacylglycerols and triacylglycerols (104). The activity of the transacylase in safflower microsomes is of the same order of magnitude as the diacylglycerol acyltransferase. Hence in any diacylglycerol acyltransferase assays using radioactive diacylglycerols, it would not be possible to discriminate triacylglycerol formation via transacylation or direct acylation.

Experimental evidence also shows that the diacylglycerols, arising directly by the so-called Kennedy pathway, or via transacylation, rapidly interconvert with phosphatidylcholine, probably through the reversible action of choline phosphotransferase (96). Any oleoyl substrate entering phosphatidylcholine via choline phosphotransferase is readily desaturated and the polyunsaturated fatty acid products become incorporated into the triacylglycerol oil. Transacylation, therefore, can account for the further enrichment of preformed triacylglycerols with polyunsaturated fatty acids observed *in vivo* (101). It cannot be ruled out, of course, that such a desaturation can occur *in vivo* while the oil is still associated with the endoplasmic reticulum, and presumably before stabilization in the oil body. In this respect a solubilized  $\Delta 12$ -desaturase from the chloroplast was found to utilize, to some degree, other substrates (free fatty acids, acyl-CoA, and the complex lipid monogalactosyldiacylglycerol) (105). It is clear, however, that the consequence of any reaction that gives rise to diacylglycerols will also bring about the further enrichment of the glycerol backbone with C18-polyunsaturated fatty acids. Transacylation could also account for the previous observation with microsomal membranes that radioactivity in diacylglycerols would accumulate in triacylglycerols in the absence of acyl-CoA (97), and that *in situ*-synthesized triacylglycerols are remodeled with acyl groups from polar lipids (102).

Our current understanding of triacylglycerol assembly and turnover *in vitro* in developing oil seeds and the relationship to microsomal desaturation is outlined in Figure 3. It is also apparent that microsomal membranes catalyze the production of lysophosphatidylcholine from monoacylglycerols (103). This appears to occur via a phosphocholine transfer between phos-

phatidylcholine and the monoacylglycerol, the products being diacylglycerols and lysophosphatidylcholine. The lyso derivative can be rapidly reacylated from acyl-CoA. Such a combination of reactions could yield triacylglycerols without the participation of diacylglycerol acyltransferase and without any accumulation of monoacylglycerols.

If transacylation occurs *in vivo*, what might be its biological significance? Clearly, it can provide even further opportunity for desaturation and the enrichment of the oil with C18-polyunsaturated fatty acids. The reactions that channel oleate to phosphatidylcholine for its subsequent desaturation help to concentrate substrate and give a greater chance(s) for desaturation. It is possible that desaturation of complex lipids, such as phosphatidylcholine, is not an efficient process and that a number of mechanisms have evolved, including transacylation, which enables the rapid formation of polyunsaturated fatty acids for storage and membrane lipid assembly. One might also speculate that the transacylation may play some role in the assembly of triacylglycerols containing > 70% of a particular fatty acid and particularly those of an unusual nature perhaps by giving rise to species of diacylglycerols which are immediately acylated directly with the required fatty acid. Transacylation, however, could have a more profound biochemical importance. It may help to regulate the size of an active diacylglycerol pool, a possible necessity which prevents the detrimental net movement of phosphatidylcholine to diacylglycerols (via cholinophosphotransferase) and the consumption of endoplasmic reticulum structural lipid during the period of extremely rapid oil deposition that is found in the developing seed.

## V. OXIDIZED FATTY ACIDS

### A. Autoxidation and Antioxidants

Historically, the oxidation of fatty acids has been perceived as a deleterious process resulting in the generation of off-flavors in commercial produce. The process of oxidation can be considered as either autoxidation, a chemical reaction that usually takes place at ambient temperatures between atmospheric oxygen and an organic compound, or as an enzyme-catalyzed reaction. The complexity of the autoxidation reaction has been well documented (106). The insertion of oxygen is also accompanied by the movement of double bonds resulting in the formation of a conjugated diene with a maximal absorbance at 234 nm. Spectral measurements at this wavelength have been used to monitor hydroper-

oxide formation (107). An important feature of autoxidation is that it is autocatalytic, the rate of oxidation being slow at the start (the induction period) and increasing as the reaction progresses. In common with other radical chain reactions, autoxidation can be divided into three separate processes: initiation, propagation, and termination. Initiation is perhaps the process most difficult to define because of the low concentration of radicals and the likelihood of there being more than one process, since a large number of different radicals can abstract hydrogen from RH to form R<sup>•</sup> + H. The initiating species may be, for example, a transition metal ion, a radical generated by photolysis or high-energy irradiation, or a radical generated by decomposition of a hydroperoxide. In the propagative phase, further reactive species are generated as in the generation of a radical R<sup>•</sup> from the alkene RH and its subsequent reaction with oxygen. In the termination phase there is an interaction of radicals to produce non-initiating and nonpropagating products.

Autoxidation is facilitated by pro-oxidants and inhibited by antioxidants. Pro-oxidants, such as metals or other radical initiators, operate by promoting the initiation step or else they may inhibit the activity of antioxidants. Antioxidants are frequently added to fats and fat-containing foodstuffs to prolong shelf life (108). These are often phenolic compounds which act by interfering with the propagation sequence by conserving propagating radicals into nonpropagating species (109, 110). Their effectiveness is often increased by compounds such as citric acid, ascorbic acid, or phosphoric acid (called synergists). In this regard, there is considerable evidence for a contributory, antioxidant role for vitamins E and C and the carotenoids—constituents of fruit, vegetables, beverages, and grains—in the maintenance of health and the protection from coronary heart disease, cataracts, and certain cancers (111).

Recent work indicates possible important roles of polyphenolic components (the flavonoids, phenylpropanoids, and phenolic acids) as contributors to antioxidant activities and also as agents of other mechanisms contributing to cardioprotective and anticarcinogenic actions. Epidemiological evidence suggests a negative correlation between dietary antioxidants and coronary arterial disease. Such an association may involve a mechanism whereby antioxidants delay the onset or progression of the disease by reducing oxidative reactions, downregulating thrombotic mechanisms, and attenuating endothelial dysfunction.

A large range of flavonoids and phenylpropanoids found in fruit, vegetables, and beverages are more

effective antioxidants in in vitro systems than vitamin C or vitamin E (111). Examination of the antioxidant status of a number of consumables gave a hierarchy of red wine > black tea = green tea > red grape juice = blackcurrant juice > white grape juice = orange juice > white wine = apple juice. Indeed, in what has become known as the "French paradox" (their relatively high fat consumption but relatively low coronary disease) has been attributed, in part at least, to the beneficial effects derived from the consumption of red wine containing the flavonoid constituents derived from the black grape skins.

There is also increasing epidemiological evidence for an association between dietary intake of carotenoid-containing fruit and vegetables and a decreased incidence of coronary heart disease and certain cancers (111, 112). Recent studies (113) have shown that dietary intake of lycopene-rich foods was inversely associated with a risk of prostate cancer. These effects have been ascribed in part to the antioxidant activity of carotenoids. In addition to direct radical scavenging properties of some compounds given above, others such as the glucosinolates (114) (present in high amounts in vegetables such as brocolli, Brussels sprouts, and cabbage) or cysteine sulfoxides (115) in *Allium* (garlic and onion) act by stimulating the animals' own enzymic defenses (116, 117). This appears to operate via the antioxidant responsive element present in the 5'-flanking region of many antioxidant enzymes such as glutathione S-transferases, glutathione peroxidases, quinone reductase, and superoxide dismutase.

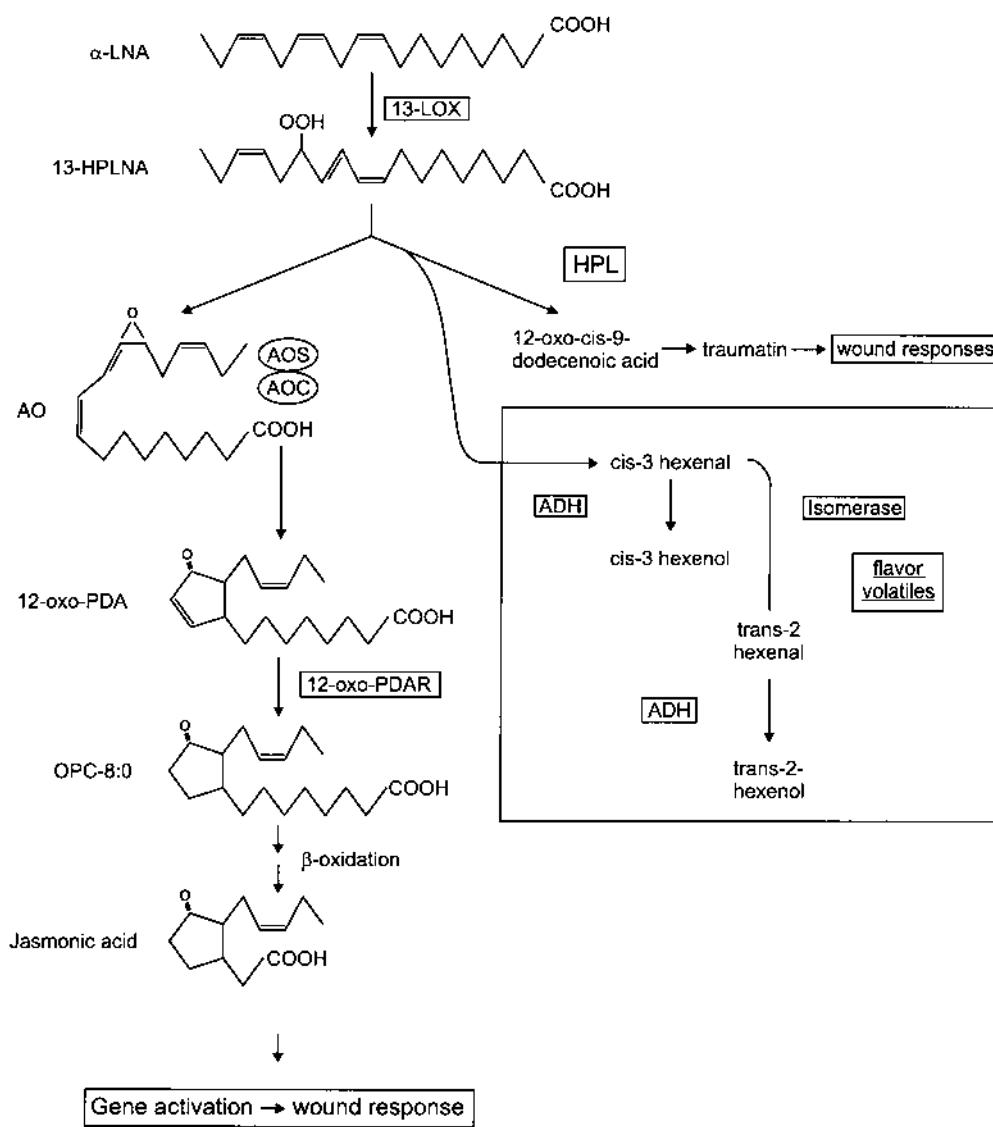

## B. Oxylipin Biosynthesis (Fig. 4)

Much of the early work concentrated on characterizing lipoxygenase (LOX), a nonheme dioxygenase that catalyzes, as a primary reaction, the hydroperoxidation, by molecular oxygen, of linoleic acid and other polyunsaturated fatty acids that contain a *cis*, *cis*-1,4-pentadiene moiety. Unesterified fatty acids have been regarded as the principal substrates for the enzyme although LOX isoforms with activity toward complex lipid substrates have been reported (118). LOXs are ubiquitous in plants and are encoded by large gene families which may result in the presence in a given tissue of LOX isoforms differing in substrate preferences, kinetic parameters, and stereospecificity of oxygenation (119). Linoleic and linolenic acid are the major polyunsaturated fatty acids in plant tissues, and insertion of the oxygen takes place at either the  $\Delta 9$  or  $\Delta 12$  position to generate the corresponding 9- or

13-hydroperoxides (107, 118). While most LOXs so far characterized are soluble cytosolic enzymes, some are chloroplastic, mitochondrial, or located in the vacuoles (118). In soybean, lipoxygenases have been identified with involvement in nitrogen and assimilate partitioning and appear to be regulated in response to plant nitrogen status in both tissue-specific and developmentally controlled patterns (120). A key role for some LOX isoforms is in the generation of fatty acid hydroperoxides destined for jasmonic acid (JA), which triggers gene activation during wound response in plants (121, 122).

The fatty acid hydroperoxides generated by the activity of LOX are potentially deleterious to membrane function by causing increased rigidity and would not, therefore, be expected to accumulate (123). Hydroperoxides can be metabolized by several routes. Glutathione transferases (GSTs) exhibiting glutathione peroxidase activity toward phospholipid hydroperoxides have recently been demonstrated in mammalian tissues (124). GSTs in plants perhaps having analogous roles in hydroperoxide detoxification could be envisaged (125). Hydroperoxide fatty acids can also be metabolized by the peroxygenase cascade (126–128). This involves (a) an intramolecular transfer of one oxygen atom from fatty acid hydroperoxide yielding an epoxyalcohol and/or co-oxidation reactions such as epoxidation of double bonds of unsaturated fatty acids, and (b) an epoxide hydrolase, which preferentially hydrates the epoxides formed by the peroxygenase (127). The chloroplast envelope membranes appear to be a major site of these metabolic activities (128); it is suggested that the products of this pathway may play roles in plant defense mechanisms.

During jasmonic acid synthesis upregulation of the allene oxide synthase (AOS) gene results in the conversion of 13-hydroperoxide to 12,13-epoxylinolenic acid, and is the first committed step in jasmonic biosynthesis. This conversion step has been proposed to be the rate-limiting step in the octadecanoid pathway (129). AOS is a cytochrome P450 of the CYP74A family, and cDNA clones have been obtained from a number of species (130, 131). The protein contains a peptide leader sequence typical for chloroplast import, indicating that it is targeted to this organelle. 12,13-Epoxylinolenic acid is very unstable and rapidly cyclized to racemic 12-oxophytodienoic acid (12-oxo-PDA). In vivo, a stereospecific reaction catalyzed by allene oxide cyclase (AOC) occurs specifically yielding the 9(S), 13(S)-12-oxo-PDA isomer. The AOC gene has not been cloned to date. The 12-oxo-PDA is the first cyclopentenone in the jasmonate pathway and is

**Figure 4** Oxylipin biosynthesis.  $\alpha$ -Linolenic acid ( $\alpha$ -LNA; C<sub>18</sub>:3<sup>Δ9,12,15</sup>) is converted to 13-hydroperoxylinolenic acid (13-HPLNA) by a 13-lipoxygenase isoform. The 13-HPLNA can be metabolized by several enzymes of which the formation of jasmonic acid (JA) and flavors volatilities are illustrated. The first step in JA synthesis is catalyzed by allene oxide synthase (AOS) forming an unstable allene oxide (AO) which is converted to 12-oxo-phytodienoic acid (12-oxo-PDA) by allene oxide cyclase (AOC). These reactions are considered plastidic. The 12-oxo-PDA is likely exported to the cytosol and acts as a substrate for 12-oxo-PDAR reductase (12-oxo-PDAR) forming 3-oxo-2-(2'-pentenyl)-cyclopentane-1-octanoic acid (OPC-8:0), which yields JA by  $\beta$ -oxidation. When 13-HPLNA is metabolized by hydroperoxide lyase (HPL), short-chain aldehydes and  $\omega$ -oxo acids are generated. The figure depicts the formation of the C<sub>6</sub> aldehyde (*cis*-3-hexenal) and the 12-oxo-*cis*-9-dodecenoic acid which in turn can be metabolized to traumatin. The chain length of the aldehydes and  $\omega$ -oxo acids produced in a particular tissue is dependent on the cleavage site of the C-C bond by HPL. The downstream metabolism of the aldehydes by alcohol dehydrogenases (ADH) and isomerases generates many of the characteristic flavors and aromas of fruits and vegetables.

subsequently converted to jasmonic acid by reduction of the  $\Delta$ 10 double bond by 12-oxo-PDA reductase, considered to be a cytosolic enzyme (132) and is followed by three rounds of  $\beta$ -oxidation that may occur in the peroxisomes. Thus jasmonic acid synthesis may involve the cooperation of three subcellular compartments, the chloroplast, cytosol and peroxisomes. The 12-oxo-PDA together with its metabolite, jasmonic acid (collectively termed jasmonates), either directly or indirectly triggers gene activation in a range of responses of which the defense response has probably been the most recently well documented (119, 122, 133).

Fatty acid hydroperoxides can also serve as substrates for the fatty acid hydroperoxide lyase (HPL) resulting in the formation of aldehydes and  $\omega$ -oxoacids; the former contributes to the volatile aldehydes and alcohols which are major constituents of characteristic aromas and flavors of many fruits and vegetables (107). Specificity of cleavage of the C–C bond of the hydroperoxide varies from species to species, although the most predominant products are of the C6 and C12 chain length (e.g., in soy and bell pepper) (134, 135). In pear, for example, the products are two C9 fragments (136), while in mushroom the principal products appear to be of C10 and C8 chain lengths (137), with the downstream C8 alcohol generated through the action of alcohol dehydrogenase contributing significantly to the characteristic mushroom odor. Of particular interest to the food industry is the generation of “green notes,” of which hexenal is a major component used as a natural flavoring compound. Recently, a cDNA encoding the HPL from bell pepper was cloned (138). The encoded protein comprises 480 amino acids and shares similarity with P450-type proteins especially at the C-terminus. Interestingly, the most related P450 protein is AOS with 40% amino acid identity and hence the HPL is classified as a new P450 subfamily, CYP74B. It is a future possibility that crops could be engineered with enhanced or altered flavor characteristics through the introduction and expression of “foreign” lyase enzymes.

## VI. CONCLUDING REMARKS

In this review we have attempted to summarize our present understanding of fatty acid biosynthesis and triacylglycerol assembly in plants. In the last decade, enormous advances have been made in lipid molecular biology with many genes cloned and character-

ized. This, together with biochemical studies, has made it possible to manipulate fatty acid profiles in oil seeds and even introduce the capacity to synthesize foreign fatty acids, not normally present, in transformed species. As knowledge and technology advance, it will become even more feasible to produce valuable new lipid products in plants to satisfy the demands of the food, nutraceutical, and pharmaceutical industries.

### I. PLANT PHOSPHOLIPIDS

Phospholipids are a minor (0.1–3%) but important component of all edible plant oils. They are removed during refining as a “gum” fraction but they are not discarded. Collectively known as lecithin, they are used as high-value emulsifiers and wetting agents in food manufacturing (1). The phospholipid fraction of vegetable oil, and indeed of all plant tissues, consists mainly of phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), phosphatidylglycerol (PG), and diphosphatidylglycerol (DPG). In addition, there are a number of less abundant phospholipids derived from phosphatidylinositol (2).

All emulsifiers can be characterized by their hydrophilic-lipophilic balance (HLB). Among plant phospholipids PC has the highest HLB value, PE is intermediate, and the other phospholipids have a low HLB. Thus, PC has the greatest value as a soluble oil-in-water emulsifier; it is used, for example, in lowering the viscosity of cocoa butter during chocolate manufacture. PE is more useful as a wetting agent—for example, in increasing fat absorption during the preparation of cake doughnuts (1). For this reason, commercial lecithin preparations are often separated into PC and PE fractions using ethanol, and there may be some value in genetically manipulating the ratio of phospholipids in plant oils for particular food applica-

tions. To achieve this it is necessary to understand the pathways of phospholipid biosynthesis in plants and have available the genes that encode phospholipid pathway enzymes.

Many of the enzymes involved in plant lipid biosynthesis are also similar to their yeast and animal counterparts (2), although there are important differences in the pathways which predominate. For example, in most animal tissues PC is predominantly synthesized from diacylglycerol and CDP-choline via a phosphoaminoalcohol pathway often referred to as the Kennedy pathway (3–5). In liver tissues and in yeast PC is synthesized mainly by the sequential methylation of PE, catalyzed by a single enzyme in animals (6) and two separate methylases in yeast (7). In many plants the first step in committed PC biosynthesis is the methylation of ethanolamine phosphate, followed by the synthesis of phosphatidylmonomethylethanolamine and then methylation to PC (see 2). The enzyme involved in this initial methylation of ethanolamine phosphate has recently been identified and its gene cloned from spinach and *Arabidopsis* (8, 9). Interestingly, no yeast or animal counterpart has been reported.

In general, however, the phospholipid pathways of all eukaryotes may be divided into those in which the glycerol backbone of the phospholipid molecule derives from CDP-diacylglycerol and those that it derives from diacylglycerol (DAG). For example,

phosphatidylethanolamine may be made from ethanolamine and diacylglycerol, by the Kennedy pathway, or by decarboxylation of phosphatidylserine, derived from CDP-diacylglycerol and free serine (Fig. 1).

The advent of modern genomics and the rapid advances in the understanding of yeast phospholipid biosynthesis has led to the cloning, heterologous expression, and characterization of many plant phospholipid biosynthetic enzymes that had previously been difficult to purify and characterize. Thus, a great deal of recent understanding of plant phospholipid biosynthetic enzymes has been derived from the molecular approaches described here. The 30 years or so of classical enzymological studies that laid the groundwork for these recent advances are described in earlier reviews (2, 10).

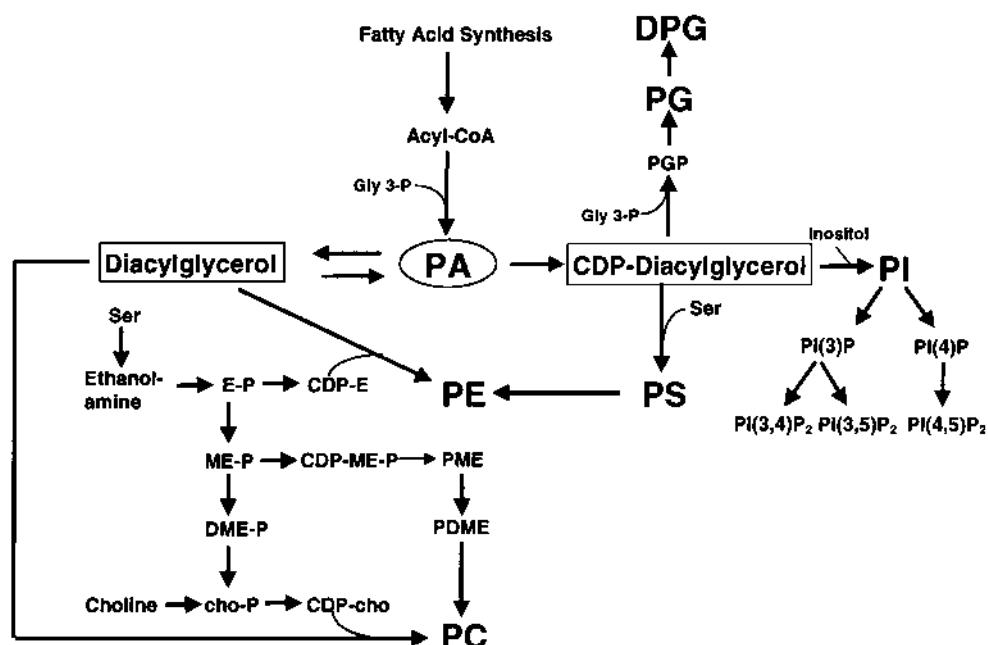

## II. BIOSYNTHESIS OF CDP-DIACYLGLYCEROL IN PLANTS

Diacylglycerol and CDP-diacylglycerol are both derived from phosphatidic acid (PA), synthesized by the sequential acylation of glycerol-3-phosphate by two acyltransferases—**glycerol-3-phosphate acyltransferase** and **1-monoacylglycerol-3-phosphate acyltransferase**—use acyl-CoA as a

source of acyl moieties. PA can then be converted either to CDP-diacylglycerol or to DAG. The former reaction is catalyzed by **CDP-diacylglycerol synthase** (CTP:phosphatidate cytidyltransferase, EC 2.7.7.41) and the latter by **phosphatidic acid phosphatase** (phosphatidate phosphohydrolase, EC 3.1.3.4).

The identification of the yeast gene encoding CDP-diacylglycerol synthase (*CDS1*) led to the construction of a null allele at this locus (11). These studies verified that CDP-diacylglycerol synthase activity is essential for cell viability and established *CDS1* as the only gene in yeast that encodes this activity. This latter observation was somewhat surprising considering that this enzyme is distributed between two very distinct organelles—the mitochondria and the endoplasmic reticulum.

Studies in animal systems reveal that, in addition to their involvement in bulk phospholipid synthesis, CDP-diacylglycerol synthase are also critical components of the phosphoinositide signal transduction cycle. A mutation in an eye-specific *Drosophila* CDP-diacylglycerol synthase resulted in the loss of IP<sub>3</sub>-mediated light perception in photoreceptor cells (12). This defect was attributed to the inability of these cells to adequately regenerate the necessary PI pools required to maintain the signaling cascade. Multiple CDP-diacylglycerol synthase isoforms in animals may

**Figure 1** Major pathways of phospholipid synthesis in higher plants.

be produced from independent genetic loci (13), or derived from the alternative splicing of a single gene (12).

In plants, CDP-diacylglycerol synthase activity has been detected in a number of organelles (2, 14). The ability of researchers to identify and isolate plant cDNAs that encode enzymes involved in glycerolipid biosynthesis, based on their homology to yeast and animal genes, has been greatly accelerated by the recent proliferation of plant-derived expressed sequence tagged (EST) databases. Where sequence information for a given protein and/or gene has been elucidated in a nonplant species, computer searchers of EST databases can rapidly identify candidate plant cDNAs that are likely to encode the same function (15). Additional experimentation, such as expressing and assaying the candidate cDNA in a heterologous system that lacks the activity in question, is subsequently used to verify function.

Recently, Kopka and coworkers (14) utilized this approach to isolate cDNAs encoding CDP-diacylglycerol synthases from plants. Using the CDP-diacylglycerol synthase sequence from *E. coli* as the query sequence, a candidate *Arabidopsis* EST was identified and subsequently used as a molecular probe to obtain full-length cDNAs from both *Arabidopsis* and potato gene libraries. The deduced plant proteins had predicted molecular masses of 49 kDa and possessed eight potential membrane-spanning domains. Although the subcellular location of the encoded *Arabidopsis* and potato proteins was not established, the absence of potential mitochondrial or chloroplast targeting sequences suggested that they represent microsomal CDP-diacylglycerol synthases. To confirm the function of the putative potato CDP-diacylglycerol synthase, a GST/potato cDNA fusion construct was generated and expressed in *E. coli*. The purified fusion protein displayed CDP-diacylglycerol synthase activity when assayed in vitro.

### III. SYNTHESIS OF PHOSPHOLIPIDS FROM CDP-DIACYLGLYCEROL

#### A. Phosphatidylglycerol and Diphosphatidylglycerol

PG in plants has been found in a number of plant organelles but is mainly associated with chloroplast thylakoids (16), whereas diphosphatidylglycerol (DPG), also known as cardiolipin, is restricted to the inner mitochondrial membrane (2, 16). In yeast the synthesis of PG is catalyzed by two enzymes, **PGP**

**synthase** (glycerophosphate:CDP diacylglycerol phosphatidyltransferase, EC 2.7.8.5) and **PGP phosphatase** (phosphatidylglycerolphosphate phosphohydrolase, EC 3.1.3.27). The first catalyzes the reaction of CDP-diacylglycerol with glycerol phosphate to yield phosphatidylglycerolphosphate and CMP, and the second the dephosphorylation of phosphatidylglycerolphosphate to PG. In yeast both reactions are localized exclusively in the inner membranes of mitochondria (17) whereas in plants they have been reported in mitochondria, chloroplasts, and microsomes (10, 18). These enzyme activities have been well characterized in animals and yeast (19–21), and a hamster cDNA-encoding PGP synthase has been cloned and shown to complement a PGP-synthase defective mutant in CHO cells (22). In plants, however, both of these enzymes remain substantially uncharacterized and their individual activities have not been measured.

DPG is synthesized in plant mitochondria as it is in yeast, by reaction of PG with CDP-diacylglycerol (2). The reaction is catalyzed by the enzyme **phosphatidylglycerol:CDP diacylglycerol phosphatidyltransferase**, about which very little is known in plants except that the enzyme requires either magnesium, or surprisingly, cobalt, for activity (10).

Because of its ubiquitous presence in the mitochondria of eukaryotes, DPG has long been assumed to serve a critical function within the mitochondrial membrane. The observation that DGP is required for the *in vitro* activities of several mitochondrial enzymes, and studies indicating a need for this unique phospholipid for the import of proteins into mitochondria, further supported this presumption (23, 24). Doubts were raised concerning the essential nature of DPG when a yeast strain possessing no detectable DPG owing to a null mutation at the locus encoding cardiolipin synthase was shown to be capable of growth on both fermentable and nonfermentable carbon sources (25). A more recent report by Jiang and coworkers (26) demonstrated that although no obvious growth defects were observed when the null mutant strain was incubated at 30°C, no colony formation was observed at 37°C. Thus, there does appear to be an absolute requirement for DPG in yeast for growth at elevated temperatures.

#### B. Phosphatidylinositols

The enzyme **PI synthase** (CDP-diacylglycerol:myo-inositolphosphatidyltransferase, EC 2.7.8.11), which catalyzes the reaction between free inositol and CDP-diacylglycerol, to yield PI and CMP, has been charac-

terized in the membrane fractions of many different plants (2, 10, 27).

Identification of an *Arabidopsis* EST displaying homology to the yeast PI synthase sequence resulted in the first reported characterizations of a plant PI synthase cDNA (28, 29). The *Arabidopsis* cDNA encodes a protein of 227 amino acids with a predicted molecular mass of 25.9 kDa. Because *E. coli* lacks PI, it provides an ideal background for functional verification of putative PI synthases. Expression of the *Arabidopsis* cDNA in *E. coli* resulted in the production and accumulation of PI to levels as great as 19% of the total lipid extracted from the bacteria (28). The cDNA has also been shown to complement a yeast PI synthase mutant (29). Studies of the recombinant enzyme in heterologous systems have confirmed the requirement of Mg<sup>2+</sup> ions for full activity of this enzyme (29).

In yeast and animals PI, in the presence of ATP, is converted to PI 4-phosphate [PI(4)P] and AMP, a reaction catalyzed by the enzyme **PI 4-kinase** (ATP:phosphatidylinositol 4-phosphotransferase, EC 2.7.1.67). Alternatively, PI can be phosphorylated at the D-3 position of the inositol ring by a **PI 3-kinase** (ATP:phosphatidylinositol 3-phosphotransferase) to give rise to PI(3)P. Among the bisphosphorylated PI derivatives, there is a vast body of literature documenting the cellular functions of PI(4,5)P<sub>2</sub>, a species most commonly produced by the ATP-dependent phosphorylation of PI(4)P by a **PIP kinase** (ATP:phosphatidylinositol 4-phosphate 5-phosphotransferase, EC 2.7.1.68). Although PI(4,5)P<sub>2</sub> is clearly the best characterized of the polyphosphoinositides, PI(3,4)P<sub>2</sub> and PI(3,5)P<sub>2</sub> species have also been found among a diverse array of eukaryotic species, including plants (30–32). In mammals, PI(3,4)P<sub>2</sub> is synthesized primarily through the degradation of PI(3,4,5)P<sub>3</sub> by a 5-phosphatase, with lesser amounts generated via the 4-phosphorylation of PI(3)P and 3-phosphorylation of PI(4)P (33,34). In plants, the 4-phosphorylation of PI(3)P is the only documented route of PI(3,4)P<sub>2</sub> synthesis (30); the 5-dephosphorylation of PI(3,4,5)P<sub>3</sub> to produce PI(3,4)P<sub>2</sub> is doubtful, given that PI(3,4,5)P<sub>3</sub> has not been detected in any plant species (35). Although the specific route of PI(3,5)P<sub>2</sub> synthesis has yet to be confirmed in plants, the 5-phosphorylation of PI(3)P has to be considered the most likely, given that both animals and yeast generate PI(3,5)P<sub>2</sub> in this manner (31, 36).

In animal cells the synthesis and turnover of polyphosphoinositides play an essential role in the response of animal cells to various agonists (37), and in yeast

polyphosphoinositides (or their breakdown products, DAG and inositol trisphosphate) are involved in the regulation of cell proliferation and membrane trafficking (38, 39). Polyphosphoinositides, and their corresponding lysophospholipids, have also been detected in many plant tissues (2, 35, 40, 41) although PIP and PIP<sub>2</sub> species represent < 1% each of the total inositol lipid. In contrast, PI accounts for ~ 93% of the total inositol lipid but < 10% of total lipid phosphorus in plant cells (35).

PI 3-kinase, PI 4-kinase, and PIP 5-kinase activities have been measured in plasma membranes isolated from a number of plant species (2, 42–44). PI 4-kinase activity has also been characterized in soluble fractions (45) and in nuclear membranes of plant cells (46). The soluble PI 4-kinases have molecular weights in the 80-kDa range (45) whereas the membrane-associated enzymes have reported molecular weights ranging from 65 kDa to 500,000 kDa (42, 47).

The existence of both membrane and soluble PI 4-kinases has been confirmed by molecular studies. The cloning of PI 4-kinase cDNAs from animals and yeast has shown that there are two distinct isoforms that differ in size, subcellular location, and presence or absence of specific motifs (48). The smaller isoforms correspond to proteins ranging from ~ 90 to 125 kDa that are primarily found in the cytosol or associated with the Golgi. In contrast, the second class represents PI 4-kinases that are considerably larger (200–230 kDa) and are strictly membrane associated. The plant PI 4-kinase cDNAs that have been reported to date are predicted to encode products that generally fall into similar classes. An *Arabidopsis* cDNA encoding a 126-kDa PI 4-kinase was identified that showed greatest sequence homology to the smaller PI 4-kinase isoforms of animals and yeast (49). A partial cDNA corresponding to a distinct *Arabidopsis* PI 4-kinase isoform has also been identified (50). Western blot analysis using antibodies raised against the encoded partial protein sequence established the size of the complete polypeptide to be 205 kDa. The 205-kDa enzyme is associated with microsomal membranes and possesses a pleckstrin homology domain, features common to the larger PI 4-kinase isoforms of animals and yeast.

The cDNAs encoding the 126-kDa and 205-kDa PI 4-kinase isoforms described above appear to represent the complete complement of PI 4-kinase genes found in *Arabidopsis* (51). It remains to be determined if the smaller isoforms purified from plasma membranes (45, 47) represent the products of new, uncharacterized plant PI 4-kinase genes, or result from the proteolytic

cleavage or alternative splicing of either of the two documented isoforms.

Similar to the PI 4-kinases, animal and yeast PIP 5-kinases can also be categorized into two families, designated types I and II, based on their structural and biochemical properties. Type I PIP 5-kinases favor PI(4)P as the substrate, whereas type II enzymes preferentially utilize PI(5)P (each yielding PI(4,5)P<sub>2</sub> as the end product). Both types also vary according to their ability to recognize D-3 PI substrates (reviewed in 52, 53). The *Arabidopsis* PIP 5-kinase cDNA characterized by Mikami and coworkers (54) encodes a 638-amino acid product that is equally divergent from both of these families. Furthermore, the genomic sequences of additional candidate *Arabidopsis* PIP 5-kinase genes (accession Nos. U95973, AF007269, and Y12776) are equally difficult to classify as either type I or type II enzymes based on amino acid sequence homology. Although these observations suggest that plants may possess a novel class of PI(4)P 5-kinase, an analysis of the substrate specificities and subcellular localization of individual plant isoforms is clearly warranted in order to establish their specific role within the plant cell.

Four distinct classes of PI 3-kinases have been characterized in animals that differ according to their substrate specificities and their ability to complex with specific regulatory adaptor proteins (55). Plants and yeast, in contrast, appear to possess a single type of PI 3-kinase, one that exclusively phosphorylates PI to produce PI(3)P. PI(4)P and PI(4,5)P<sub>2</sub> are not recognized as substrates. Two soybean cDNAs encoding this class of PI 3-kinase have been characterized (44). Although closely related in size (812 and 814 amino acids) and sequence identity (98%), these two genes were differentially expressed during root module organogenesis. The modulation of gene expression for one isoform was coincident with the membrane proliferation during nodulation, lending support to the hypothesis that, similar to their yeast counterparts, plant PI 3-kinases participate in events associated with membrane trafficking. A PI 3-kinase cDNA was also characterized from *Arabidopsis* (56). Normal growth and development were severely inhibited in transgenic plants that expressed antisense constructs of this cDNA, demonstrating the essential nature of this gene in plants.

Similar to their animal counterparts, a growing body of literature suggests that polyphosphoinositides and their metabolites function as regulators of a variety of cellular processes in plants. These include responses to light, osmotic stress, and pathogen attack.

In addition, polyphosphoinositides are believed to participate in the regulation of the cytoskeletal architecture of the cell and the processes controlling membrane trafficking. Some of these functions are believed to be mediated by the ability of polyphosphoinositides to alter the activities of several enzymes, including protein kinases (57), the plasma membrane ATPase (58), and certain isoforms of phospholipase D (59). For a comprehensive description of the functions of polyphosphoinositides in plants, several recent reviews are recommended (35, 40, 41, 51).

### C. Phosphatidylserine and Phosphatidylethanolamine

In yeast PS is synthesized from CDP-diacylglycerol and serine, a reaction catalyzed by the enzyme CDP-diacylglycerol:L-serine O-phosphatidyltransferase (**PS synthase**, EC 2.7.8.8). Plant PS synthase activity was originally reported in spinach leaf microsomes (10) and has since been detected in many other plant tissues (2). The recent characterization of a wheat cDNA encoding a PS synthase provides definitive evidence that plants are capable of producing PS directly from CDP-diacylglycerol (60). The wheat cDNA encodes a hydrophobic 239-amino acid polypeptide that was recovered through a heterologous screening strategy intended to identify cDNAs whose expression in yeast resulted in enhanced aluminum tolerance. Although the mechanism by which PS synthase activity could serve to increase aluminum tolerance in yeast was not clear, aluminum-stressed wheat roots showed increased accumulation of PS synthase transcripts, suggesting that the enzyme also plays some role in this phenomenon in its native environment. Overexpression of the wheat PS cDNA in transgenic *Arabidopsis* proved to be very effective in increasing the cellular PS content. Though normally found only in trace quantities in plants, PS represented > 15% of the labeled phospholipid detected in the transgenic *Arabidopsis* after a 24-h incubation with ortho-<sup>32</sup>P. Interestingly, overexpression of the wheat cDNA in both *Arabidopsis* and tobacco led to the formation of necrotic lesions on leaves. It was hypothesized that overaccumulation of PS could have resulted in increased PS on the outer surface of these cells, a condition which induces an apoptotic response in animals (61).

In yeast PS is a precursor to both PE and PC (7). PS is first decarboxylated to PE, a reaction catalyzed by **PS decarboxylase** (EC 4.1.1.65) (62), and then PE is sequentially methylated to PC by the action of two

N-methyltransferases, which utilize S-adenosylmethionine as the methyl donor. The first of these enzymes **PE N-methyltransferase** (EC 2.1.1.17) catalyzes the methylation of PE to phosphatidyl methylethanolamine (PME) and the other enzyme **phospholipid N-methyltransferase** catalyzes the two methylations necessary to convert PME to PC.

PS decarboxylase activity has also been measured in a number of plants (see 2). Thus some plant tissues, like yeast, are capable of synthesizing PE without the participation of DAG. The presence of PE methyltransferases in plants would also mean that PC could be synthesized from PE. This has led to the suggestion that all plant phospholipids could be synthesized without the involvement of DAG.

The methylation of PE to PC in plants has not been confirmed, however, although plant cDNAs encoding phospholipid N-methyltransferase activities have been isolated. Computer-based homology searches of plant EST databases resulted in the identification of *Arabidopsis* and soybean cDNAs encoding proteins (162 and 164 amino acids, respectively) that displayed low but significant sequence homology to the yeast phospholipid N-methyltransferase (R.E. Dewey, A. J. Kinney, unpublished results). The substrate specificities of the plant enzymes were established by expressing the *Arabidopsis* and soybean cDNAs in yeast mutants lacking either PE methyltransferase or phospholipid N-methyltransferase activities (or both), followed by enzymatic analysis. Similar to the yeast phospholipid N-methyltransferase, the plant enzymes were capable of methylating both PME and PDME.

Negligible activity of the plant N-methyltransferases was detected using PE as a substrate (R.E. Dewey, A. J. Kinney, unpublished results) suggesting that PE is not directly methylated in either soybean or *Arabidopsis*. This is supported by the classic radiotracer studies of Datko and Mudd in the 1980s (see reference 2 for a detailed review of these studies). More recent radiotracer evidence and some very thorough computer modeling studies (63) presented clear evidence that the major methylation flux in tobacco is via phosphoethanolamine and not CDP-ethanolamine or PE. The recent cloning and characterization of **phosphoethanolamine N-methyltransferase** cDNAs from spinach (8) and *Arabidopsis* (9) provide additional support for this pathway. Thus, while most plant phospholipids can be synthesized via CDP-diacylglycerol, it appears that the major pathway for synthesis of PC is via diacylglycerol.

#### IV. BIOSYNTHESIS OF DIACYLGLYCEROL IN PLANTS

Diacylglycerol, a precursor of PC and PE in plants, is made from the dephosphorylation of PA to form DAG and inorganic phosphate. The reaction is catalyzed by the enzyme **phosphatidate phosphohydrolase** (EC 3.1.3.4). This enzyme has been detected in organelle, membrane, and soluble fractions of a number of plant tissues (2, 64, 65). A microsomal phosphatidate phosphohydrolase has been purified to apparent homogeneity as a 49-kDa species from avocado (66).

Another enzyme that has the potential of influencing the flux of fatty acids through the PA, DAG, and CDP-DAG pools is **diacylglycerol kinase** (EC 2.7.1.107). Opposing the reaction catalyzed by phosphatidate phosphohydrolase, diacylglycerol kinases direct the synthesis of PA through the ATP-dependent phosphorylation of DAG. Although the influence of this enzyme is generally not considered to be of major consequence in the de novo synthesis of the major phospholipids or triacylglycerols, in animal systems it is clearly an essential component of inositol lipid signaling pathways. Similar to the CDP-diacylglycerol synthase mutant described above, retinal degeneration is observed in *Drosophila* possessing mutations in an eye-specific diacylglycerol kinase locus due to their inability to regenerate essential PI pools (67).

Diacylglycerol kinase activities have been documented in several plant species (68–70), and the isolation of their corresponding cDNAs from *Arabidopsis* and tomato has been reported (71, 72). The identification of a calmodulin-binding diacylglycerol kinase isoform from tomato lends further support to the speculation that the plant enzymes function primarily as components of signal transduction pathways (72).

#### V. SYNTHESIS OF PHOSPHATIDYLETHANOLAMINE AND PHOSPHATIDYLCHOLINE FROM DIACYLGLYCEROL

Flux modeling experiments in tobacco support the idea that the flux of ethanolamine into PE is split equally between PS decarboxylation (or base exchange; see below) and incorporation of phosphoethanolamine via CDP-ethanolamine and diacylglycerol (63). Phosphoethanolamine is probably derived from free or phosphorylated serine by decarboxylation (73, 74) although no enzyme operating on anything other than

phosphatidylserine has been convincingly demonstrated. In contrast, it is apparent that choline in plants is not synthesized via a free base pathway but by the methylation of phospho- and phosphatidylmonooethanolamine (see 2, 74). Furthermore, the bulk of the flux into choline compounds is likely initiated via the methylation of phosphoethanolamine (63). Free choline may then be synthesized by dephosphorylation of phosphocholine. Evidence from many different plant families supports the idea that PC is synthesized by the methylation of PME derived from methylated ethanolamine phosphate or by conversion of phosphocholine, also from methylated ethanolamine phosphate, to CDP-choline (2, 74). Both pathways utilize DAG as the source of glycerol and fatty acids (see Fig. 1). Free choline is rapidly incorporated into PC (2), suggesting that the plants can also make PC from choline reserves or exogenous choline. This hypothesis is supported by the observation that methylation of phosphoethanolamine is repressed by free choline in plant tissue cultures (75). Thus, in addition to the phosphoethanolamine methyltransferase described above, three types of enzymes are needed to make PE and PC using DAG: aminoalcohol kinases, phosphoaminoalcohol cytidylytransferases, and aminoalcohol phosphotransferases. There is good evidence that all these activities exist in plants for both the ethanolamine and the choline pathways.

The phosphorylation of ethanolamine is catalyzed by the enzyme **ethanolamine kinase** (ATP:ethanolamine phosphotransferase, EC 2.7.1.82) and the phosphorylation of choline is mediated by an equivalent enzyme, **choline kinase** (ATP:choline phosphotransferase, EC 2.7.1.32). The yeast gene for choline kinase (CK1) was cloned by complementation of a choline kinase mutant and was shown to encode a polypeptide of about 66 kDa (76), which corresponded to the native molecular weight of a partially purified yeast choline kinase (77). However, when the CK1 gene was expressed in *E. coli*, both choline kinase and ethanolamine kinase activities were observed. Disruption of the CK1 gene in wild-type yeast resulted in the loss of both choline and most of the ethanolamine kinase activities (76). Thus it is possible that both reactions are catalyzed by the same enzyme in yeast. In contrast, the bulk of the biochemical evidence favors the hypothesis that there are separate ethanolamine and choline kinase in plants (see 2 for discussion), and this hypothesis is supported by recent molecular studies. Using an *Arabidopsis* EST that displayed homology to yeast and mammalian choline kinases, three distinct choline kinase isoforms were isolated from soybean (78).

Two of the cDNAs, designated GmCK1 and GmCK2, were full-length encoding proteins of 359 and 362 amino acids, respectively. Although the third isoform, GmCK3, was reported to be considerably larger than the other two, its final predicted size was unknown because the characterized cDNA was not full length. Subsequent work, however, revealed the GmCK3 cDNA to encode a 650-amino acid protein, with most of its increase in size derived from a degenerate 11-amino acid sequence that is repeated 23 times at the N-terminus of the protein (D.E. Monks, R.E. Dewey, unpublished results). Expression of the three soybean choline kinase cDNAs in yeast and/or *E. coli* demonstrated that each functions strictly as a choline kinase; ethanolamine kinase activity was negligible (78; R.E. Dewey, D.E. Monks, unpublished results).

The discovery of two distinct size classes of soybean choline kinases may provide an explanation for discrepancies in molecular-weight estimations previously reported in the literature. A smaller, 36-kDa choline kinase from soybean reported by Wharfe and Harwood (79) may represent the product of the GmCK1 and/or GmCK2 genes, whereas larger choline kinase species (58 and 60 kDa) reported by Mellor and coworkers (80), also from soybean, may in fact be the product of GmCK3. Although computer searches could detect no entries in protein databases that displayed significant amino acid sequence homology to the large N-terminal extension found on the GmCK3-encoded protein, the 11-residue repeat structure is reminiscent of the 11-mer repeats of apolipoproteins and choline phosphate cytidylyltransferase that mediate the association of these proteins with membrane phospholipids (discussed below). Consistent with this hypothesis, a considerable amount of choline kinase activity was observed in the microsomal fraction when GmCK3 was expressed in yeast; in contrast no membrane-associated choline kinase activity was detected upon expression of GmCK1 or GmCK2 in yeast (R.E. Dewey, D.E. Monks, unpublished results).

The conversion of ethanolamine phosphate and choline phosphate to their respective CDP-aminoalcohols is catalyzed by phosphoaminoalcohol cytidylyltransferases. **Choline phosphate cytidylyltransferase** (CTP:choline phosphate cytidylyltransferase, EC 2.7.7.15) has been extensively characterized in animals (81, 82) and shown to play an important regulatory role in membrane biosynthesis in regulating the flux through the CDP-choline pathway for PC biosynthesis (5). The animal enzyme comprises four distinct subdomains: an amino-terminal nuclear localization signal; a highly conserved catalytic core; a

membrane/lipid binding domain; and a carboxyl-terminal phosphorylation domain (82). The discovery of the nuclear targeting signal is consistent with immunolocalization studies that unexpectedly revealed the nucleus, rather than the cytosol, to be the intracellular compartment where the majority of the protein resides. The lipid/membrane-binding domain consists of three 11-residue repeats that are predicted to form an amphipathic alpha helix. This region is critical not only for mediating the reversible association of the enzyme with membranes, but also for regulating enzymatic activity per se. Current models suggest that in the absence of activating lipids, the membrane/lipid-binding domain inhibits the catalytic activity of the enzyme; lipid binding increases enzymatic activity > 50-fold by ameliorating the inhibitory effects of this region (82, 83). The function of the carboxyl-terminal phosphorylation domain is less clear. Although early studies demonstrated that the membrane-associated, enzymatically active choline phosphate cytidylyltransferase was dephosphorylated, and the soluble, inactive form of the enzyme was highly phosphorylated, recent studies using phosphorylation-deficient mutants revealed that the modulation of phosphorylation does not appear to be critical either for the reversible translocation of the enzyme to membranes or in maintaining cellular growth (82).

Using an elegant yeast complementation strategy, Nishida and colleagues (84) recovered cDNAs corresponding to four distinct choline phosphate cytidylyltransferase isoforms from *Brassica napus*. Subsequently, choline phosphate cytidylyltransferase clones from *Arabidopsis* and pea were also reported (85, 86). Although extensive sequence homology between the plant enzymes and their animal and yeast counterparts is observed only across the region defined as the catalytic domain, the presence of a predicted amphipathic alpha helical motif immediately following the catalytic domain suggests that plant choline phosphate cytidylyltransferases may possess membrane/lipid binding domains that are functionally similar to those observed in animals.

Because of the polyploid nature of *Brassica napus*, the initial observation of multiple choline phosphate cytidylyltransferase isoforms in this species was not considered surprising, as functionally equivalent genes could have been derived from different ancestral parents (84). The presence of multiple isoforms is also evident in pea and soybean (86, 87). Given the recent discovery of a previously unrecognized, distinct choline phosphate cytidylyltransferase isoform in mammals, however, consideration of the possibility

that different isoforms serve unique cellular functions is warranted. The newly discovered animal choline phosphate cytidylyltransferase differs from the well-characterized isoform in its subcellular location (cytoplasm as opposed to nucleus) and tissue-specific expression profile (88). With the availability of numerous plant choline phosphate cytidylyltransferase cDNAs, the tools are now available to dissect and define the function of specific structural domains of the protein and test whether different isoforms are functionally distinct.

The enzyme **ethanolamine phosphate cytidylyltransferase** (CTP:ethanolamine phosphate cytidylyltransferase, EC 2.7.7.14) has not received much attention from plant scientists but, like cholinephosphate cytidylyltransferase, it has also been well studied in yeast and animals (89, 90). Human, rat, and yeast cDNAs encoding ethanolamine phosphate cytidylyltransferases have been isolated and characterized (91–93). Not surprisingly, significant homology is observed between portions of the ethanolamine phosphate cytidylyltransferases and the catalytic domains of choline phosphate cytidylyltransferases. Uniquely found in the ethanolamine phosphate cytidylyltransferase enzymes, however, is a repeat of the first half of the catalytic domain, located adjacent to the “full-length” version of this region. Although considerable amino acid sequence homology is shared between the catalytic regions of the two aminoalcohol phosphate cytidylyltransferases, this step of the parallel PE and PC biosynthetic pathways is the only one where no functional redundancy has been reported in any biological system (89). Ethanolamine phosphate cytidylyltransferase was first reported in plants in the membrane fractions of mitochondria and ER from castor bean endosperm (94). Curiously, most of the castor bean ethanolamine phosphate cytidylyltransferase activity (80%) was in the mitochondria, whereas the choline phosphate cytidylyltransferase is found mainly in the ER and cytosol (94). The mitochondrial ethanolamine phosphate cytidylyltransferase has recently been partially purified from postgermination castor bean endosperm (95). The castor bean enzyme, predicted to have a molecular mass of 30–35 kDa, was modestly activated by the addition of phospholipids. Membrane association of both the mitochondrial and ER-localized ethanolamine phosphate cytidylyltransferases of castor bean appears to be much stronger than that observed with their mammalian counterparts, as the plant enzymes remained completely insoluble when treated with salt or detergent concentrations that completely solubilize the animal enzymes (95).

PE and PC are synthesized from their cognate CDP-aminoalcohol and DAG, reactions catalyzed by the aminoalcohol phosphotransferase enzymes **cholinephosphotransferase** (CDP-choline:1,2-diacylglycerol cholinophosphotransferase, EC 2.7.8.2) and **ethanolaminephosphotransferase** (CDP-ethanolamine: 1,2-diacylglycerol ethanolaminephosphotransferase, EC 2.7.8.1). These enzymes have been measured and characterized in many different plant tissues (see 2), but they have remained recalcitrant to solubilization and purification. The first cDNA encoding a plant aminoalcohol phosphotransferase was obtained from soybean by complementation of a double-mutant yeast strain defective in both CPT1 and EPT1 activities using a colony autoradiography assay (96). The predicted amino acid sequence of the soybean protein showed equal similarity to both the yeast CPT1 and EPT1 proteins, and inhibition studies suggested that the plant enzyme shared equal affinity for both CDP-choline and CDP-ethanolamine. These observations led to the speculation that the enzyme encoded by the soybean cDNA functions as a general aminoalcohol phosphotransferase and as a result, was designated AAPT1 (*aminoalcohol phosphotransferase 1*). Although this report presented compelling evidence that plants possess enzymes that can function as both choline and ethanolamine phosphotransferases, Southern blot data revealed that additional isoforms of the gene were likely to reside in the soybean genome, leaving open the possibility that aminoalcohol phosphotransferases with more restrictive substrate specificities may exist, similar to the situation found in yeast.

The recent characterization of cDNAs encoding two AAPTs from *Arabidopsis* provides even further evidence that plants utilize broad-specificity aminoalcohol phosphotransferases (97). Southern blot analysis suggested that the two *Arabidopsis* AAPT cDNAs encode the complete complement of AAPT enzymes found in that species. Although subtle differences in substrate preference, and  $\text{Ca}^{2+}$  and CMP inhibition profiles were observed among the two *Arabidopsis* AAPTs and the soybean AAPT1 gene product, it was clear that all three plant enzymes could effectively utilize either CDP-choline or CDP-ethanolamine to produce PC and PE, respectively. An additional AAPT cDNA has been isolated from Chinese cabbage; however, the enzymatic properties of the encoded protein were not reported (98).

Although the cytidyltransferase-catalyzed steps are generally recognized as the most important in regulating the net biosynthesis of PC and PE within the cell, the ease with which the reverse AAPT reactions

can be detected in vitro suggests that factors altering the directionality of this activity could also influence the ultimate PC and PE composition of eukaryotic membranes. This may be particularly relevant during seed development in oil seeds, where the reverse reaction of choline phosphotransferase is believed to function in supplying polyunsaturated fatty acids directly into DAG pools destined for triacylglycerol biosynthesis (99). Consistent with previous observations using isolated plant microsomes, the activities of the soybean *AAPT1* gene and two *Arabidopsis* AAPT isoforms described above were shown to be readily reversible when expressed in yeast (97). The ability of CMP to inhibit the forward reaction and provide a necessary substrate for the reverse reaction, makes this compound a good candidate for regulating the direction of AAPT-catalyzed reactions *in vivo*. Further investigation of endogenous CMP pools in plants and their influence on phosphatidylamine metabolism, particularly during seed development, is warranted.

## VI. PHOSPHOLIPID MODIFYING ENZYMES

There are a number of enzyme activities in plant cells that modify either the polar or lipid portion of phospholipid molecules. The best documented polar modification enzymes are those which catalyze phosphoaminoalcohol exchange of preexisting phospholipids with a similar or different heads. The best characterized of the head group exchange reactions is the synthesis of PS by the reversible exchange of serine with the headgroup of PE by the  $\text{Ca}^{2+}$ -dependent, microsomal enzyme **PE:L-serine phosphatidyltransferase** (10, 100). No progress has been reported in the characterization of this enzyme or in understanding the function of the serine/ethanolamine exchange reaction since an earlier review on the subject (2). This is also true of the PI/inositol base exchange reaction in castor bean endosperm (2) although a similar reaction has been measured in a number of animal cells (101).

Only marginally better understood than these headgroup modifying enzymes are enzymes that exchange fatty acids with phospholipids, especially PC. The activity of an enzyme capable of catalyzing the exchange of 18:1-CoA with the fatty acid at the sn-2 position of PC (LPCAT EC 2.3.1.23) (**acyl-CoA:lysophosphatidylcholine acyltransferase**) has been assayed in a number of plant tissues (102). This enzyme has a potentially important role to play in plant lipid

metabolism since PC is the substrate for fatty acid desaturation of 18:1 to linoleic acid. However, little is known about the structural and functional properties of the LPCAT protein. Recently, Tumaney and Rajasekharan (103) used photoaffinity labeling of soybean LPCAT with azidophospholipids to demonstrate molecular masses of 54 kDa and 114 kDa for putative LPCAT proteins. These relative masses are in agreement with earlier studies in castor bean endosperm using photoaffinity probes (104).

Plants also contain a **phospholipid:diacylglycerol acyltransferase** (PDAT) that can transfer the *sn*-2 acyl chain from PC to DAG, forming lyso-PC and TAG (105). This enzyme is thought to play a role in TAG biosynthesis and is related to the **lecithin:cholesterol acyltransferase** (LCAT) enzyme family found in animal cells (106). It is quite possible that other LCAT-like enzymes are present in plants since ESTs for LCAT homologs have been found in many plant cDNA libraries (A.J. Kinney, unpublished data).

Finally, there is an enzyme in animals and plants which transfers an acyl group to a polar headgroup. **N-acylphosphatidylethanolamine synthase** (NAPES) was first identified in plants in cotton seed extracts (107) and appears to be an ATP-, calcium-, and CoA-independent acyltransferase that catalyzes the direct acylation of PE with free fatty acids. This 64-kDa microsomal protein was subsequently purified from cottonseed homogenates and shown to be highly specific for PE (108). It is not known if N-acylphosphatidylethanolamine itself plays an important physiological role in plants, but NAPES is possibly involved in scavenging free fatty acids (108).

### I. INTRODUCTION

Oxidative and reductive processes play an important role in foods. They influence not only the taste but also the texture, appearance, shelf life, nutritional value, and process tolerance of food products. Both enzymatic and nonenzymatic redox processes are involved. In some cases redox processes lead to undesirable effects such as off-flavor, reduced shelf life, or textural problems. In other cases, they contribute in a positive way to the final aroma, an improved texture, a more desirable appearance, or an increased shelf life. Controlling the redox behavior in food systems during all stages of processing and storage is therefore of utmost importance.

Up until now redox reactions in foods were controlled mainly by carefully selecting raw materials, by adapting process conditions, by adding chemicals or antioxidants, or by designing air-tight packaging materials. As yet, little attention has been paid to tailor redox reactions in foods by the addition of oxidoreductases or by changing the profile or content of oxidoreductases in food raw materials by genetic tools. Presumably, the major bottleneck for the application of oxidoreductases to foods is that economically efficient enzyme production is, with a few exceptions, still

not feasible. In addition, public concerns about the use of recombinant enzymes in food products is slowing down their market introduction.

In this chapter the current and potential usage of oxidoreductases in controlling the taste, texture, appearance (i.e., color), shelf life, and the nutritional value of food products will be discussed. Increasingly, redox enzymes are being used for biosensor applications in food systems. This topic will not be discussed in this chapter, however. **Table 1** lists the most important redox enzymes and their functions in food systems. Most attention will be paid to the market segments bakery, beverages, and dairy and to oxidases, since relatively little is known about role and applications of reductases in food systems. Furthermore, the emphasis will be on added enzymes and not on enzymes already present in the food product constituents. For detailed information on the properties of the individual oxidoreductases the reader is referred to in Sec. IIA of this book.

### II. TASTE

Many oxidoreductases play a role by influencing the taste profile of food products. They are involved in the *in vivo/in situ* biogenesis of desirable aroma compo-

**Table 1** Overview of the Main (Potential) Applications of Oxidoreductases in Food Products

Enzymes	Taste	Texture	Appearance	Shelf life	Nutritional value
Lipoxygenases (LOX)	In situ and in vitro (off)-flavor production	Dough extensibility and strength	Flour bleaching		Destruction vitamin A
Alcohol oxidases and dehydrogenases (AO, ADH) (I±LOX)	In situ and in vitro flavor production			AO plus catalase, O <sub>2</sub> removal	
Sulfhydryl oxidases (SOX)	Removal of cooked flavor in UHT-milk	Dough strengthening in combination with POX			
Peroxidases (POX, LPO)	In vitro flavor production and debittering	Crosslinking biopolymers	Assisting PPO in color formation	LPO, antimicrobial agent	
(Poly)phenol oxidases (PPO)	Debittering of coffee, cacao, and olives		(Dis)coloration; in vitro production of colors	Laccase, O <sub>2</sub> removal	
Carbohydrate oxidases (GOX, HOX, PYROX)	GOX, mild acid production	Dough strengthening via H <sub>2</sub> O <sub>2</sub> ; thickening agent		GOX plus catalase, O <sub>2</sub> removal	
Ascorbic acid oxidase (AAO)			Browning	AAO plus catalase, O <sub>2</sub> removal	Destruction vitamin C
Xanthine oxidases (XO)				Antimicrobial agent	
Superoxide dismutases (SOD)				Removal reactive O species with catalase	
Catalases				Removal excess H <sub>2</sub> O <sub>2</sub>	
Cholesterol oxidoreductases					Cholesterol reduction

nents, in the in vitro production of flavoring topnotes, and in the endogenous formation of off-flavors. The main redox enzymes are discussed below.

### A. Lipoxygenases

Lipoxygenase (LOX, EC 1.13.11.12; see [Chapter 43](#), for detailed information), formerly known as lipoxygenase or carotene oxidase, is an iron-containing dioxygenase which catalyzes the oxidation of polyunsaturated fatty acids containing *cis*, *cis*-1, 4-pentadiene groups (linoleic, linolenic, and arachidonic acids) to the corresponding conjugated *cis*, *trans* dienoic mono-hydroperoxides. In addition LOX also accepts a relatively broad range of phenolic compounds as substrates (1) and is capable of oxidizing other substrates than the actual substrate. This process is known as co-oxidation and includes compounds like carotenoids and polyphenols (2).

LOX is one of those endogenous enzymes that play an important role in both flavor generation and off-flavor formation in virtually all food products derived from plant raw materials. Depending on the final concentration and the type of food product the same flavor component can be a desired aroma component or an off-flavor at higher concentrations. For example, C6-aldehydes and alcohols derived by the LOX-catalyzed oxidation of (poly)unsaturated fatty acids have, in most cases, a positive effect on the aroma profile (e.g., wines and juices), but in other beverages, have an undesired flavor effect (e.g., beer). Likewise, endogenous LOX is known to generate carbonyl compounds in dough systems and hence influences bread flavor (3).

The formation of C6 compounds requires the sequential action of four enzymes of which two are redox enzymes, namely an acylhydrolase, a lipoxygenase, a hydroperoxide lyase, and a yeast-derived alcohol dehydrogenase (4). Typically, off-flavor formation is prevented by using crop variants deficient in LOX isoenzymes, either by screening or by genetic tools (5) or by controlling the oxygen levels during processing (6), as well as by removing the malodorous oxidation products afterwards. The deodorization of off-flavors can be achieved by physical techniques such as adsorption, or enzymatically by converting the undesired aldehydes (e.g., with aldehyde dehydrogenase/oxidase), or alcohols (e.g., with alcohol oxidase) into their corresponding less flavorful carboxylic acid. The use of redox enzymes for this purpose has been claimed for several products such as margarine, cream, fish oil, noodles, cooked rice, and soybean products (7, 8).

LOX is also used for the in vitro production of several natural topnote flavors, which are mainly added to beverages and dairy products to tailor the flavor profile (9, 10). Typical examples include the conversion of polyunsaturated fatty acids into various short to medium-chain aldehydes/alcohols (13), or into S(-)- $\delta$ -decalactone (butter flavor; 12). Well-known fatty acid-derived flavoring aldehydes/alcohols include the above mentioned C5 and C6 compounds, as well as (E2, E6)-nonadienal (cucumber), 1-octen-3-one (field mushroom), (Z5)-octadien-3-one (geranium leaves), (E3, E5)-undecatriene (blasamic), and (E3, Z5, Z8)-undecatetraene (seaweed). Depending on the degree of unsaturation and the regioselectivity of the lipoxygenase, different hydroperoxy compounds are formed, from which the above-mentioned compounds can be derived by subsequent enzymatic reactions. For (Z3)-hexenol, linolenic acid is used as a substrate, while for most of the other aldehydes/alcohols higher unsaturated fatty acids are required. The production of (Z3)-hexenol has recently been commercialized using plant homogenates (e.g., alfalfa sprouts, green peppers) which are relatively rich in hydroperoxide lyase, the enzyme required to split the hydroperoxide fatty acid into smaller fragments. The generated (Z3)-hexenal was converted into (Z3)-hexenol using the reductive enzymatic power of bakers yeast (13). A very elegant approach has been taken recently by Givaudan-Roure. To unify all three enzymes involved in the formation of (Z3)-hexenol, they have cloned and overexpressed both soybean LOX and the hydroperoxide lyase from banana in bakers yeast. In this way they have developed a “single-step” process which produces (Z3)-hexenol in relatively high yield (14).

For the production of lactones a different strategy has to be followed after the formation of the linoleic acid hydroperoxide. It involves the fermentative  $\beta$ -oxidation of the hydroperoxide intermediate by the yeast *Pichia etchellsii*, and the subsequent cyclization of 5-hydroxydecanoic acid to the corresponding S(-)- $\delta$ -decalactone (10).

As shown by Quest International (1), lipoxygenases also accept a relatively broad spectrum of phenolic compounds as substrates. Of interest to the flavor industry are the LOX-catalyzed conversions of isoeugenol and coniferyl benzoate from Siam resin into vanillin. At present the commercialization of these biotransformations is hampered by the fact that isoeugenol is not readily available and that coniferyl benzoate is difficult to handle in a reactor.

Other well-known reactions of LOX include the co-oxidation reaction of carotenoids to yield, among

others,  $\beta$ -ionone (2, 15). More recently is the generation of a toasted or cookie-like flavor in starchy materials by a combination of LOX and an  $\alpha$ -amylase (16).

## B. Alcohol Oxidases and Dehydrogenases

In general, aldehydes are more potent flavor compounds than their alcoholic counterparts. Hence, alcohol oxidases are interesting enzymes for the in vitro production of flavoring preparations which, among others, can be applied in beverages. Typical examples include the use of methanol oxidase from *Pichia*, *Hansenula*, and *Candida* (17) for the production of natural acetaldehyde from ethanol. This enzyme is induced during growth on methanol. At the end of the logarithmic growth phase cells are harvested and incubated with ethanol. In this way concentrations of  $\sim 1.5\%$  natural acetaldehyde can be achieved, which can be concentrated further to the desired application level. From yeast to yeast the substrate specificity of the alcohol oxidase is different. Hence, this procedure can also be used to convert other alcohols, such as hexenol and other long-chain alcohols, to their corresponding aldehyde (10, 18).

As alternatives to alcohol oxidases the corresponding dehydrogenases could in principle be used (19). A severe drawback, however, is that these dehydrogenases require the expensive cofactor NAD(P) $^+$  instead of (cheap) oxygen as an electron acceptor. Although various sophisticated NAD(P) $^+$  cofactor regenerating systems have been designed and substantial cost reductions have been realized in this way, it is evident that in commercial applications oxidases are preferred over their dehydrogenase counterparts. The use of dehydrogenases for food purposes seems to be restricted to whole-cell conversions.

Vanillyl alcohol oxidase (VAO) from *Penicillium simplicissimum* is a special type of alcohol oxidase. Recently, it has been shown that this stable, flavin-containing enzyme has a very broad substrate specificity and readily converts *para*-substituted phenols into interesting flavor precursors or flavoring compounds (20–22). Apart from natural vanillin and coniferyl alcohol, different vinylphenols (e.g., *para*-vinylguaiacol) and allylphenols can be produced from cheap raw materials and oxygen as an electron acceptor. VAO can also be used for generation of flavor building blocks. To that end a natural mix of phenolic compounds could be treated with VAO to enrich foods or flavor preparations with a range of vinylic/allylic and aldehydic substances.

## C. Sulphydryl Oxidases

Sulphydryl oxidase (SOX, no EC number assigned; see [Chapter 41](#) for more details) catalyzes the formation of disulfide bonds from (protein) thiols. SOX is an Fe/Cu-containing glycoprotein and has been detected in bovine, human, goat, pig, rabbit, and rat milks (23). The enzyme is capable of oxidizing the sulphydryl groups of cysteine and glutathione, as well as milk proteins to their corresponding disulfides using molecular oxygen as electron acceptor (24). In practical applications bovine milk SOX may be added to UHT milk to reduce cooked flavors. Patents (see Refs. in 24) for this application have been issued. The enzyme has been immobilized on porous glass, and its effectiveness in ameliorating the cooked flavor has been demonstrated on a pilot scale using immobilized enzyme columns.

## D. Peroxidases

Peroxidases (POX, EC 1.11.1.7; see [Chapters 28](#) and [29](#) for more details) occur widely in nature and is the general name for a group of both highly specific and nonspecific enzymes which use hydrogen peroxide instead of oxygen as an electron acceptor. Peroxidases, especially the heme-containing ones, can catalyze a large number of different reactions including sulfoxidation, N-demethylation, oxidation, and hydroxylation and hence are of potential interest in the production of specific flavoring topnotes. A recent example involves the demethylation of methyl *N*-methylanthranilate (ex *Citrus*) to monomethylanthranilate (25). The latter compound is an important top-note flavor in Concord grapes. Soybean, horseradish, and microperoxidases were found to be convenient catalysts for this reaction. In addition POX gives rise to a fresh flavor profile when added to tomato paste (26).

## E. Polyphenol Oxidases

Polyphenol oxidases (PPO) are a group of several enzymes. Different activities can be found within this group: tyrosinase (monophenol monooxygenase, EC 1.14.18.1; see [Chapter 39](#)) converting a phenol into a catechol group; 1,2-diphenol oxidase or catechol oxidase (EC 1.10.3.1) converting catechol into an *o*-quinone, and laccase (EC 1.10.3.2; see [Chapter 40](#)) converting a 1,4-diphenol into *p*-quinone. Usually the first two activities are linked, as catechol is much more readily oxidized than a phenol. Most enzymes that catalyze 1,4-diphenol oxidation also act on 1,2-diphenols.

The bitter taste in many food products is often the result of the presence of polyphenolic compounds such as guaiacols. PPOs are capable of oxidizing these compounds and hence can be applied to reduce bitterness. At present the debittering of coffee beans (27), Adzuki beans (28), and cacao beans (29) by PPOs have been claimed. Another application involves the use of laccase to debittering olives by treating stoned, chopped olives in the presence of air at increased temperatures (30).

### III. TEXTURE

The use of oxidoreductases in texturizing food is based on their ability to crosslink proteins and/or polysaccharides. This property is of particular interest to improve the texture of dough and paste products (softness, volume, elasticity, crunchiness) or dairy products (mouth feel, appearance), and of fish and meat pastes. Basically, enzymatic crosslinking can occur via two routes:

1. Indirect via enzymatically produced hydrogen peroxide (e.g., glucose oxidase, hexose oxidase, ascorbic acid oxidase), or via the enzymatic production of radicals (e.g., peroxidase, lipoxygenase).

2. Direct via the oxidation of functional groups in the protein. Examples include the linkage of tyrosine and ferulic acid residues by tyrosinase and laccases, linkages of lysine residues by lysyl oxidase, or the formation of disulfide bridges by sulfhydryl oxidase.

An alternative, nonredox procedure for direct crosslinking is being explored using transglutaminases (see [Chapter 51](#)).

These enzymatic routes are being explored to replace chemical oxidizers, such as dehydroascorbic acid and potassium bromate. Replacement of the non-specific chemical compounds by redox enzymes could have the benefit of more specific and better-controlled oxidation processes. Other disadvantages of the chemical substances are related to safety and labeling issues. One of the major challenges in the baking industry is to find a good replacer for potassium bromate, which is a difficult task since bromate is still more effective and cheaper than the enzymatic alternative. The most important texturizing redox enzymes will be discussed below.

#### A. Lipoxygenases

A rich source of LOX is soybeans. Soybean LOX contains three distinct lipoxygenase isoenzymes, designated as L1, L2, and L3. These isoenzymes have

been isolated from seeds of commercial cultivars and have been well characterized (31, 32). Recent studies indicate that L2 has the greatest effect among LOX isoenzymes on dough extensibility and strength (33) and is also mostly responsible for the production of undesirable aroma compounds in bread doughs (34; see Sec. II, [Chapter 43](#)). For L3 an increase in foaming activity has been reported, as well as an overall improvement in breadmaking quality of wheat flour (35). The bakery yeast *Saccharomyces cerevisiae* also contains LOX. Recently, this enzyme was partially purified (36), but its potential, if any, on breadmaking remains to be established.

Nowadays, it is feasible to change the profile and content of LOX (iso)enzymes in plants either by classical means (5), or potentially by genetic modification. For example, by appropriate crosses, near-isogenic soybean seeds have been developed that lack either isoenzymes L1 and L3, or isoenzymes L2 and L3. These LOX-minus mutants still grow well in the field (37). In principle, transgenic plants lacking or overexpressing one or more LOX isoenzymes could be constructed and tailored to specific applications (38). To that end the heterologous expression of one or more soybean LOX isoenzymes in wheat could be of interest.

#### B. Sulfhydryl Oxidases

The action of SOX (see Sec. II, [Chapter 41](#), for general information) may be the same as those of chemical oxidizing agents, provided the formation of disulfide bonds is the primary mode by which these agents function. In extensive testing (39, 40) it was found that SOX alone has no influence on loaf volume, dough strength, or mixing tolerance. Also, relatively high concentrations using recombinant SOX from *Aspergillus awamori* did not have any significant positive effect (40). One reason could be that SOX has only a limited affinity for thiol groups in gluten proteins and as a result its application in the food industry seems to be limited to the removal of small off-flavor molecules (see Sec. II, [Chapter 41](#)).

#### C. Peroxidases

For detailed information about POX see Section II, [Chapters 28 and 29](#). Wheat flour contains a peroxidase that can crosslink phenolic constituents such as ferulic acid and vanillic acid. However, the pH optimum of the wheat enzyme is 4.5, and in the pH range of 5–6 of wheat doughs the activity is considerably lower than at pH 4.5 (41). Although the dough-improving effect of

peroxidase is well documented, the reactions involved in the dough are only poorly understood.

Model studies with peroxidase, glutathione, and cysteine indicate that sulphydryl and/or lysyl groups may be involved (42). Peroxidase-catalyzed reactions result in a decreased amount of lysine recovered from proteins after acid hydrolysis. Peroxidases, or the quinones formed by the enzyme, oxidatively deaminate lysyl residues to form lysylaldehydes, resulting in the formation of protein polymers, as was revealed by gel filtration. These aggregates could not be dissociated by detergents, which indicates that covalent bonds were formed. In addition, the dough-strengthening effect of peroxidases is also ascribed to the crosslinking of carbohydrates and the coupling of carbohydrates to proteins. The gelation of wheat pentosans is due to the oxidative dimerization of ferulic acid moieties, which are covalently linked to pentosans (43).

Recently, a study has been described showing the effect of different peroxidases on the baking performance of German "Kaiser" rolls (41). Deliberately sticky doughs were prepared in order to demonstrate the effects of added peroxidases. Especially the addition of soybean POX led to strengthening of wheat doughs as determined by the stability of the dough after "shaking" the dough for 1 min in a laboratory shaker. This improving effect was observed at both short and long fermentation times. Dough volume increased after application of these peroxidases. Compared with (GOX), the results of peroxidases are better or at least equal in terms of stability and volume.

In bread dough, peroxidases seem to act without the extra addition of hydrogen peroxide in spite of their peroxide dependence. This may indicate that peroxide is present in dough at sufficient amounts, or that it is generated as a result of the peroxidase reaction. In this way, substrate radicals formed by peroxidase can react with oxygen to form hydrogen peroxide. When this reaction is occurring, catalytic amounts of peroxide present in dough are sufficient to get the cycle started, and may explain why no hydrogen peroxide has to be added together with a peroxidase. An alternative explanation is that wheat contains endogenous oxidases, which are active enough to produce some hydrogen peroxide *in situ*. Indeed, the addition of hydrogen peroxide-producing enzymes such as GOX has a beneficial effect on baking (44–46).

In other systems than doughs, POX has been claimed as a thickening and stabilizing agent in, for example, ice creams, deserts, sauces, and jams and jellies (47). There is also a recent patent application (48) on the POX-catalyzed gelling of hemicelluloses to form

gels or viscous media for application as fat or gelatin replacer, as well as for flavor delivery, coating, or glazing.

## D. Glucose Oxidases

Glucose oxidase (GOX, EC 1.1.3.4; see [Chapter 30](#) for detailed information) catalyzes the conversion of glucose into the mild-tasting gluconic acid via glucono- $\delta$ -lactone and hydrogen peroxide. GOX complies with the FAO/WHO and GRAS requirements for food grade enzymes and is one of the few commercially available oxidases from *Aspergillus niger* and *Penicillium* strains at relatively low costs. Especially, the generation of hydrogen peroxide is believed to give the antiweakening effect in bread doughs (40). In a recent study by Hilhorst et al. (49) the effect of GOX on Dutch rusk dough was dough stiffening with a clear loss in extensibility. This made the overall effect quite undesirable. For comparison, they also tested peroxidase (see Sec. III.C above). This enzyme gave a dough-stiffening effect without loss in extensibility. The authors explain the difference by the fact that hydrogen peroxide from the GOX-catalyzed reaction oxidizes randomly and links the gluten network with the arabinoxylan network, whereas the peroxidase only increases the amount of crosslinks in the arabinoxylan fraction without affecting the gluten network or the coupling between the networks.

It has been found that synergistic effects occur when using a combination of oxidative enzymes like the combination of GOX and SOX (50). Furthermore, the dough has an increased stability.

## E. Hexose Oxidases

A newcomer in the field of redox enzymes for bakery products is hexose oxidase (HOX, EC 1.1.3.5) from red seaweeds. This glycosylated flavoprotein is related to GOX but has a broader substrate specificity toward hexose sugars, including oligomers. Like GOX, it acts on the C1-position of the sugar moiety (51). Recently, the enzyme from *Chondrus crispus* has been isolated, cloned, and overexpressed in several recombinant organisms such as *Pichia pastoris*, *Saccharomyces cerevisiae*, and *E. coli* (51, 52). However, the production levels of active enzyme are still poor at this moment and have to be improved. For this reason, and because *C. crispus* has a long standing tradition as an edible organism, efforts have been made to develop a large-scale production method with the use

of carrageenase, which reduces the viscosity of the crude extract (51).

For HOX similar applications can be envisaged as for GOX (see above). In particular, its application in bakery products is foreseen (53), since HOX is able to generate more H<sub>2</sub>O<sub>2</sub> owing to its broader substrate specificity, and hence should be more effective than GOX in dough strengthening. Likewise, combinations of HOX and H<sub>2</sub>O<sub>2</sub>-consuming enzymes, such as POX, may be envisaged.

Another enzyme with similar properties as HOX, isolated from *Acremonium strictum* T1, has been reported in the literature (54). The enzyme is called an oligosaccharide oxidase and is able to oxidize several di- and oligosaccharides at the anomeric site, yielding the corresponding di- and oligobionic acids. A detailed comparison between HOX and oligosaccharide oxidase performance in dough applications has not been made yet.

## F. Pyranose Oxidases

Pyranose oxidase (PYROX, EC 1.1.3.10; see Refs. 55–57, 59 for more detailed information) catalyzes the oxidation of several monosaccharides at the C2-position and is therefore different from GOX, which oxidizes glucose at the C1-position. While GOX is very specific, PYROX is able to catalyze other substrates such as maltose and pentoses (e.g., xylose). As a result, the PYROX oxidation product of glucose is 2-ketoglucose and not gluconic acid. At present, this enzyme has been purified from several white rot fungi and a *Bacidiomycetous* fungus (55–57). PYROX has also been reported to show significant activity toward D-glucono-1,5-lactone, which is produced by the GOX-catalyzed oxidation of glucose (58). So if PYROX is combined with GOX, there will be more substrate available for PYROX, thereby prolonging the activity of PYROX and enhancing the total amount of hydrogen peroxide produced (59). The claimed effects in baking are gluten strengthening, reduced dough stickiness, and increased volume and crumb structure for bread (59).

## IV. APPEARANCE/COLOR

Apart from texture, the appearance of food products is determined to a large extent by their color. Several redox enzymes are known to influence the color of foodstuffs. The most important ones will be discussed below.

### A. Lipoxygenases

It is interesting to note that the use of soybean lipoxygenase was described in the 1930s as a means to bleach the flour in preparation of white bread. More recent experiments have shown that carotenoids present in wheat flour are destroyed by co-oxidation. Wheat flour itself contains little LOX activity, but LOX is abundantly present in, for example, soybeans. To that end wheat flour is often fortified with up to 0.5% enzyme-active soy flour (34, 60). Other applications of LOX include the bleaching of noodles, whey products, rice, and wheat bran (61–64).

### B. (Poly)phenol Oxidases and Peroxidases

PPOs (see Sec. II, [Chapter 39](#) for general information) play an important role in the browning of fresh fruits and vegetables (65, 66), in the coloring and flavoring of tea (67, 68), and in improving the quality of coffee (69).

A major concern in the food industry is to prevent the development of enzymatic browning prior to the processing of fruits and vegetables (70). This is accomplished by removing oxygen or by inhibiting PPO activity using inhibitors such as metal chelating agents, inorganic ions (e.g., halide anions), benzoic acid and some substituted cinnamic acids, reducing agents (e.g., L-cysteine, glutathione, sulfite, SO<sub>2</sub>, ascorbic acid), small “natural” peptides, and combinations thereof (68). In contrast, during the fermentation of black tea PPO is used to initiate browning by oxidation of polyphenolic substances such as catechins to theaflavins.

The quality of tea, based on sensory evaluation of color and bitterness, has been correlated with total theaflavin content (71). Theaflavins, thearubigins, and caffeine are all essential ingredients in high-quality teas. The addition of microbial laccases and/or peroxidases to green tea has shown that no higher theaflavin levels can be obtained than with endogenous PPO. Addition of exogenous laccase/peroxidase to black tea, however, did yield a very significant increase in the color intensity of the tea (72).

Polyphenol oxidases also play an important role in coffee processing (69). The activity of PPO in green coffee beans has been consistently related to the quality of the coffee beverage. The exact role of PPO in cocoa beans is less well understood. There are, however, indications that it plays a role in browning during the curing of the cocoa beans (73).

In cereals, PPO is responsible for the darkening of the breadcrumb, particularly in whole-grain and rye

breads. The rate of browning is greatest in sourdough baking. Excessive discoloration can be prevented by the addition of sodium metabisulfite or ascorbic acid (41). Exogenous PPO is also reported to have a positive influence on the rheological properties of bread (74).

PPO can also be used for the *in vitro* production of colors. For example, Pruidze (75) reported the production of a whole range of natural colors by treating waste streams of beet and tea with PPO. Furthermore, it was claimed that safflower pigments become darker red when safflower petals were sprayed with a dilute laccase solution (76).

The role of endogenous POX in (dis)coloration is not fully understood. It seems that the oxidative role of peroxidases is useful in assisting PPOs in oxidizing the polyphenols and ultimately contributing toward the color and flavor of tea. The same seems to be true for coffee and cocoa.

### C. Ascorbic Acid Oxidases

Ascorbic acid oxidase (E.C.1.10.3.3; see Ref. 77 for detailed information) plays a role in beverages such as lemon and grapefruit juices, where it is responsible for the initiation of browning and loss of vitamin C activity during storage (77). The extent of browning can be minimized by steam blanching or by the exclusion of oxygen. The rate of ascorbic acid oxidation increases markedly in the presence of metallic ions, especially copper and iron. Hence, food processed in tin cans and processing equipment should be copper free. While the loss of ascorbic acid cannot be prevented completely, it can be reduced to a minimal level during processing.

## V. SHELF LIFE

The application of redox enzymes for improving the shelf life of food products includes mainly enzymes which are capable of removing oxygen or reactive oxygen species (e.g., H<sub>2</sub>O<sub>2</sub> and superoxide anion), as well as enzymes that are able to generate antimicrobial agents. In this way the stability of foods can be increased significantly with respect to taste, appearance, and microbial spoilage.

### A. Lactoperoxidases

Lactoperoxidase (LPO; see Ref. 78 and [Chapters 19](#) and [20](#) for detailed information) is the most prominent

enzyme in bovine milk, where it is found in concentrations around 30 mg/L. It is a glycoprotein with a single, covalently bound heme group (78). Lactoperoxidase requires hydrogen peroxide and thiocyanate (SCN<sup>-</sup>) for antibacterial activity. All three components are referred to as the LP system. The growth inhibitory effect of the LP system is mediated by the generation of SCN<sup>-</sup> oxidation products, mainly hypothiocyanate ions (OSCN<sup>-</sup>), which attack sulphydryl groups of vital metabolic enzymes of the microorganisms. Mammalian cells are not affected by the LP system. Only 10–20 ppm of lactoperoxidase is required for an effective system. The cofactor requirements are also very low: 10–25 ppm for thiocyanate and 10–15 ppm for H<sub>2</sub>O<sub>2</sub>. Without the enzyme H<sub>2</sub>O<sub>2</sub> is also bactericidal, but at much higher concentrations: 300–900 ppm (79). Therefore LPO is often applied in combination with H<sub>2</sub>O<sub>2</sub>-generating enzymes. From a toxicological point of view, the levels of the cofactors in the LP system as well as the oxidation products are reported to be harmless.

The envisaged applications of the LP system are food products (e.g., liquid milk, cheese, meat, fish and poultry products, and functional foods), feed and veterinarian products (e.g., milk replacers, and antidiarrhea and antimastitis preparations), and dental products (78–80). Typically, applications have been claimed for *Lactobacillus* fermented milk products (81), pickled foods (82), fish products (LPO in combination with GOX; 83), and white mold cheeses such as Camembert (84). Also of interest is the effect of LPO on yogurt. By adding LPO to yogurt the excessive acid production of lactic acid bacteria in the yogurt is suppressed (85). These applications are becoming within reach now that it is possible to isolate lactoperoxidase from milk with high purity on an industrial scale (79). Currently, LPO is already commercially available at relatively low costs.

### B. Xanthine Oxidases

Xanthine oxidase (XO, EC 1.2.3.2; see [Chapters 19](#) and [42](#) for detailed information) is widely distributed in animals, plants, and microorganisms. It catalyzes the oxidation of hypoxanthine to xanthine and xanthine into uric acid. In addition XO is able to oxidize a wide range of purines, aldehydes, and pteridines with concomitant reduction of O<sub>2</sub> to H<sub>2</sub>O<sub>2</sub>. Under certain conditions XO also produces the highly reactive superoxide anion. Bovine milk is very rich in XO (~ 35 mg/L; 86). XO has been implicated in the oxidative deterioration of milk and dairy products via the

production of superoxide anion during oxidation of its substrates (87). However, Bruder et al. (88) found no evidence to support a role for native bovine milk XO in lipid oxidation. The results of Weihrauch (89) seem to indicate that in the presence of purines, XO activity generates H<sub>2</sub>O<sub>2</sub> for the lactoperoxidase system in milk, making it a bactericidal or bacteriostatic agent in milk (23).

### C. Superoxide Dismutases and Catalases

Superoxide dismutase (SOD; EC 1.15.1.1) and catalase (EC 1.11.1.6; see [Chapters 27](#) and [38](#) for detailed information) are present in milk and are able to remove reactive oxygen species generated by other (bio)chemical processes (90). SOD catalyzes the reduction of superoxide anion, as produced, for example, by XO, to H<sub>2</sub>O<sub>2</sub> and O<sub>2</sub>. In turn, catalase is able to neutralize H<sub>2</sub>O<sub>2</sub> to water and oxygen. A low level of exogenous SOD, coupled with catalase, is a very effective antioxidant in dairy products (91).

Recently, SOD has been shown to protect beer against free radical damage (92). Obviously, the commercial feasibility of SOD as an antioxidant depends on cost, particularly compared to chemical antioxidants, if permitted. As far as is known, SOD is not used commercially as an antioxidant in food systems.

Catalase is used for the cold-sterilization of milk in regions lacking refrigeration and could in principle be applied in developed countries for the treatment of cheese milk (90). Good sources for catalase are beef, liver, *Aspergillus niger*, and sweet potato. There is also interest in using immobilized catalase reactors for milk pasteurization or for glucose oxidase–catalase reactions (93). Besides the removal of reactive oxygen species by SOD and catalase, other enzymes can be applied to remove the less but still reactive oxygen. Typical examples include glucose oxidase, D-amino acid oxidase, alcohol oxidase, and ascorbic acid oxidase. The disadvantage of these oxidases is that they produce H<sub>2</sub>O<sub>2</sub>, which by itself is a powerful oxidant. Catalase can be added to remove H<sub>2</sub>O<sub>2</sub>, but then oxygen is produced again. More recently, polyphenol oxidases such as laccase have been proposed as a deoxygenation tool for beer (94) and juices (95, 96). These enzymes have the advantage that they do not produce H<sub>2</sub>O<sub>2</sub>, and thus the combination with catalase is not necessary. As a result PPOs allow a more efficient oxygen removal.

## VI. NUTRITIONAL VALUE

Redox enzymes can have both pro- as well as antinutritional effects. For example, lipoxygenase, apart from all its other functions in food products (see [Table 1](#)), is involved in the oxidative destruction of liposoluble vitamins (provitamin A) and essential fatty acids (3). Likewise, ascorbic acid oxidase has an antinutritional effect since it oxidizes vitamin C (97).

Increasingly, redox enzymes are being claimed to improve the “healthiness” of especially beverages. For example, peroxidase and catalase have been claimed for the removal of “unhealthy” hydrogen peroxide in coffee and tea (98). Other examples include the use of cholesterol oxidase, epicholesterol dehydrogenase and cholesterol reductase to lower the cholesterol level in foods such as meat, fish, milk, and egg products (99–101).

## VII. CONCLUDING REMARKS

Compared to the usage of hydrolytic enzymes such as proteases, carbohydrates, and lipases, the application of oxidoreductases as a tool to improve the processability and quality of food products is still in its infancy. Like hydrolytic enzymes, oxidoreductases are capable of tailoring the taste, texture, appearance, shelf life, nutritional value, and process tolerance of foods and the properties of all major food constituents (*e.g.*, proteins, carbohydrates, oils, fats, flavors; see [Table 1](#)). In both cases, they can exert a positive as well as a negative effect on the food quality parameters, which can be reduced or eliminated by careful selection of the raw materials, by properly controlling the process condition, by the addition of counteracting ingredients, and by genetic tools. Likewise, hydrolytic and redox-active enzymes often have more than one effect. A typical redox example is the multifunctional enzyme lipoxygenase, which can be applied to influence either taste, texture, appearance, and/or nutritional value of food products. The key difference resides in the types of reactions they catalyze. As a result, redox enzymes can be combined with hydrolytic enzymes in a variety of food products to create improved or even new functionalities, which cannot be realized by either one of them.

At present, major bottlenecks for the large-scale application of oxidoreductases include their limited availability, their safety status (not GRAS), their stability, and the fact that they often initiate radical reac-

tions, which propagate *via* redox-active food constituents such as metal ions and quinones and hence are difficult to control. In addition, many oxidoreductases require expensive cofactors for catalysis. Despite these disadvantages over hydrolytic enzymes, certain oxidoreductases are increasingly finding a home in food processing. The first generation (see Table 1) includes enzymes which are cofactor independent and thrive on oxygen (*e.g.*, oxidases) and hydrogen peroxide (*e.g.*, peroxidases). Owing to advances in recombinant DNA technology the low-cost, large-scale production of these enzymes in GRAS host microorganisms is becoming within reach, and the tools are ready to tailor redox enzymes to specific needs by site-directed mutagenesis and directed evolution. Also feasible will be the *in planta* overexpression of desired redox enzymes in food raw materials and the deletion of undesirable redox traits. The usage of cofactor-dependent oxidative enzymes seems tentatively to be confined to whole-cell systems, in which the cofactor can be regenerated, and hence to the *in vitro* as well as the *in situ* production of functional food ingredients such as flavors. The same seems to be true for reductases, since most if not all require reducing equivalents in the form of a small protein, hydrogen, and/or NAD(P)H.

Clearly, the usage of oxidoreductases in food processing is emerging. The benefits and limitations are becoming known, which allows a promising and focused search for new opportunities.

### I. INTRODUCTION

In terms of cost-effectiveness, plants can compete with any other production system. All that is required is a suitable plant, sunlight, mineral salts from the soil or fertilizers, and water. The overall costs of production in plants is largely determined by the existing and very efficient infrastructure and facilities in agriculture for growing, harvesting, storing, and processing of crops. Furthermore, traditional breeding has resulted in plant varieties optimized for a high yield of harvestable produce (1). Crops grown in the field can yield bulk quantities of biomass. Millions of tons of carbohydrates, lipids, and proteins for the food, feed, or processing industries are produced annually from the harvested biomass.

Biotechnology enables us to produce compounds of commercial interest in domesticated crops that were previously available only from exotic plant species, from other organisms or in limited quantities. Transgenic plants are an attractive and cost-effective alternative for the production of these biomolecules, as demonstrated by the steadily increasing number of carbohydrates (2), fatty acids (2), high-value pharmaceutical (poly)peptides (2–4), industrial enzymes (2–

38), and biodegradable plastics (2) successfully produced in plants using this “molecular farming” approach.

Plants are gradually earning their place among other systems for production of proteins and peptides. Although research focused initially on the production of high-value pharmaceutical (poly)peptides (2), plants are equally suited as a competitive source of nonpharmaceutical enzymes (2–38). The activity and interest in this area are clearly increasing as demonstrated by existing collaborations between small plant biotechnology boutique and established enzyme or agrochemical companies, such as between Prodigene and Genencor, Sembiosys and Dow Agrosciences, Zeneca MOGEN (formerly MOGEN International) and DSM Food Specialties (formerly Gist-brocades), Agracetus (now part of Monsanto), and FinnFeeds (part of Cultor; Cultor was recently acquired by Danisco).

This chapter will summarize the method to generate transgenic plants, give an overview on what has been achieved in this area, compare plants with other methods of enzyme production, describe unique application methods for enzymes produced in plants, and finally present an illustrative example of an enzyme, phytase, applied in animal feed.

## **II. GENERATION OF TRANSGENIC PLANTS EXPRESSING ENZYMES**

### **A. Transformation and Regeneration of Plants**

In general, expression of (poly)peptides relies on stable integration of the encoding genes in the plant genome. An advantage of this approach is that identical offspring can be obtained by self-fertilization of the transgenic crops and consequently the stable inheritance of the trait. An alternative is production by transient expression in plants via genetically engineered viruses as CaMV (39), TMV (40–42), or CPMV (43–45).

Stable integration of genes generally consists of three phases: (a) introduction of foreign DNA into tissue amenable to transformation by methods as PEG-mediated transformation, particle bombardment, Whiskers, and *Agrobacterium tumefaciens*-mediated transformation; (b) selection of transformed material in the nontransgenic background by either selecting for tolerance to antibiotics, herbicides or another toxic chemical and/or by screening for expression of visual markers like luciferase, anthocyanin and GFP; (c) regeneration of shoots and roots after the successful selection of transgenic cells. This last phase may be quite cumbersome as cells amenable to transformation (competent cells) may not have the ability to regenerate.

Transformation of plants has developed over the last decades into a routine procedure for many crop species, including tobacco, tomato, potato, canola, soybean, alfalfa, sugar beet, lettuce, carrot, cotton, apple, rubber, rice, corn, wheat, and banana. Preference for *Agrobacterium tumefaciens*-mediated transformation exists as this generally leads to precise integration of only a limited number of copies of the gene of interest into the plant genome. However, cereals have appeared very recalcitrant to this method. Hence, the extensive use in the past of particle bombardment. With the recent development of a commercial transformation procedure for rice and the initial successes with the method in corn, wheat, and barley, it is likely that *Agrobacterium tumefaciens* will become the general vehicle for DNA delivery into plant species.

### **B. Expression of Enzymes in Plants**

Even when using an identical expression cassette, the expression levels obtained in plants will differ from gene to gene (7, 28, 46), just as in other production systems. However, some general principles apply to achieve high-level expression of proteins in plants,

like the use of promoters, enhancers, leader sequences, optimizations in codon usage, removal of mRNA-destabilizing sequences, etc. Other methods to increase the levels of heterologous proteins in plants can be found in the use of, e.g., integration-independent expression, enhancement of correct folding by coexpression of disulfide isomerases or chaperone proteins and production of polyproteins for stabilization of especially small peptides. Reduction of protein degradation by, e.g., expression in tissues, as seeds, where the level of protease inhibitors is high, by expression in tissues where the activity of the degrading enzymes is low as in seeds owing to the low water content, by targeting the enzyme to the ER or by avoiding the presence of susceptible protease-cleavage sites in the enzyme will also result in an increase of the expressed enzyme.

A unique aspect of expression in higher eukaryotes is the choice in the species, variety, and the location and timing for expression. Firstly, there is a choice in the plant species to be used for expression. A choice no longer severely limited by transformation technology (see above). If the protein content of a crop (tissue) would correlate with the accumulation of the transgene protein, crops with higher protein contents would be more cost-effective for production. However, as far as we are aware, no proof is available that this is indeed the case. Moreover, the argument may be turned around—i.e., crops that are already accumulating high levels of endogenous protein may have little capacity left for the accumulation of heterologous protein. Secondly, there may even appear to be differences among varieties of one and the same species. It is well known that different germplasms differ in agronomic characteristics as yield, disease resistance, etc. It would therefore not be surprising if they would also differ in their ability to accumulate heterologous proteins. Thirdly, the enzyme can be expressed in various organs or tissues using appropriate promoters. Fourthly, expression in the plant, tissues, or organs can be limited to certain periods of development using promoters active only during these stages. Finally, the enzyme can be targeted to specific cellular compartments as the vacuoles, the protein bodies (in seed), the chloroplasts, the mitochondria, and the ER or to the apoplast using appropriate targeting signals described in the literature (47).

Expression by integration in the plastid genome is another way to express enzymes. This can lead to dramatic increases in expression levels as demonstrated by the expression of  $\beta$ -glucuronidase (GUS) that accumulated to 2.5–30% of total soluble protein (20).

Combination of all these possibilities gives an almost unlimited choice. As these cellular compartments differ with regard to pH, ionic strength, and other environmental factors, these choices in fact allow the choice for a location within a plant species or a variety where active enzyme can be accumulated to the highest possible level.

No study describing the application of a range of these possibilities for enhancing the expression level has been published; there are still ample opportunities for optimization. Step increases in expression of proteins in plants can be expected, as was the case with microbial systems in their early stages of use. Competing systems are much more mature and improvements in expression levels will therefore be much more modest for the latter expression system. The fact that in its present state plants can already be competitive shows that they should have a bright future as hosts for enzyme production.

### C. Downstream Processing

If purification is mandatory (which is not always the case, as shown below), rapid and economical downstream processing of the recombinant protein is essential. The benefits of the plant-based production should not be offset by increased downstream processing costs. Any decrease in these costs will increase the competitive advantage of plants. The economic feasibility of protein purification from plant biomass has not been investigated in any detail, and if at all, mainly on a lab scale, except for Austin et al. (6), who focus on extraction and purification of industrial enzymes from alfalfa; by van Rooijen et al. (48; see below), Wilcox et al. (27), who purified bovine lysozyme from transgenic tobacco to 93% homogeneity in an easily scalable process; and by Kusnadi et al. (49), who described purification of GUS and avidin from transgenic corn. Downstream processing from plant biomass is generally assumed to be difficult and expensive. One reason for this assumption is the low ratio of recombinant protein to total biomass. Concentration and purification of the protein in the first step would reduce this assumed disadvantage considerably. As only few studies have been published, no final verdict is available regarding the cost of downstream processing. With step increases in expression level still feasible (see above), the economics of production will improve. In turn this will make it easier to use plants for production, even in cases where costly purification is mandatory.

### D. Exploitation of Plant Characteristics

Various production systems have been developed that are based on specific plant characteristics, on the use of plant regulatory DNA sequences, or on the exploitation of existing plant processing systems.

Prodigene (College Station, TX) used a ubiquitin promoter that preferentially directs expression of proteins to the germ portion of corn seeds. The crude protein is present in the waste fraction of the corn wet-milling process, and thus essentially produced free of charge in that process. The only costs involved in production are downstream costs for extraction and purification of the protein. A comparison of the costs for production in the germ versus the whole seed is given by Howard (50). Similarly, starch or oil crops may be interesting as hosts for production, because the enzymes may be produced as byproducts in addition to the primary product (starch or oil), thus reducing the production costs.

A very ingenious way to reduce these downstream costs was found in the use of plant seed oil bodies as carriers for proteins and peptides (48). Nonplant (poly)peptides were fused to the structural oil body protein oleosin and expressed in *Brassica napus*. The lipophilic nature of oleosins forms the basis for a highly efficient purification system for (poly)peptides. The feasibility of this approach has been demonstrated with  $\beta$ -glucuronidase (GUS; 19, 48) and as a first commercial example the expression and purification of the thrombin inhibitor hirudin (51). Alternatively, this system may be used to immobilize industrial enzymes as oleosin fusion proteins on the surface of oil bodies (19).

Expression during germination of seeds, using germination-specific promoters, has the advantage that a well-established process, available equipment, and factories of malt production for, e.g., the brewing industry can be used. An additional regulatory advantage is obtained, because the actual expression takes place in a contained environment; i.e., seeds are allowed to germinate in a malting factory (52, 53).

Using wound-inducible HMG2-derived promoters, expression can be effected postharvest by mechanical wounding of the leaves. An advantage is that growth of the plants is separated from the expression of the protein, which allows expression of proteins that would normally have a detrimental effect on the plant during growth or development. As the proteins are expressed in a contained environment postharvest, this approach could have regulatory advantages as well (54).

An elegant way to produce and harvest proteins is described by Boffey et al. (55). Proteins are expressed in the easily harvestable latex fraction of the rubber tree, constituting a continuous source of the protein. The relatively simple composition of the latex would allow easy purification of the protein from the tapped latex. A disadvantage may be the long generation time and consequently the long time to develop this into a commercially operating system.

Extracellular expression of proteins in the roots of hydroponically grown tobacco plants, termed rhizosecretion, is yet another way to optimize expression, as well as to facilitate purification (37).

### III. ENZYMES PRODUCED IN PLANTS

A substantial number of enzymes have meanwhile been produced in plants (see Table 1) (2–38). Expression of an enzyme in the vicinity of its potential substrate does not necessarily have a negative effect on the agronomic characteristics of the plant. Endogenous cell wall degrading enzymes like glucanases, polygalacturonases, and pectin esterases are present at the same location as their substrates without a detrimental effect on the plant. Also, extracellular expression of a vacuolar glucanase—i.e., an enzyme that normally does not have access to the glucan substrate—did not result in aberrations in growth or morphology (56). Xylanase can be expressed in tobacco or *Pisum sativum* without an effect on plant phenotype (9, 16, 35). In one publication (35), the authors suggest that the high temperature optimum of the enzyme prevents substantial degradation at ambient temperatures. As the enzyme exhibits considerable residual activity at this temperature, a more likely explanation may be that, for unknown reasons, the apoplastically expressed enzyme does not, or does only to a very limited degree, degrade the xylans in the plant cell wall.

Active  $\beta$ (1-3,1-4)glucanases can be expressed in tobacco without phenotypic alterations despite their apoplastic location (16). A thermostable  $\beta$ (1-3,1-4)glucanase, consisting of parts from two *Bacillus* spp. expressed in barley aleurone protoplasts and in transgenic barley under control of the germination-specific high-pI barley  $\alpha$ -amylase promoter yielded fertile plants (17). In contrast, no viable transgenic tobacco plants could be obtained after transformation with an endo- $\beta$ (1-4)glucanase gene construct. This was most likely due to degradation of cell wall  $\beta$ -glucans, because transient expression in tobacco protoplasts showed that cell wall synthesis was never resumed

(14). A cellulase from *Thermomonospora fusca* was expressed in alfalfa, tobacco, wheat, and maize (10, 11). In one of these studies (11), the gene was put under the control of a chemically inducible promoter to prevent detrimental effects of the cellulase. Production of manganese-dependent lignin peroxidase in alfalfa severely affected plant growth and development. Affected plants showed yellowing foliage. However, they survived and set seed. In field trials the dry matter content was reduced, as was the plant height. The enzyme was most likely directed to the ER (6, 8).

GUS ( $\beta$ -glucuronidase) is used in molecular biological experiments as a reporter for visualizing gene expression in plants. GUS, produced in transgenic corn seed and rapeseed (18–20), is the first enzyme produced in plants that is commercially available from Sigma. The enzyme is produced by Prodigene (College Station, TX). Sigma is also selling another protein, avidin, produced by Prodigene in corn (57). Alcohol and aldehyde dehydrogenases produced in corn (5) can find application in prevention of alcohol toxicity when taken before social drinking. They should be formulated with NAD to ascertain activity in a pill, paste, or foodstuff.

Although cyclodextrin glycosyl transferase (CGTase) was produced in potato tubers for the *in planta* production of cyclodextrins (13), these transgenic plants could find application as a source of the enzyme as well, provided the enzyme levels can be increased considerably. Hen egg white and bovine and T-4 bacteriophage lysozymes have been expressed in tobacco (24–27). This research was partially driven by the desire to create plants resistant to bacterial pathogens. However, lysozymes produced in this way can find application as preservative in food, feed, cosmetics, and agriculture.

Other enzymes expressed in plants include lipase (22, 23),  $\beta$ -galactosidase (21),  $\alpha$ -amylase (3, 6–9),  $\beta$ -amylase (38), and phytase (28–34 this chapter).

### IV. COMPARISON OF HOSTS FOR ENZYME PRODUCTION

Bacterial and fungal cells selected for high-level expression have traditionally been used for production of industrial enzymes (58). Extraction from these nonrecombinant sources will, for some enzymes, remain the preferred method of production. For the production of commercially interesting proteins, with the use of recombinant DNA techniques, various host organisms

**Table 1** Plants as Bioreactors for the Production of Enzymes

Enzyme	Origin of gene(s)	Application	Plant species	Ref
Alcohol dehydrogenase	Human	Prevention alcohol toxicity	Corn	5
Aldehyde dehydrogenase	Human	Prevention alcohol toxicity	Corn	5
Alpha-amylase	<i>Bacillus licheniformis</i>	Liquefaction of starch	Tobacco, alfalfa, <i>Vicia narbonensis</i> , <i>Pisum sativum</i>	3, 6–9
Beta-amylase	Barley	Brewing	Barley	38
Cellulase	<i>Thermomonospora fusca</i>	Ethanol production, paper and pulp	Alfalfa, tobacco, corn, wheat	10, 11
Chymosin	Calf	Dairy industry	Tobacco, potato	12
Cyclodextrin glycosyltransferase (CGTase)	<i>Klebsiella pneumoniae</i>	Production cyclodextrins	Potato	13
Glucanase	<i>Trichodema reesei</i> , Hybrid from two <i>Bacillus</i> spp., <i>Ruminococcus</i> <i>flavefaciens</i>	Brewery, feed	Barley cells	14–17
GUS ( $\beta$ -glucuronidase)	<i>Escherichia coli</i>	Molecular biology tool	Corn, canola	18–20
Lactase ( $\beta$ -galactosidase)	<i>Escherichia coli</i>	Lactose intolerance	Maize, sunflower	21
Lipase	Dog gastric preduodenal, <i>Rhizopus niveus</i>	Food, medical, fatty acid production	Tobacco, corn, canola, tomato	22, 23
Lysozyme	Hen egg white, bovine, bacteriophage T4	Food preservation	Tobacco, potato	24–27
Manganese-dependent lignin peroxidase	<i>Phanerochaete chrysosporium</i>	Bleaching and pulping of paper	Alfalfa	6, 8
Phytase	<i>Aspergillus niger</i>	Feed	Alfalfa, tobacco, canola, soybean, soybean cell suspension cultures, wheat	28–34
Xylanase	<i>Clostridium thermocellum</i> , <i>Cryptococcus albidus</i> , <i>Ruminococcus flavefaciens</i>	Feed, brewing, paper and pulp, bakery	Tobacco, <i>Pisum sativum</i>	9, 16, 35–37

are currently used: bacteria (in particular *Escherichia coli* and *Bacillus subtilis*), filamentous fungi, yeast, mammalian cells (in particular Chinese hamster ovary [CHO] cells), insect cells, transgenic animals and transgenic plants, as well as a number of other organisms that are less important. The first tier of biotechnology companies have mainly used filamentous fungi, yeast, and bacteria for production of enzymes.

Well-known industrial problems in developing systems for the production of heterologous proteins included instability and insolubility of the product, disappointing production rates, instability of selected cell lines, difficulties in scaling up, purification of the recombinant product, and complicated registration procedures (59). A specific problem for industrial enzymes is the production costs, because of the small margins on these products. Economic factors influencing the choice of production system are the rate of biomass production, equipment costs, medium composition and costs, processes for protein recovery and purification, product yields, and the potential hazard of contamination. A lot of development work is driven by the intended commercial application and by regulations set by the FDA and other organizations.

A suitable host for production is selected based on its ability to fulfill all the technical and economic requirements set by the protein of interest and its application. The production of proteins, by whatever system, remains an empirical process, making it impossible to predict the expression level. Such predictability may come with an increase in understanding of the molecular biology, biochemistry, and physiology of the expression systems and of the expressed proteins. Because expression in each organism is gene dependent, and this dependency differs from organism to organism, some proteins will express well in one system and not well in another. This argues strongly for the availability of a multitude of production systems, each having its own (dis)advantages. Plants will earn their place among these systems. A comparison of different hosts for production of enzymes is given in [Table 2](#) (60).

## V. UNIQUE APPLICATION METHODS FOR ENZYMES PRODUCED IN PLANTS

The feasibility of different methods for application of enzymes produced in plants as described below can be nicely demonstrated with  $\alpha$ -amylase from *Bacillus licheniformis* expressed in tobacco (7). Alpha-amylases

from bacterial and fungal origins find wide application in e.g. the starch processing and alcohol industry for liquefaction, in the brewing industry for production of low-calorie beer, in bakery for increasing bread volume, in the juice and wine industries for clarification and in the detergent industry for removal of starch stains (61–64). The  $\alpha$ -amylase from *B. licheniformis* is the most commonly used enzyme in starch liquefaction, because of its extreme heat stability and its activity over a wide pH range (61, 65).

### A. Production and Purification from Plants ([Fig. 1a](#))

*Bacillus licheniformis*  $\alpha$ -amylase was expressed extracellularly in tobacco at a level of maximally 0.5% of soluble protein in leaves (7, 66). The properties of the enzyme as produced in tobacco were very similar to the bacterial one. However, the protein is, in obvious contrast with the bacterial protein, glycosylated. The enzyme produced in tobacco was active and exhibited extreme thermostability, similar to the *Bacillus* enzyme. No apparent effect of the presence of the enzyme on plant phenotype was observed. Purification from tobacco has not yet been carried out for bacterial  $\alpha$ -amylase.

### B. Process-Dependent Conversion ([Fig. 1b](#))

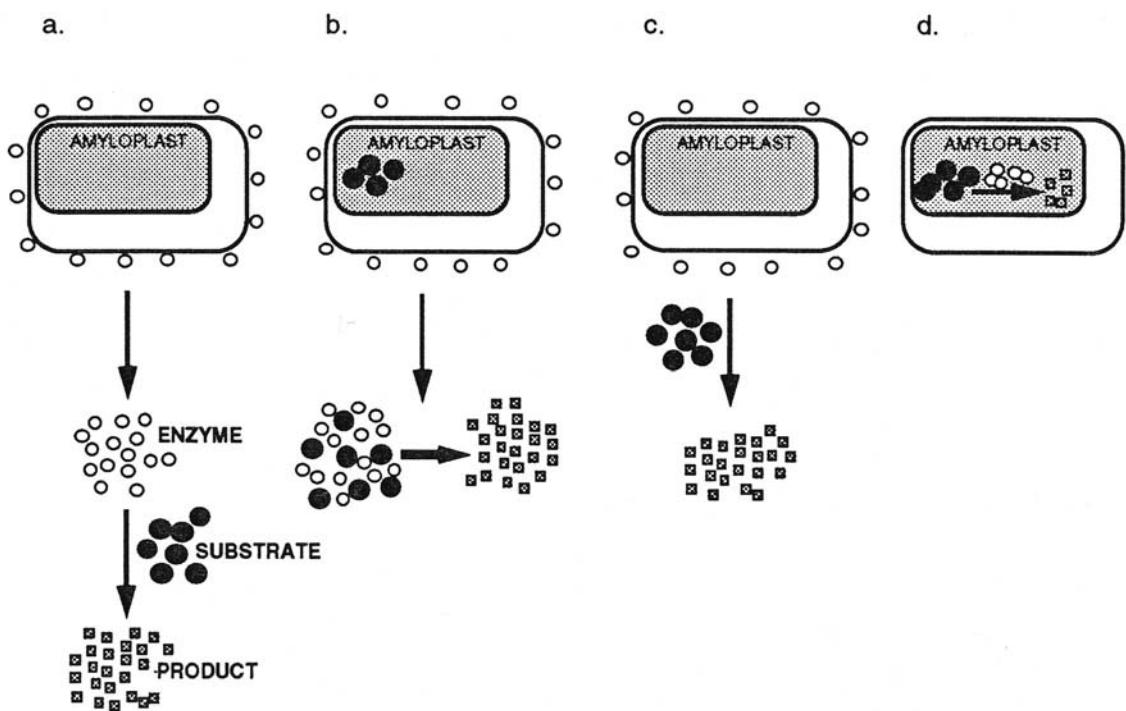

Enzymes produced in crops can be expressed at a sequestered location in the crop that also harbors its substrate. Alternatively, the enzyme may be expressed at the same location as the substrate, but in an active form. The conversion thus becomes process dependent. During processing of the crop, enzyme and substrate are brought into contact (or the enzyme is activated), resulting in conversion of the substrate into product. In this approach, the plant becomes equipped with the enzyme having optimal characteristics for conversion of its endogenous substrate. In planta conversion of the substrate into the desired product ([Fig. 1d](#)), by expression of active enzyme at the same location as the substrate, will have similar advantages as process-dependent conversion, but will not be suitable if the enzymatic activity has a negative effect on the plant's phenotype or its agronomic characteristics. The feasibility of this concept is exemplified by extracellular expression of  $\alpha$ -amylase. Extracellular expression of  $\alpha$ -amylase does not have an effect on endogenous starch, as is expected from the separated locations of enzyme and substrate. Moreover, the transgenic plants do not show any aberrations in their phenotype.

**Figure 1** Application methods of industrial enzymes produced in transgenic crops. (a) Production and purification: The enzyme is purified from the plant, formulated and subsequently applied in the industrial process. (b) Process-dependent conversion: Expression of the enzyme in the crop sequestered from its substrate. Conversion of the substrate occurs during processing. (c) Seed-formulated enzymes: The transgenic seeds are directly, without any purification of the enzyme, applied in the industrial process. (d) In planta conversion: Expression of the enzyme in planta at the same location as its substrate results in conversion of the substrate and consequently accumulation of product in planta.

Homogenization of transgenic leaf material, followed by incubation at 95°C, resulted in conversion of endogenous starch by the transgene product (Table 3). In starch potatoes, the  $\alpha$ -amylase levels as obtained in tobacco (7, 66) would be sufficient to hydrolyze all the starch present in the tuber. Similar applications for  $\alpha$ -amylase and other enzymes may be found in other industrial processes, like for instance the application of  $\alpha$ -amylase in the production of bioethanol, heat-stable  $\beta$ -glucanases for the degradation of cell wall material in the brewing industry, and the production of fatty acids in oil plants (23).

In this approach the aim is *not* producing enzymes in crops per se, but creating either a higher-quality input resource or an enabling process through expression of the enzyme inside the plant. This application has unique advantages. Firstly, enzyme manufacturing costs will be low, because there is no need for purification and formulation of the enzymes. Secondly, it obviates the necessity for separate production of enzymes. Thirdly, expression in the vicinity of the substrate assures better access to its substrate than is achieved

by in vitro addition of the enzyme. In some cases as wood pulping, in vitro addition has limited success because the enzymes do not have sufficient access to the substrate. Finally, expression in the crop guarantees an optimal dispersion of the enzyme throughout the biomass; *i.e.*, an optimal homogeneous mixture of enzyme and substrate is obtained. This is less easily achieved by in vitro addition of enzymes.

### C. Seed-Formulated Enzymes (Fig. 1c)

Another concept for application is the direct use of engineering plant material in the processing, food, or feed industry. The transgenic plant material serves as novel formulation for the expressed enzyme. Other plant material can be used, depending on the process, but in general seeds may be the plant organ of choice, because these create a stable environment for long-term storage of the enzymes. The potential of plants as production vehicles for enzymes is enormously increased by producing the enzyme in seeds and directly applying these in the industrial process.

**Table 3** Process-Dependent Conversion of Leaf Starch by Expressed  $\alpha$ -Amylase

Sample	Incubation time (min)		
	0	30	60
Control tobacco	+	+	+
Control tobacco + 0.02 T.A.U. <i>B. licheniformis</i> $\alpha$ -amylase/mg	+	+/-	+/-
Control tobacco + 0.2 T.A.U. <i>B. licheniformis</i> $\alpha$ -amylase/mg	+	+/-	-
Control tobacco + 2 T.A.U. <i>B. licheniformis</i> $\alpha$ -amylase/mg	+	-	-
Transgenic tobacco line MOG227.3	+	-	-

Homogenization of transgenic leaf material containing *Bacillus licheniformis*  $\alpha$ -amylase, followed by incubation at 95°C for 30 min hydrolyzed starch present in the leaves. Addition of 2 T.A.U./mg *Bacillus licheniformis*  $\alpha$ -amylase to the nontransgenic control leaf homogenate for 30 min or of 0.2 T.A.U./mg for 60 min had the same effect, while incubation of nontransgenic control leaf homogenate had no visible effect on the endogenous starch during the time of the experiment. The presence of starch, as demonstrated by I<sub>2</sub>/KI-staining is indicated with +, intermediate staining with +/- and absence with -.

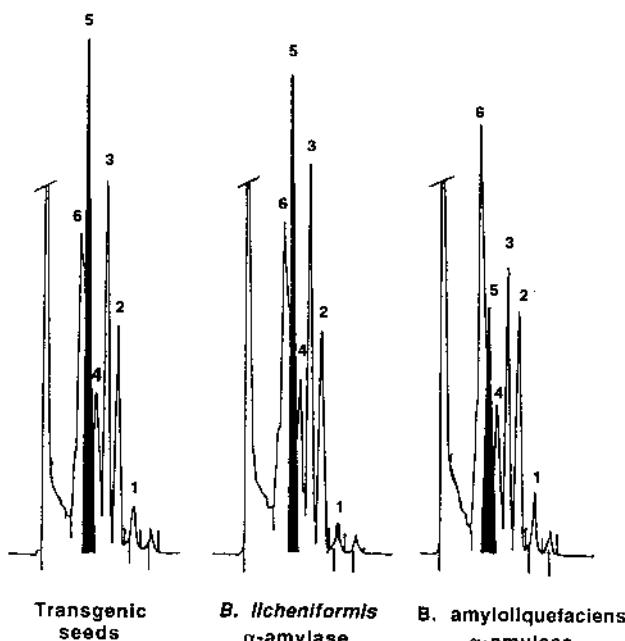

Compared with the production followed by purification, this concept has additional advantages over traditional production systems. Firstly, the formulation of the enzyme as obtained by genetic engineering of the crop is convenient; *i.e.*, it does not require an extra step in the manufacturing process, and it guarantees stable and safe storage of the enzyme. No allergenic problems due to the enzymes are to be expected, because these are contained in the seeds. Secondly, the manufacturing costs will be lower, because purification and formulation of the enzyme are no longer required. This concept is most easily applied in, but certainly not limited to, cases where enzymes are required for application in (processed) food or feed. The enzyme can then be expressed in the plants and plant organs that are the natural component in this animal feed and food. The transgenic plant material containing the enzyme is used as delivery vehicle for the protein with the same advantages as described above.

The transgenic seeds are a novel specialty enzyme product to be added in small quantities into the industrial process, provided the expression level is sufficiently high ("additive route"). This creates flexibility, because various enzymes can be engineered into plants in the same manner and used and combined according to the needs of the user. The total premium for production, transportation, etc., of transgenic plant material will be lower than in case the transgene is built into the commodity crop. Production, transportation, and marketing can be strictly and simply controlled, preventing the mingling of transgenic with nontransgenic seeds. Alternatively, the enzyme can be expressed at low levels in all (or a large part of the) seeds used in the application ("bulk route"). A comparison between these two approaches in various aspects is given in Table 4.

This enzymes-in-seed approach is exemplified by the direct application of milled transgenic  $\alpha$ -amylase seeds in liquefaction of corn and potato starch (Fig. 2). Seeds of a transgenic plant line were milled and used without any further purification in the liquefaction of potato and corn starch. From the nature and the quality of the hydrolysis products obtained from corn and potato starch with the transgenic seeds it can be concluded that the enzyme as produced in tobacco is as suited for liquefaction of starch as the *Bacillus licheniformis* amylase. As shown in Table 5, the dextrose equivalent (DE) values, which were calculated from the HPLC patterns, were found to be similar to those obtained with the commercial preparations and within the commercially acceptable range (DE-12, preferably DE16; 67). Seeds containing  $\alpha$ -amylase maintained full enzyme stability for at least a year. When seeds are the only organs used, seed-specific expression is preferred, because it will minimize the chance of effects on agronomic characteristics.

**Table 4** Comparison of Bulk and Additive Application of Enzymes in Seed

	Additive	Bulk
Expression level	High	Low
Research costs	Medium	Low
Amount of plant material	Low	High
Importance host	Low	High
Agronomic performance	Less critical	Critical
Development costs	Low	High
IP production	+	?
Level of control	High	Low
Maintenance added value	High	Low

**Figure 2** Liquefaction of potato and corn starch. Oligosaccharide HPLC patterns obtained from hydrolysis of corn starch by milled transgenic seeds of plant line MOG227.3 expressing  $\alpha$ -amylase (left), *Bacillus licheniformis*  $\alpha$ -amylase (middle), or *Bacillus amyloliquefaciens*  $\alpha$ -amylase (right). The degree of polymerization (DP) of glucose is indicated by the numbers. The products obtained with the transgenic seeds and with *Bacillus licheniformis* amylase are virtually identical and clearly different from those obtained with *B. amyloliquefaciens* amylase. The main difference distinguishing the two specificities is the amount of DP5 (indicated in black).

Plants will often still be a competitive source, because of the low-cost production of biomass. The novel concepts of seed-formulated enzymes and process-dependent conversion will find application in various markets. For process-dependent conversion the increased access to the substrate will for some industrial processes create the required competitive advantage. For seed-formulated enzymes, application will depend on the compatibility of the seeds with the industrial process. A first commercial example of the latter concept is described below.

## VI. AN EXAMPLE: PHYTASEED

### A. Feed Enzymes

In livestock farming of pigs and poultry, the supplementation of animal feed with industrial enzymes to

**Table 5** Dextrose Equivalent (DE) Values Obtained from Hydrolysis of Corn and Potato Starch

DE values	Potato starch	Corn starch
Transgenic tobacco seeds (MOG227.3)	16	13
Nontransgenic tobacco seeds	0	0
<i>Bacillus licheniformis</i> amylase	18	16
<i>Bacillus amyloliquefaciens</i> amylase	15	18

improve digestibility and utilization of nutrients has become common practice. Examples are industrial enzymes such as  $\beta$ -glucanase and endoxylanase which are added to diets containing high contents of barley, triticale, and wheat to improve growth, quality of eggs, and feed conversion ratio in poultry (68). Favorable effects of the inclusion of these enzymes in the diets of pigs have been reported as well. Another example is the enzyme phytase which is used to optimize phosphorus utilization in monogastric animals such as pigs, fish, and poultry.

### B. Phytase

Phytases (myoinositol hexakisphosphate phosphohydrolase, EC 3.1.3.8) are widely distributed in all classes of organisms. The enzyme catalyzes the conversion of phytate into myoinositol and phosphorus. The substrate of this reaction, phytate, is a salt of phytic acid and divalent cations of calcium, magnesium, iron, or zinc. In plant seeds up to 80% of the total phosphorus has been reported to be present in the form of phytate (69). During the germination process phytate is rapidly converted into myoinositol and phosphorus for growth and development of the seedlings.

Seeds of crops like wheat, corn, soybean, and barley are used in large amounts in animal feed. The amount of phosphorus present in these seeds would be more than sufficient to meet the animal's requirements for optimal growth. However, monogastric animals, such as pigs and chickens, are only able to use a small portion of the phosphorus present in these seeds, because the remaining part is present in the form of phytate. These animals cannot convert phytate into myoinositol and inorganic phosphate. Therefore, inorganic feed phosphate has to be added to feed. As a consequence the manure of the animals contains a huge amount of phosphate, which, released into the environment, causes pollution through eutrophication of surface waters. In many countries, especially those with inten-

sive livestock farming, there is a strong tendency to reduce the amount of phosphate. For example, in the Netherlands, farmers are taxed based on the amount of phosphate released into the environment. In Singapore, pig production is banned because of the related environmental problem. The amount of manure secreted into the environment is enormous. Even in as small a country as the Netherlands, 215 million kg of phosphate ( $P_2O_5$ ) from animal manure is added to the soil per year.

Application of the enzyme phytase will optimize phosphorus utilization by pigs and poultry (70–74). Feed phosphate can be substituted by the enzyme phytase, thus reducing the environmental problems caused by phosphate considerably.

The phytase gene has been cloned successfully from *A. niger* var. van Tieghem (75, 76). The enzyme is produced on an industrial scale by means of fermentation of *A. niger*. The phytase gene is overexpressed by placing the gene under control of the *A. niger* amyloglucosidase promoter. Phytase is secreted as a large percentage of total protein by this filamentous fungus during growth in a fermenter. After fermentation, the enzyme is separated from the broth through a series of filtration steps. The final ultrafiltrate is either stabilized and sold as a liquid product or dried and formulated to a free-flowing product. The unique pH optima at 2 and 5.5 allow application of the enzyme in feed for monogastric animals because of the optimal compatibility with the environment in the gastrointestinal tract of these animals and the crop of poultry. The microbial phytase from *Aspergillus niger* is marketed by the alliance of DSM Food Specialties (former Gist-brocades) and BASF under the brand name Natuphos for use in animal feed.

### C. Expression of Phytase in Tobacco

By expressing the phytase gene in plants instead of in *A. niger*, we are substituting an existing production process by a novel and innovative way of producing industrial enzymes. To demonstrate this concept, tobacco was transformed with a gene construct (28), encoding phytase from *Aspergillus niger* (75). The construct contains a DNA sequence encoding the tobacco PR-S signal peptide that will give export of the enzyme to the extracellular space (77). The cauliflower mosaic virus (CaMV) 35S promoter (78) was used that gives expression of phytase in all parts of the plants.

A total of 72 independent transgenic tobacco plants were analyzed for phytase expression in leaves and seeds. The highest expression level, measured 3 weeks

after transfer of the plants to the greenhouse, was 1.7% of total soluble protein in leaves and 1% of total soluble protein in seeds. In leaves, phytase accumulated during further maturation of the plants up to a maximum level of 14.4% of soluble protein ~ 7 weeks after transfer to the greenhouse, showing the extreme stability of phytase in the extracellular space of leaves (33).

The molecular mass of tobacco-derived phytase from leaves was ~ 70 kDa and from seeds ~ 68 kDa, compared to ~ 80 kDa for the *Aspergillus* enzyme. The difference in molecular weight between phytase expressed in seeds and leaves and between plant-derived and *Aspergillus* phytase was found to be caused by differences in glycosylation, which was not unexpected because a total of 10 potential asparagine-linked sites are present in the primary structure and the *Aspergillus niger* enzyme is known to be heavily glycosylated (75). Deglycosylation experiments showed that both leaf- and seed-derived phytase contain highmannose, as well as complex-type, carbohydrate chains. Tissue-dependent differential glycosylation of proteins, as found here for seeds and leaves, has been described before (79). Despite the differences in glycosylation, the specific activity of purified leaf-derived phytase was found to be identical with that of the purified *Aspergillus niger* enzyme.

### D. PhytaSeed®

For the development of a commercially viable product, the fact that plants and plant organs are natural components of animal feed was fully exploited. PhytaSeed, the enzyme formulated by genetic engineering in canola seed, is used directly without any other post-harvest treatment than milling. In other words, the seeds are used as the packaging material and the delivery vehicle for the protein.

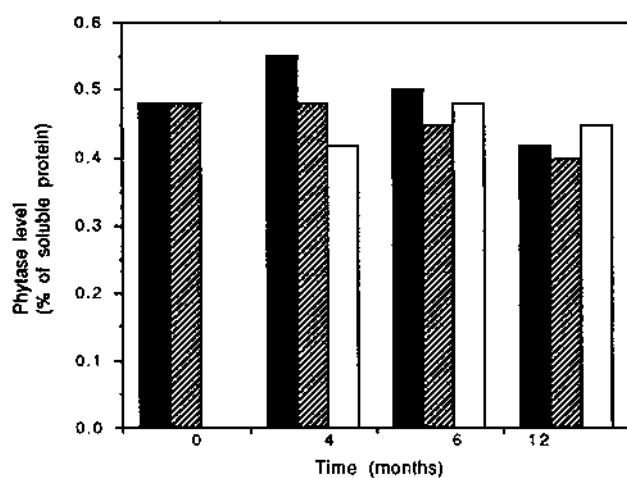

*Aspergillus niger* phytase was expressed extracellularly under control of the seed-specific cruciferin promoter in canola (*Brassica napus* cv. Westar) seeds. Canola is commonly used in animal feed, albeit in low amounts. Therefore, transgenic phytase-containing canola seeds can be simply incorporated. Transformation of canola is simple and routine, so many independent transgenic lines can be obtained. As PhytaSeed, canola seeds containing phytase, is envisioned to be marketed as an enzyme product, and since expression levels are high (see below), there is no need to incorporate the enzyme in seeds of crops that are major constituents of animal feed like soybean, corn, wheat, or barley. Small amounts of canola seed containing sufficient enzyme for the conversion of the phy-

tate present in the feed mixture will be added. The nutritional value of the seeds will be a bonus to the enzyme formulation.

A total of 95 independent transgenic canola lines were generated and grown in the greenhouse, and mature seeds were tested for phytase activity. The average phytase expression level was found to be 0.85% of total soluble protein. The highest phytase expression level obtained was 9.3%, sufficient for further development into the commercial product PhytaSeed. The application experiments described below were carried out using transgenic tobacco seeds, but similar results (to be reported elsewhere) were obtained with PhytaSeed (80–82).

#### E. Application of Transgenic Seeds Containing Phytase

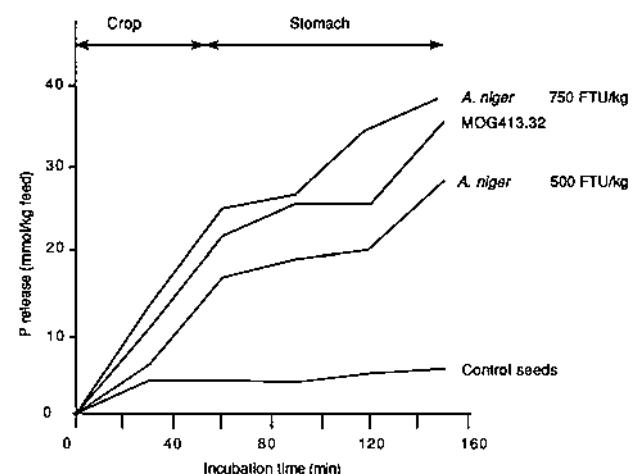

Phytase packaged in seeds by genetic engineering techniques was found to be extremely stable. Even milled seeds did not show loss of enzyme activity when stored at room temperature for a period of a year (Fig. 3). This characteristic, brought about by the stable seed environment, is commercially very important because it generates a reliable supply to customers, as a reduced seed yield in a particular year can be replenished with

**Figure 3** Stability of phytase packaged in tobacco seeds. Unmilled transgenic tobacco seeds (MOG 413.25) stored at 4°C (■) and room temperature (▨), and milled seeds stored at room temperature (□) were analyzed for phytase activity (vertical axis) at different time points during storage (horizontal axis). Milled transgenic seeds stored at 20°C were not analyzed at the first time point.

stored seeds from the previous year. Packaging of the enzyme in seeds also makes it more resistant to thermomechanical processing, as for example during feed pelleting (83). The effect of addition of milled transgenic seeds on the liberation of inorganic phosphate from phytate in animal fodder was tested by first incubating a standard poultry feed sample under conditions simulating chicken crop and stomach conditions. Milled transgenic seeds released inorganic phosphate from the fodder, whereas milled control seeds had no activity (Fig. 4). This experiment shows that phytase as produced in plant seeds has retained the essential characteristics to exert its activity in the gastrointestinal tract and crop of monogastrics animals.

The effect of transgenic seeds containing phytase on animal growth was tested in vivo by milling and subsequent addition to the basal diet of broilers. Diets supplemented with nontransgenic seeds and diets with and without added phosphate were used as controls. In addition, the commercial phytase preparation from *Aspergillus niger*, Natuphos, was used for comparison. Growth during the 4-week course of the experiment was used as a measure of the effect of each supplementation. Diets supplemented with transgenic seeds resulted in significantly higher growth rates

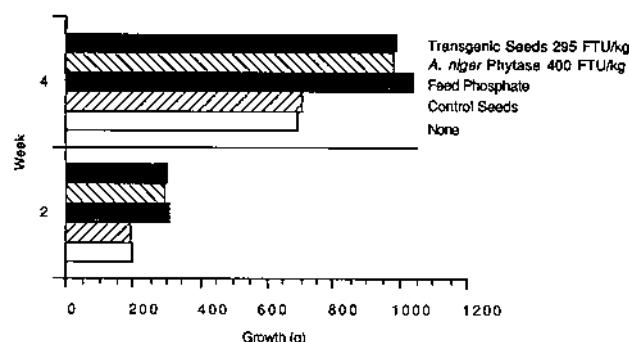

**Figure 4** In vitro testing of transgenic phytase tobacco seeds under conditions simulating the digestive tract of poultry. Seeds containing phytase from a transgenic tobacco line (MOG 413.32) and from nontransgenic tobacco were used. For comparison, *Aspergillus* phytase was used in doses of 500 and 750 FTU/kg feed. During the incubation period samples were taken and analyzed for the amount of phosphate released.

than those with control seeds or without any addition (Fig. 5). Growth rates obtained with transgenic seeds were not significantly different from those obtained with *Aspergillus* phytase as a supplement or those with inorganic phosphate addition. This feeding experiment conclusively demonstrates that transgenic seeds containing phytase, added to animal feed without prior extraction of the enzymes, can compensate for the lower amount of inorganic phosphorus available to the animals.

#### F. Low-Phytate Mutants

Low-phytic acid mutants have been generated in several crop species such as corn and barley by Victor Raboy and coworkers (84). These mutants might be considered to become an alternative to the use of phytase for optimizing phosphorus utilization from feed components if the agronomic performance is unaltered. However, application of phytase in low-phytate corn-based diets still results in a marked improvement in the availability of phytate phosphorous from these diets in poultry. It seems likely that there is an opportunity for both technologies to reduce the phosphate contents in manure from monogastric animals.

**Figure 5** Effect of phytase-containing transgenic tobacco seeds on the growth of broilers. Milled transgenic seeds of line MOG413.25 was used in a concentration of 295 FTU/kg. As controls, diets supplemented with feed phosphate, non-transgenic seeds, and *A. niger* phytase (400 FTU/kg) were included. Growth was measured after 2, and 4 weeks. Growth observed for diets supplemented with *A. niger* phytase, feed phosphate, or transgenic seeds was not statistically different but better than for those with nontransgenic seeds or with no addition. This demonstrates that phytase-enriched seeds improve phosphorus utilization and can substitute for phosphate as a feed supplement.

#### G. Other Potential Benefits of PhytaSeed

In the processing industries, where seed and/or plant materials are used, seed-formulated enzymes may be simply incorporated in existing processes. Phytate present in corn kernels precipitates during the wet-milling process in the concentrated steep water. This causes problems in handling, transportation, and storing of the corn steep liquor. These problems may be avoided by using phytase during steeping. The addition of phytase also results in a reduction in steeping time and in an increase in starch yield (85). An efficient and elegant manner to achieve the same goal would be to package phytase in corn kernels by genetic engineering techniques.

The application of transgenic phytase seeds in food and feed may have other desirable effects. Phytate is considered to be a nutritional factor, because it chelates essential minerals like calcium, iron, and zinc, reducing their availability to monogastrics (71, 86). An increase in calcium availability by the application of microbial phytase has been demonstrated in pigs and poultry, and degradation of phytate in cereals has been shown to increase the availability of iron in vitro. Dietary addition of milled transgenic seeds containing phytase to feed or food will reduce the amount of phytate and consequently increase mineral absorption in animals as well as humans. This is especially important for infants and elderly people.

Phytate is well known to bind to proteins in general and to some digestive enzymes such as proteases and amylases in particular (87–89). Application of PhytaSeed may prevent the formation of phytate–protein complexes and thus improve digestion of feed and food.

#### VII. CONCLUSION

This example, as well as the other examples referred to, clearly demonstrate the advantages of using plants as a production system for enzymes. As many other applications can be envisioned, plants will certainly earn a prominent place among the various methods for producing enzymes.

## Enzymes in Protein Biosynthesis

**John R. Whitaker**

*University of California, Davis, Davis, California, U.S.A.*

*We shall not unravel the chemistry of life in molecular detail without knowing at atomic or close to atomic resolution the structure of the biological macromolecules especially the proteins (1).*

### I. INTRODUCTION

Proteins perform many functions in organisms. Some of these are listed in Table 1. No other polymeric compound can perform so many functions in nature. This is because proteins are so diverse in structure. Although only 20 amino acids are used to build the primary structures, they can be arranged theoretically in  $20^{19}$  different sequences. They also can fold in many different ways because of their ability to form secondary, tertiary, and quaternary structures and combination in macromolecular structures with different proteins. Table 2 gives a small sample of the diverse size of proteins. Each molecule of a specific protein has exactly the same size and amino acid sequence and fold in exactly the same way. Also, we will see later that proteins can be posttranslationally modified in at least 135 different ways.

The period 1925–1960 was very active for protein chemists and enzymologists. During that period James Sumner (2) crystallized urease and showed it to be a protein. In the 1930s, Kunitz and Northrop (3) at Rockefeller Institute learned how to crystallize trypsin, chymotrypsin, pepsin, and other enzymes, strengthening the argument that all enzymes are likely to be proteins. The development of ion-exchange

chromatography by Moore and Stein (4, 5) for separating, identifying, and quantifying amino acids from protein hydrolysates, the Edman method of sequencing proteins (6, 7), and the development of chromatographic (4) and electrophoretic methods (8) for purification of amino acids and proteins all contributed to

**Table 1** Protein Functions

---

Enzymes	
Enzyme inhibitors	
Hormones	
Carriers	
	Hemoglobin and myoglobin ( $O_2$ and $CO_2$ )
	Serum albumin (ions, lipids, hormones)
Protectors	
	Antibodies, skin, hair, nails
	Blood clotting
	Chaperones
	Osmotic regulators (serum albumin)
	Movement (contractile proteins—myosin, actin, etc.)
Connectors	
	Muscle to bone (elastin)
	Signal transducers (nerve transmission)
Recognition	
	Cell-to-cell interaction (glycoproteins)
	A, B, AB, O blood types
Elicitors (antigens)	
	Cell coating, cell “glue” (adhesion), collagen, others
Memory (brain: protein or is it DNA?)	
Taste perception (tongue)	
Vision (opsin, rhodopsin, alcohol dehydrogenase)

**Table 2** Molecular Weights of a Few Selected Proteins

Protein	Molecular weight (daltons)	Protein	Molecular weight (daltons)
Insulin	5,737	Alkaline phosphatase	80,000
Ribonuclease	13,683	Polyphenol oxidase	128,000
Lysozyme	14,100	Fumarase	194,000
Chymotrypsinogen	23,200	Catalase	232,000
$\beta$ -Lactoglobulin	35,000	Aspartate transcarbamylase	310,000
Ovalbumin	45,000	Urease	483,000
Serum albumin	65,000	$\beta$ -Galactosidase	520,000
Hemoglobin	64,500	Glutamate dehydrogenase	2,000,000

rapid advances in understanding the protein nature of enzymes.

During that period, limited thought was given to protein biosynthesis. It was generally assumed that proteins were formed from activated derivatives of amino acids, probably by use of ATP for activation. But no details of the in vivo biosynthesis were known. In the late 1950s and 1960s a few publications appeared, based primarily on studies of microorganisms, that began to give evidence that protein biosynthesis at the molecular level could be more complex than originally thought. Especially, studies based on microbial genetics indicated a precise correlation between nucleotide sequences of DNAs and some RNAs and the amino acid sequences of proteins.

## II. HISTORICAL BACKGROUND

There were many important contributions made in the long journey of understanding protein biosynthesis prior to the 1950s. Genes had been postulated before the turn of the 20th century based on the careful breeding studies of Gregor Mendel (8a). August Weismann in 1892 stated that "the essence of heredity is the transmission of a nuclear substance of specific molecular structure" (8b). In 1903, Walter Sutton linked chromosomes to Mendelian heredity (8c). He observed that all cell divisions producing germ cells also formed thread-like chromosomes, and that a gamete received only one of each of the chromosomes of different morphologic types. Through detailed studies of the fruit fly, *Drosophila melanogaster*, Morgan and his colleagues showed that the genes segregated as four linkage groups corresponding to the four chromosomes (8d). Similar observations followed for corn (10 chromosomes, 10 linkage groups) and peas (7 chromosomes, 7 linkage groups). By 1920, the chromosome theory of heredity became an accepted fact in genetics.

The discovery of the chemical nature of the gene resulted from the merging of genetics and biochemistry between 1930 and 1950. In 1909, Archibald Garrod determined that the human disease alkaptonuria was caused by a rare recessive mutation that was inherited according to Mendelian rules (8e). It was noticed that patients with alkaptonuria had black urine. The dark color was determined to be due to a breakdown product of phenylalanine. In his treatise on "Inborn Errors of Metabolism," Garrod wrote, "We may further conceive that the splitting of the benzene ring in normal metabolism is the work of a special enzyme, [and] that in congenital alkaptonuria the enzyme is wanted."

The research of Morgan and his colleagues in the early 1900s on the inheritance of eye color in *Drosophila* (8f), together with that of Beadle and Tatum on the bread mold, *Neurospora crassa*, and its rare mutant colony development, led Beadle and Tatum to conclude that "genes somehow control protein (enzyme) structure" (8g). These findings led to studies of the chemical structure of genes, as the first step in elucidating the molecular basis for the genetic control of protein synthesis. This occurred in 1944 when Avery et al., in studying *Streptococcus pneumoniae* from patients with pneumonia, showed that DNA from "smooth" colonies can transform "rough" colonies into the smooth form (9). They proved DNA was involved. Addition of several different proteases had no effect on the transforming activity, eliminating involvement of proteins. However, small amounts of purified deoxyribonuclease (DNAase) immediately inactivated the transformation.

In 1953, Watson and Crick deduced the double-helical structure of DNA, ushering in the modern era of molecular cell biology (10). At about this same time, the electron microscope was invented. Light microscopes have a resolving power of  $\sim 500$  nm. Electron microscopes in the early stage had resolving power of

1–5 nm; this was eventually reduced to 0.1–0.5 nm. Therefore, by the beginning of the 1960s the findings of geneticists, biochemists, and structural cell biologists could be brought together, working from the molecular to the subcellular level, and vice versa. Another “principle” that developed about this same time was that the activity of genes is highly regulated. It was known that genes produced proteins, but the methods by which the gene activity was controlled was still unclear. Perhaps the principle enunciated by Jacob and Monod (11) did the most to clarify gene control. They proposed that certain genes regulate the activity of other genes. At the molecular level this transforms to an understanding that specific sets of proteins are produced that build characteristic structures, and some carry out characteristic enzymatic activities.

Further discussion in this chapter will be limited to the enzymes involved in *in vivo* and *in vitro* protein biosynthesis.

### III. PROTEIN BIOSYNTHESIS

#### A. Differences Between Prokaryotic and Eukaryotic Protein Biosynthesis

Being unicellular, formation of bacterial mRNA is always accessible to ribosomes, as well as other components of the protein biosynthesis pathway. Even as the mRNA is being transcribed from DNA, the specific tRNAs and tRNA synthetases begin translation of the protein and transcription and translation are completed at almost the same rate and time. Therefore, the mRNA nucleotide bases are not modified (by methylation) as they are in eukaryotic cell mRNA. In eukaryotes, DNA transcription occurs in the nucleus, which contains ribosomal precursors undergoing formation (in the nucleolus), but there are no mature ribosomes that can perform protein synthesis. In eukaryotes, the mRNA is synthesized in the nucleus. The mRNA must then be secreted through the nuclear membrane into the cytoplasm for translation to occur. Therefore, transcription and translation are not coupled in eukaryotic cells.

In eukaryotes, the RNA is not a functional mRNA, tRNA, or rRNA until it is extensively modified in the nucleus before it is secreted into the cytoplasm where it associates with the ribosomes. Types of modification that occur in the nucleus are: (a) addition of chemical groups at both ends of the mRNA; (b) cutting the mRNA into segments; and (c) recombining the segments by splicing of original noncontiguous segments to produce a very different mRNA. Translation occurs

only when the mRNA is in the cytoplasm. This is the major distinction between prokaryotic and eukaryotic cells (Fig. 1).

Eukaryotic RNA synthesis is carried out by three separate RNA polymerases, while RNA synthesis in prokaryotic cells is performed by a single RNA polymerase. The precursor to three of the four eukaryotic rRNAs (the 28S, 5.8S, and 18S rRNAs) is produced by RNA polymerase I in the nucleolus of the cell. The precursors of the mRNAs are made by RNA polymerase II and the small RNAs (tRNAs and the 5S rRNAs) or their precursors are made by RNA polymerase III.

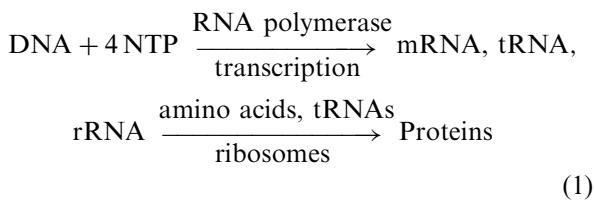

There are fundamental differences between prokaryotes and eukaryotes in chromosome structure due to the core of histones wrapped around the DNA of eukaryotes. With respect to gene control of protein biosynthesis, prokaryotes are regulated at the transcription level while many eukaryotes are primarily regulated at the translation level.

#### B. Steps in Protein Biosynthesis

There are five steps in the biosynthesis of proteins: *transcription* phase in which mRNAs, tRNAs, and rRNAs are produced; *translation* of mRNAs to give polypeptides; *termination of translation*; *posttranslational modification* of the polypeptides; and *folding* of the polypeptides into their native structures.

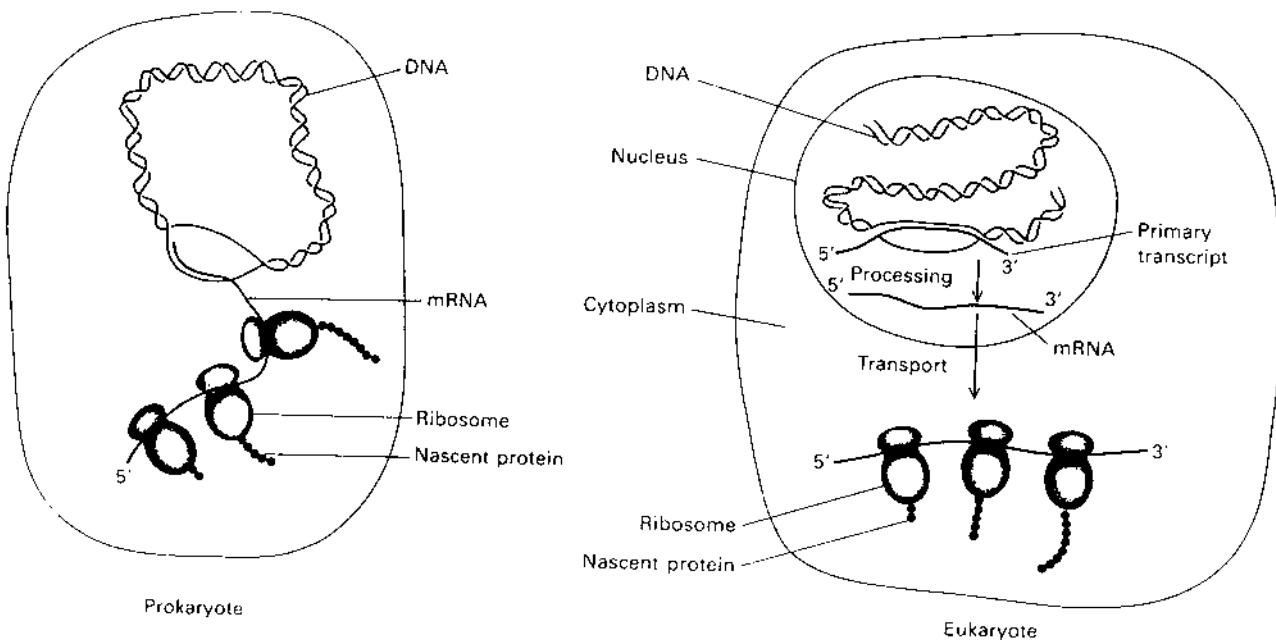

##### 1. Transcription Phase

The overall steps of transcription and translation in eukaryotes are shown in Eq. (1).

During the transcription phase, the mRNAs, tRNAs, and rRNAs are produced. The key enzyme is RNA polymerase II. The three steps are: *initiation* signalled by the promoter recognized by RNA polymerase (in the case of prokaryotes, it is a subunit of the RNA polymerase ( $\alpha_2\beta\beta'\sigma$ )); *elongation* involving a melting and unwinding of the double helix while sequentially attaching ribonucleotides at the 3' end of the growing RNA molecule; *termination* by the formation of stem-loop structures of Rho-dependent terminators.

The April 28, 2000, issue of *Science* published a detailed crystallographic study of the protein architec-

**Figure 1** The production of functioning mRNA is very different in prokaryotes and eukaryotes. In prokaryotes, the RNA transcript serves directly as the mRNA, and translation begins before transcription is completed; that is, transcription and translation are coupled. In eukaryotes, the primary RNA transcript must be modified in the cell nucleus to form mRNA. Translation takes place only after the completed mRNA is delivered to the cytoplasm. (From Ref. 12.)

ture of a yeast (*Saccharomyces cerevisiae*) RNA polymerase II at 3 Å resolution (see insert, Fig. 2) in which 10 of the 12 different subunits are shown (Table 3). The yeast RNA polymerase II has a total mass of 514 kDa. Yeast and human RNA polymerase IIs are considered to be very similar since human genes for 10 of the subunits can be substituted for the yeast genes, and a very similar enzyme is produced. Also, RNA polymerases I and III of prokaryotes contain nine of the 10 proteins of yeast RNA polymerase II.

RNA polymerase II is the key of the transcription process. Without help of other enzymes it can (see Fig. 3): (a) recognize the initiation codon, AUG (the regulated initiation complex contains RNA polymerase II, five transcription factors, and a multiprotein mediator; in all there are some 60 proteins involved); (b) recognize and respond to the operator complex; (c) proofread and unwind the DNA double helix; (d) produce specific mRNA, tRNAs, and rRNAs by catalyzing formation of phosphodiester bonds among nucleotides (Str. 1); proofread the nascent mRNA transcript and replace it if necessary; and (f) recognize the termination point containing the codon AUA, UAG, or UGA.

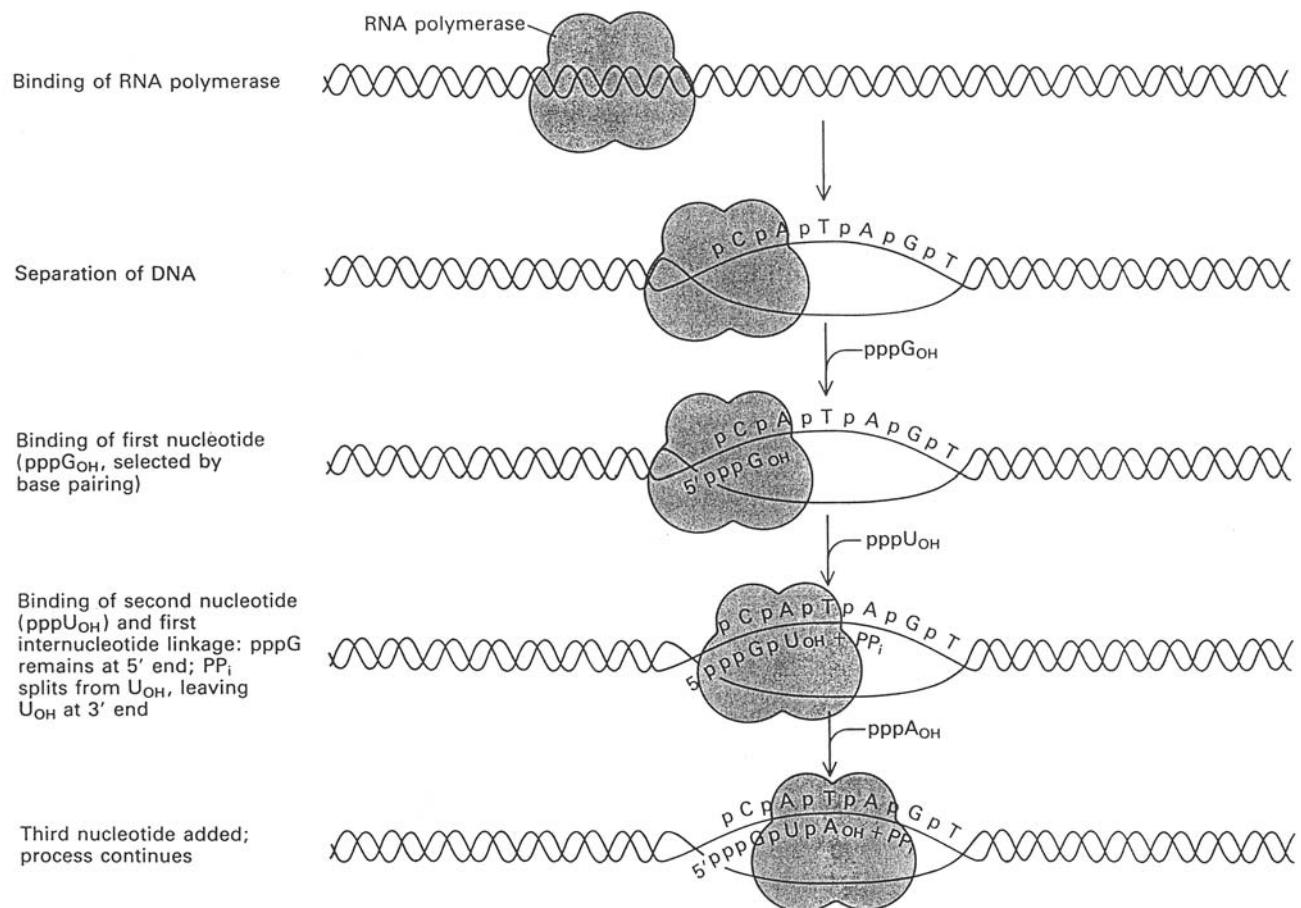

**Table 3** Yeast RNA Polymerase II Subunits

Subunit	Mass (kDa)	Amino acid residues in sequence	Identity to human (%) <sup>a</sup>
Rpb1	191.6	1733 (1449) <sup>b</sup>	52
Rpb2	138.8	1224	61
Rpb3	35.3	318	46
Rpb4	25.4	221	30
Rpb5	25.1	215	45
Rpb6	17.9	155	59
Rpb7	19.1	171	61
Rpb8	16.5	146	43
Rpb9	14.3	122	37
Rpb10	8.3	70	73
Rpb11	13.6	120	50
Rpb12	7.7	70	43
Total	513.6	4565	53

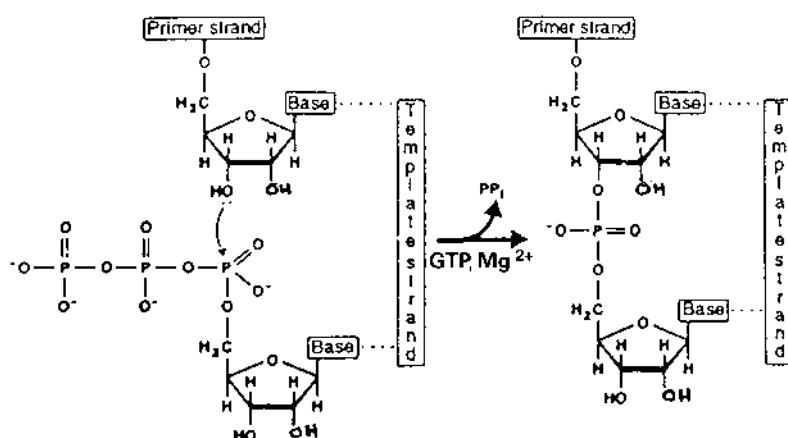

<sup>a</sup>Percentage of identical amino acid residues, for Rpb1 excluding the COOH-terminal domain.

<sup>b</sup>The number in parenthesis corresponds to Rpb1 without the unstructured COOH-terminal domain (CTD).

Source: Ref. 13.

**Figure 3** Transcription of a double-stranded DNA into a single-stranded RNA by an RNA polymerase. The five steps are identified on the left-hand side. Not shown is the termination step. (From Ref. 12.)

**Table 4** The Genetic Code<sup>a</sup>

First position (5' end)	Second position				Third position (3' end)
	U	C	A	G	
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	Stop (och)	Stop	A
	Leu	Ser	Stop (amb)	Trp	G
	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
C	Leu	Pro	Gln	Arg	A
	Leu	Pro	Gln	Arg	G
	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met	Thr	Lys	Arg	G
A	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val (Met)	Ala	Glu	Gly	G

<sup>a</sup>Bases are given as ribonucleotides, so U appears in the table instead of T. “Stop (och)” stands for the ochre termination triplet, and “Stop (amb)” for the amber. AUG is the most common initiator codon; GUG usually codes for valine, but it can also code for methionine to initiate an mRNA chain.

After synthesis of the three types of mRNAs in eukaryotes, they must be secreted from the nucleus via the cell membrane into the cytoplasm, where translation takes place. The time to produce the mRNA is estimated to be about 1–2 sec, depending on the promoter clearance time, number of RNA polymerase molecules, and size of the gene.

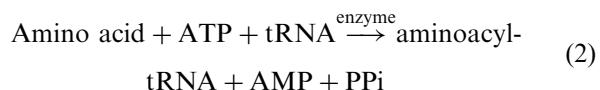

## 2. Translation Phase

The mRNA carries the genetic information for protein biosynthesis that it has transcribed from a gene located on DNA via a three-letter code (codon), complementary to that of the gene. Table 4 lists the genetic codons for each of the 20 amino acids found in proteins. The code contains some redundancies, such that 64 codons (including the “stop” codons) may be used in protein biosynthesis (Table 5).

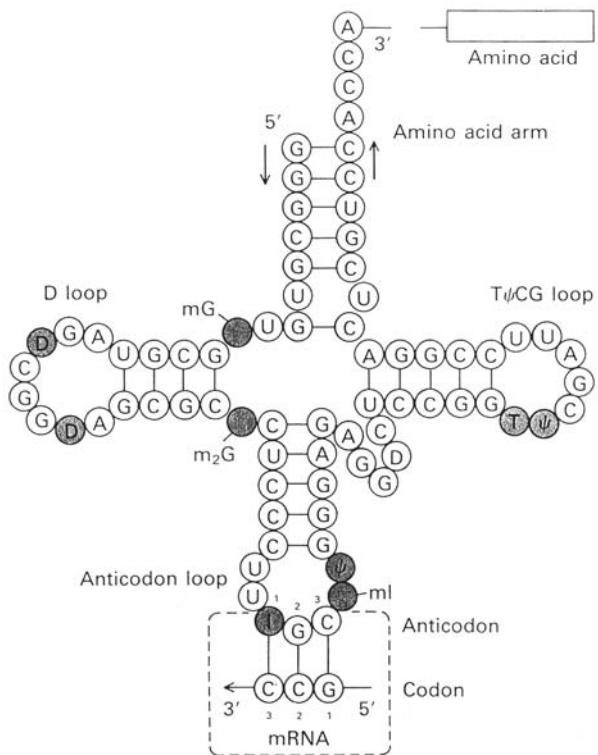

There are tRNAs and tRNA synthetases for each one of the 20 amino acids found in nascent proteins. The tRNA<sup>Ala</sup> for alanine is shown in Figure 4. The tRNAs are small ribonucleotides of ~70–80 residues. Some of the nucleotide bases are also modified following synthesis, as shown by the shaded circles in Figure 4.

The tRNA<sup>Ala</sup> contains an anticodon of IGC which recognizes and binds to the GCC codon on the

mRNA. At the end of the tRNA (rectangle labeled amino acid), there is an adeonsyl group to form a covalent binding site for the specific amino acid (Ala shown here). The tRNA synthetase is responsible for the reaction leading to the bound aminoacyl-tRNA [Eq. 2].

**Table 5** Degeneracy of the Genetic Code

Number of synonymous codons	Amino acid	Total number of codons
6	Leu, Ser, Arg	18
4	Gly, Pro, Ala, Val, Thr	20
3	Ile	3
2	Phe, Tyr, Cys, His, Gln, Glu, Asn, Asp, Lys	18
1	Met, Trp	2
Total number of codons for amino acids		61
Number of codons for termination		3
Total number of codons in genetic code		64

**Figure 4** The primary structure of yeast alanine tRNA ( $tRNA^{Ala}$ ). The tRNA is synthesized from the nucleotides A, C, G, and U, but some of the nucleotides are modified after synthesis (shown by labeled shaded circles) (abbreviations for labels: D = dihydrouridine, I = inosine, T = thymine,  $\Psi$  = pseudouridine, and m = methyl group). The primary structure is a cloverleaf consisting of four base-paired stems and three loops: the D loop, for dihydrouridine, a virtually constant constituent of this loop; the anticodon loop; and the T $\Psi$ CG loop, so named because a sequence of thymidylate, pseudouridylate, cytidylate, and guanylate is virtually always present in this loop. (From Ref. 12.)

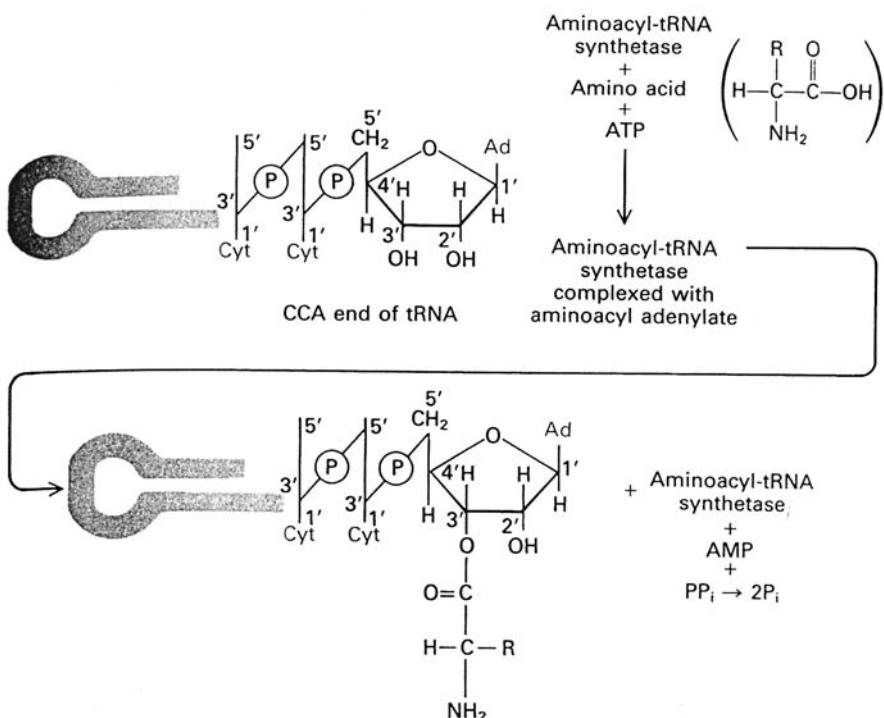

This chemical step is critical to protein synthesis in two major ways. The amino acid derivatives are activated via the ATP reaction as shown by Eq. (2). The amino acid products are shown in Figure 5. The amino acid is covalently attached via the 3' oxygen of the ribose diphosphate group of the tRNA. Secondly, the specificity for binding at the right site on the mRNA is assured (see above).

Formation of the primary sequence of a protein is carried out on the ribosomes (Fig. 6). As indicated above, the eukaryotic ribosomes are located in the cytoplasm of the cells. Protein biosynthesis consists of three major stages: *initiation*, *elongation*, and *termination*.

Darnell et al. (12:122–123) described the entire process in great detail in the following manner (Fig. 7).

a. *Initiation.* An initiation factor ( $IF_2$  in prokaryotes and  $eIF_2$  in eukaryotes) binds a molecule of GTP and a molecule of methionyl-tRNA $^{Met}$  (for prokaryote *E. coli* the methionine is replaced with N-formyl-methionine) to form a ternary complex. This complex binds to mRNA and the small ribosomal subunit (plus other initiation factors) to make an initiation complex (the 30S initiation complex in prokaryotes, and the 40S complex in eukaryotes). The Met-tRNA $^{Met}$  is now positioned correctly at the AUG initiation codon. A large ribosomal subunit then joins the complex; the bound GTP is hydrolyzed; and the initiation factors are detached. The Met-tRNA $^{Met}$  bearing the first amino acid is now bound to the ribosome at the P site. The initiation complex is ready to begin synthesis of the peptide chain.

b. *Elongation.* the met-tRNA $^{Met}$  is located at the P (for peptidyl-tRNA) site on the ribosome. The growing polypeptide is always attached to the tRNA that brought in the last amino acid. A new aminoacyl-tRNA (Phe-tRNA $^{Phe}$  here) binds to the ribosome at the A site (for aminoacyl site). During elongation in prokaryotes, a protein complex called Tu-Ts catalyzes the binding of each aminoacyl-tRNA to the ribosome. These are two “elongation factors”—EF-TU and EF-TS. (A protein complex similar in action to Tu-Ts exists in eukaryotic cells.) A third elongation factor—EF-G—controls the translocation of the A to P sites. An activated Tu-GTP complex binds the T $\Psi$ CG. The Tu-Ts complex probably binds to the T $\Psi$ CG loop found in all tRNAs and allows the tRNA to associate with the ribosome. GTP is hydrolyzed and the Ts protein rejoins GDP-Tu and reactivates it. The complex also binds GTP, whereupon GDP and Ts dissociate from Tu. The remaining GTP-Tu complex then binds to an aminoacyl-tRNA. When the whole elongation factor complex is bound to the ribosome, the GTP is hydrolyzed to GDP, yielding energy to position the aminoacyl-tRNA in the A site. After the incoming aminoacyl-tRNA is correctly placed in the A site—that is, when the codon–anticodon pairing is correct—the peptide chain (or, here, the first methionine) is transferred to the amino group of the newly arrived aminoacyl-tRNA. This generates a peptidyl-tRNA that has acquired an additional amino acid. (In our example, the compound is methionyl-phenylalanyl-tRNA $^{Phe}$ .) At this stage, the peptidyl-tRNA is bound to the ribosome at the A site. The ribosome moves one codon down the mRNA chain. (The mRNA codons

**Figure 5** Translation of an mRNA strand into a protein begins with attachment of appropriate amino acids to the appropriate tRNAs (see Fig. 4). Covalent attachment requires two steps by an aminoacyl-tRNA synthetase that uniquely recognizes and binds to a specific amino acid and its cognate tRNA (see step 1). In the second step, amino acylation of tRNA occurs by ATP to attach the -COOH group of the amino acid to the 3'-hydroxy group of the terminal adenylate of the tRNA. Alternatively, the initial attachment can be to the 2'-OH group, which then rearranges to the 3' position.

are illustrated with spaces separating them for convenience; in mRNA there are, of course, no spaces.) The translocation reaction is catalyzed in bacteria by the elongation factor G, using energy from the hydrolysis of GTP. With this movement, the empty tRNA is released from the P site, and the peptidyl-tRNA is shifted to the P site. (In eukaryotes, too, there are special proteins that serve in elongation.) The sequence of events is repeated for every amino acid added to the growing chain. Note that two molecules of GTP are used in the addition of each amino acid.

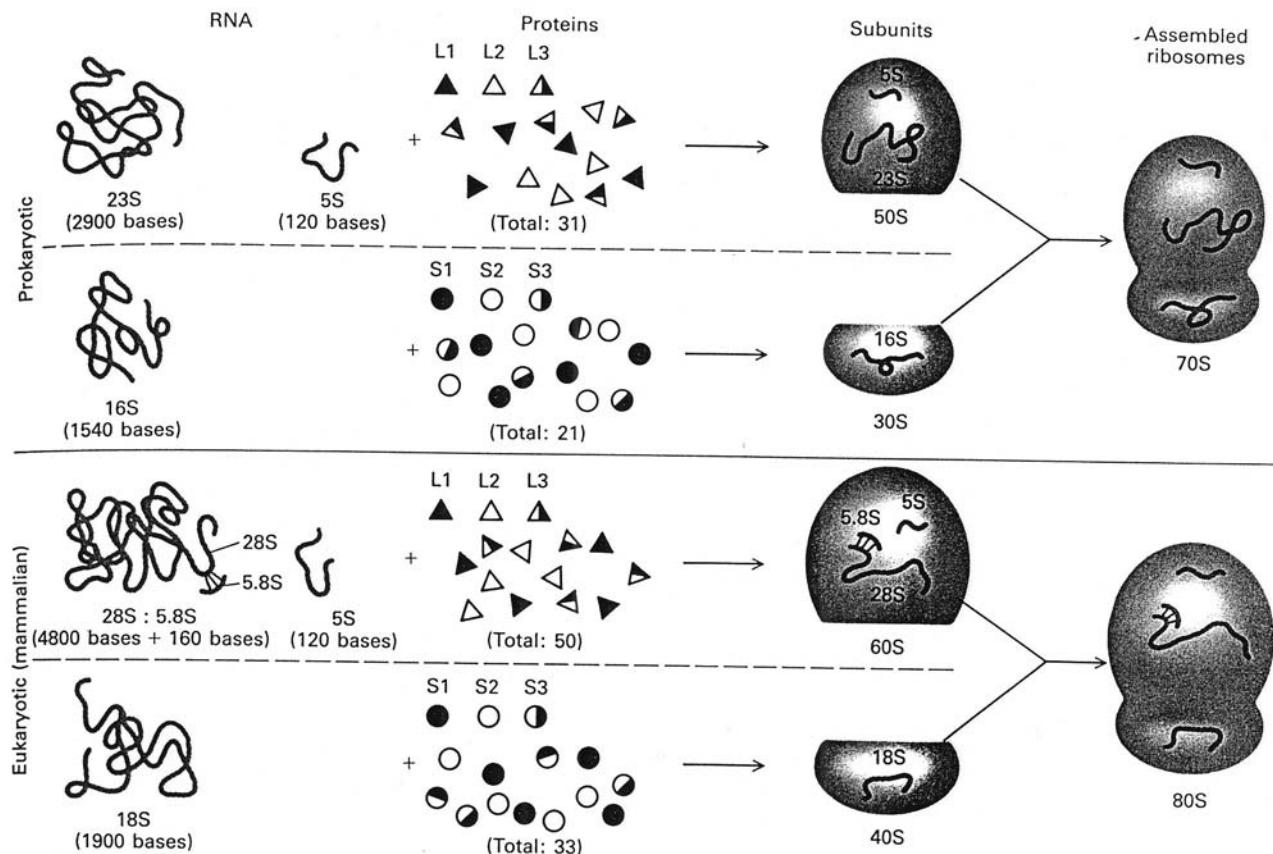

c. *Termination.* When the ribosome arrives at the codon UAG, the translation is completed with the aid of a terminator factor. Hydrolysis of the peptidyl-tRNA on the ribosome releases the completed polypeptide and the last tRNA, and the two ribosomal subunits separate. At least three TFs are involved in *E. coli*—RF1, RF2, and RF3. For eukaryotes, one termination factor eRF recognizes all termination codons.

#### IV. POSTTRANSLATIONAL COVALENT MODIFICATION OF PROTEINS

Once the primary structure of a protein is completely translated by RNA polymerase II, the protein is still biologically nonfunctional. It must undergo chemical modification involving nonhydrolytic and/or hydrolytic modification of the protein, fold into the tertiary structure, form quaternary structure (if needed) and macromolecular structure (if needed), and combine with cofactors (if needed) and often be transported to the site where it performs its function. In this section, we deal only with the posttranslational enzymatic modification.

##### A. Nonhydrolytic Posttranslational Enzymatic Modification

Table 6 lists examples of nonhydrolytic modification of 11 of the 20 amino acid residues, as well as the carboxy

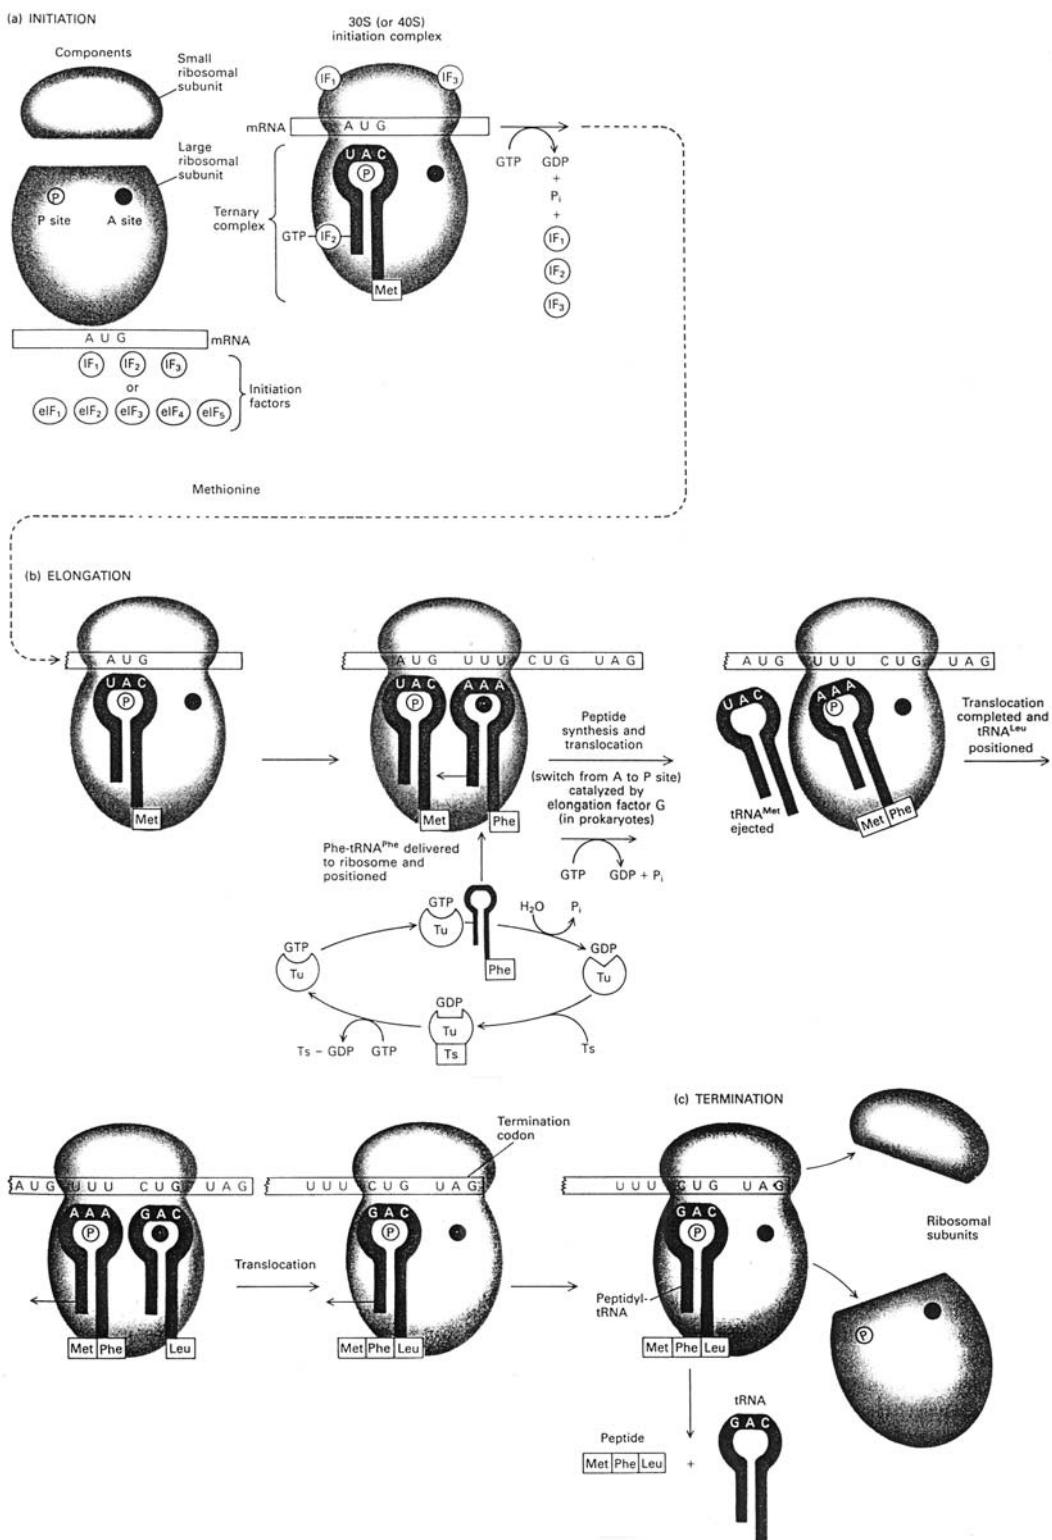

**Figure 6** The composition of prokaryotic and eukaryotic ribosomes is shown, each consisting of a large and a small subunit. The different subunits contain rRNAs of different lengths and varying numbers and types of proteins (indicated by different shadings). In addition to the two major rRNA molecules, prokaryotic ribosomes have one small 5S tRNA that is ~120 bases long. Eukaryotic ribosomes have two small rRNAs: a 5S molecule similar to the prokaryotic 5S, and a 5.8S molecule that is 160 bases long. The proteins are named L1, L2, etc., and S1, S2, etc., depending on whether they belong to the large or small subunits. (From Ref. 12.)

and amino terminal ends of the proteins (14–16). There is a highly specific enzyme for each of these modifications. Some modifications such as glycosylation and activation of the cascade of pro-proteins in blood clotting involve a number of enzymes (see below). Most likely, nonhydrolytic modifications occur as soon as the N-terminal end of the growing protein chain emerges from the ribosomal system.

A good example of posttranslational modification of a protein is that for collagen (Fig. 8). As soon as a part of the nascent primary structure is formed on the ribosome (polysome), hydroxylation of proline and lysine (see Chapters 35 and 36) and glycosylation of hydroxylysine are known to occur (17, 18). Two pro- $\alpha 1$  and one pro- $\alpha 2$  chains align with each other with the N-terminal amino acid all at one end and the C-terminal amino acid at the other end. This triple helix forms disulfide bonds among the three molecules. At this point the procollagen (MW ~115–140 kDa for each molecule) is secreted through the membrane and transported to the location where needed. Collagen is the major protein produced by animals. It forms a coating around all cells, fibrils, bundles of fibrils and, higher structures, such as the sarcomeres and fiber bundles of muscles.

At this point, highly specific and limited enzyme-catalyzed proteolysis occurs. The teleopeptides at the N-terminal end of the procollagen are removed by a specific procollagen peptidase to give molecules of ~95 kDa. The folded collagen molecules are aligned

**Figure 7** Cartoon diagram of the translation of tRNA-acylamino acids and mRNA to form a specific protein. The process involves: (a) the initiation phase; (b) the elongation phase; and (c) the termination phase. The chemistry involved is shown in Figure 5 and Eq. (2). (From Ref. 12.)

**Table 6** In Vivo Nonhydrolytic Enzyme-Catalyzed Posttranslational Modifications of Amino Acid Residues of Proteins

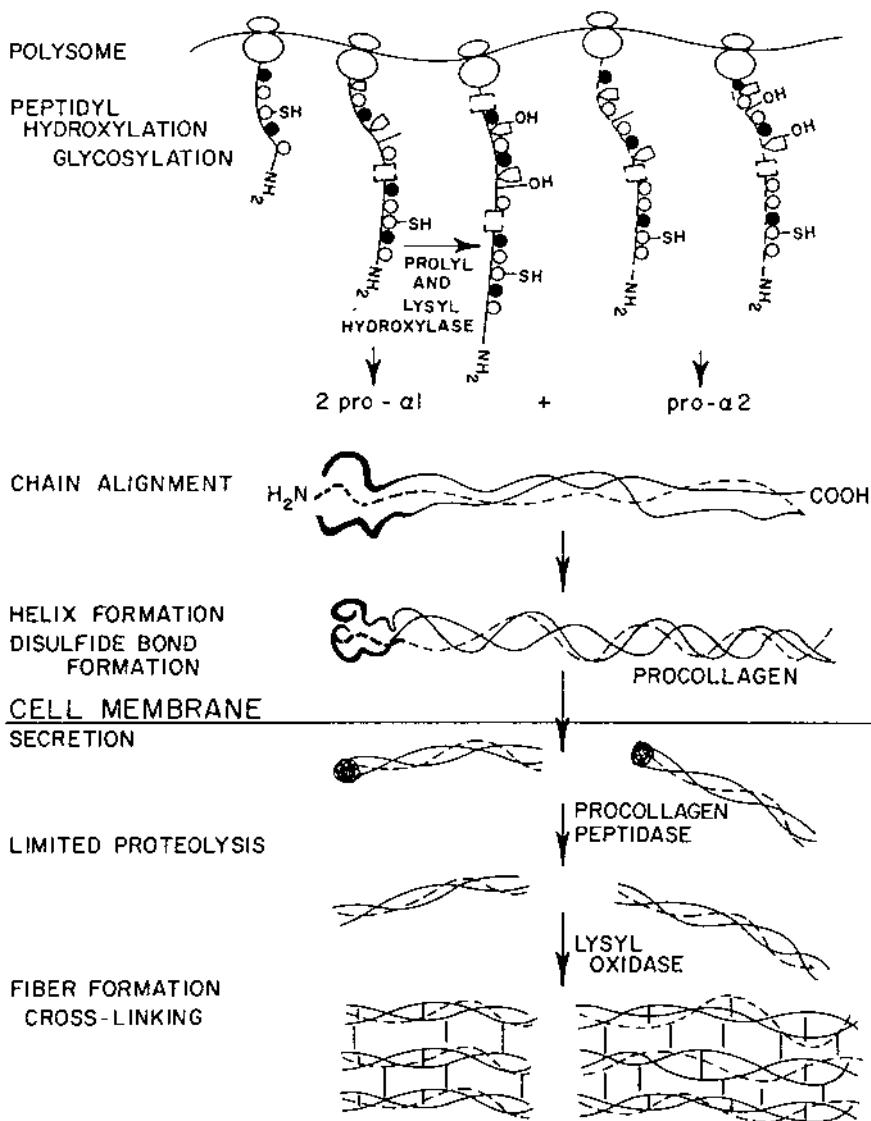

Amino acid (group)	Typical modifications	Total modifications known <sup>a</sup>	Amino acid (group)	Typical modifications	Total modifications known <sup>a</sup>

both end to end in a staggered array and laterally to give cylindrical fibrils with diameter range from  $\sim$  50–2000 Å, depending on the tissue and stage of development. There are further crosslinkages, especially through desmosine formation from four lysyl side chains by lysyl oxidase (see Chapter 37).

## B. Hydrolytic Posttranslational Enzymatic Modification

ins are probably modified by highly specific proteases, since most proteins are secreted from the cell for transport to other locations (organs and cells). Secretion

**Figure 8** Proposed scheme for in vivo posttranslational enzymatic modifications involved in collagen formation. (From Refs. 17, 18.)

from the cell requires a signal peptide targeting the nascent protein for transport. The signal peptide is required to translocate the protein out of the cell. **Table 7** lists a number of physiological systems controlled by posttranslational proteolysis. **Table 8** gives some examples of highly specific proteases involved in physiological processes.

In addition to the posttranslational hydrolytic modifications to collagen (above), three other examples (of many) will be given for preproinsulin, chymotrypsinogen A, and preproproteins in the blood-clotting cascade.

Preproinsulin (**Fig. 9**) is synthesized as a 100-amino acid polypeptide. Immediately on synthesis, a highly specific protease in the luminal space of the endoplasmic reticulum removes the N-terminal signal peptide after amino acid 16 by hydrolysis. The remaining 84-amino acid proinsulin, in which two disulfide bonds have formed correctly (a posttranslational modification), is transported to the Golgi body where a 33-amino acid segment (the C segment in **Fig. 9**) is hydrolyzed from proinsulin by two proteolytic events at two peptide bonds ( $\text{Ala}^{30}\text{--Arg}^{31}$  and  $\text{Arg}^{63}\text{--Gly}^{64}$  of proinsulin) to give two peptides (A [21 amino acid residues]

**Table 7** Physiological Systems Controlled by Limited Posttranslational Proteolysis

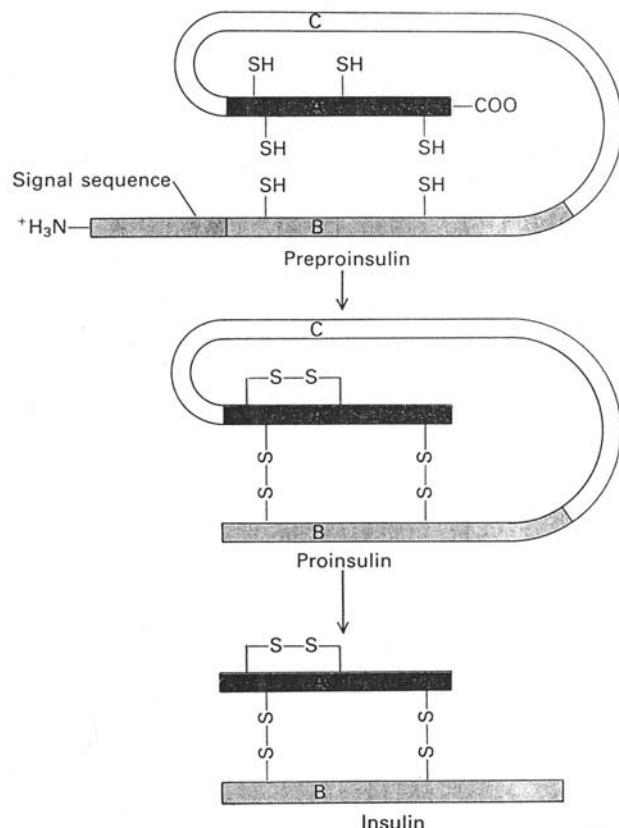

Physiological system	Example

Group-specific proteinase of mast cells which inactivates PALP-apoenzymes
Proteinases of <i>B. megaterium</i> spores which cleave spore protein
RecA gene product from <i>E. coli</i> which cleaves bacteriophage repressor
The acid proteinase renin, which cleaves angiotensinogen to angiotensin
The carboxydiptidase that cleaves angiotensin
The neutral proteinase enterokinase, which cleaves trypsinogen to trypsin
The albumin-degrading light subunit of rat kidney $\gamma$ -glutamyl transpeptidase
The plasminogen-converting streptokinase
The proteinase which cleaves the T4 prehead precursor protein
Calcium-activated protease of myofibrils
Methionine aminopeptidase

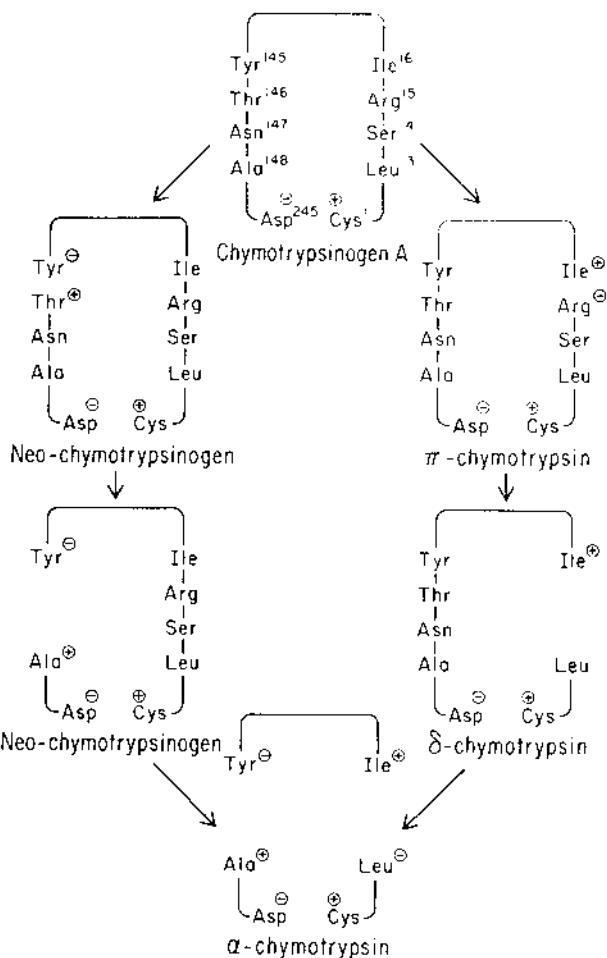

Source: Ref. 20.

**Figure 9** The processing of preproinsulin into proinsulin, and of proinsulin into insulin. The specific proteolytic cleavage of preproinsulin, which occurs immediately after the synthesis of its chain of 100 amino acids is completed, remove 16 amino acids termed the signal sequence from the amino end of the molecule. The remaining 84 amino acids constitute proinsulin, a molecule in which the correct three disulfide bonds have been formed. While the hormone is being packaged for secretion the 33 residues (of the C chain) between the A and the B chains are removed by two specific proteases to produce insulin. (From Ref. 21.)

and B [30 amino acid residues]), held together by two disulfide bonds. This is active insulin.

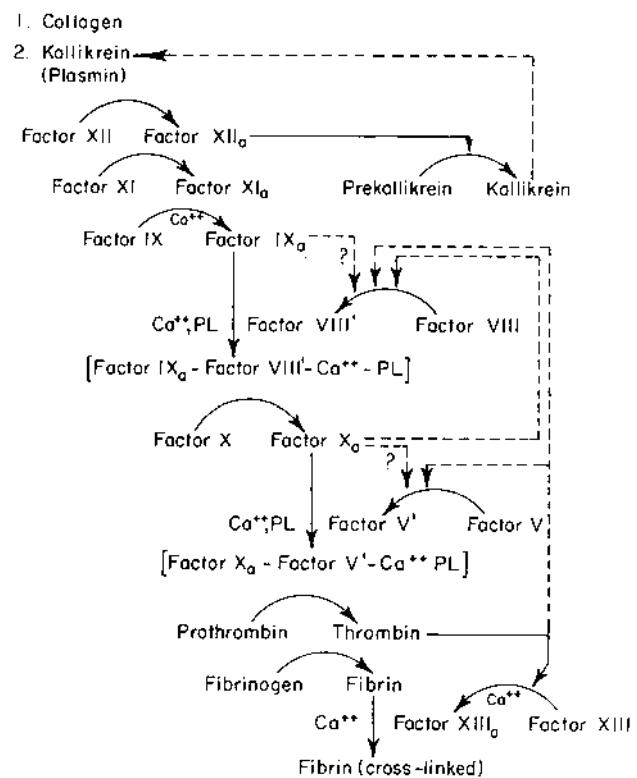

The proteolytic conversion of chymotrypsinogen A to  $\alpha$ -chymotrypsin A is shown in Figure 10. Chymotrypsinogen A is stored in the pancreas as inactive protein. Following secretion into the small intestine, it is activated by trypsin (another protease). Chymotrypsinogen A is translated on ribosomes as a single polypeptide chain of 245 amino acids. The key step in activation of chymotrypsinogen A is hydrolysis of the Arg<sup>15</sup>-Ile<sup>16</sup> peptide bond by trypsin, thereby producing  $\pi$ -chymotrypsin. The active  $\pi$ -chymotrypsin

**Figure 10** Schematic diagram of the role of several limited proteolytic steps in the conversion of bovine chymotrypsinogen A to  $\pi$ -,  $\delta$ -, and  $\alpha$ -chymotrypsins. (From Ref. 22.)

then hydrolyzes the Leu<sup>13</sup>–Ser<sup>14</sup> peptide bond to product active  $\delta$ -chymotrypsin.  $\delta$ -Chymotrypsin can then split the Tyr<sup>145</sup>–Thr<sup>146</sup> and Asn<sup>147</sup>–Ala<sup>148</sup> peptide bonds to give  $\alpha$ -chymotrypsin, a stable enzyme.  $\delta$ -Chymotrypsin can also hydrolyze the Tyr<sup>145</sup>–Thr<sup>146</sup> and Asn<sup>147</sup>–Ala<sup>148</sup> peptide bonds of chymotrypsinogen A to form inactive neochymotrypsinogen (two-step process). Proteolytic cleavage forms three large peptides and two dipeptides from the single peptide chymotrypsinogen A. The three large peptides are held together by four interchain disulfide bonds.

Posttranslational modification of the proenzymes in the blood clotting mechanism is much more complex than the two examples given above (Fig. 11). There are a total of 12 proenzymes in the activation cascade requiring 12 specific proteolytic events, along with a

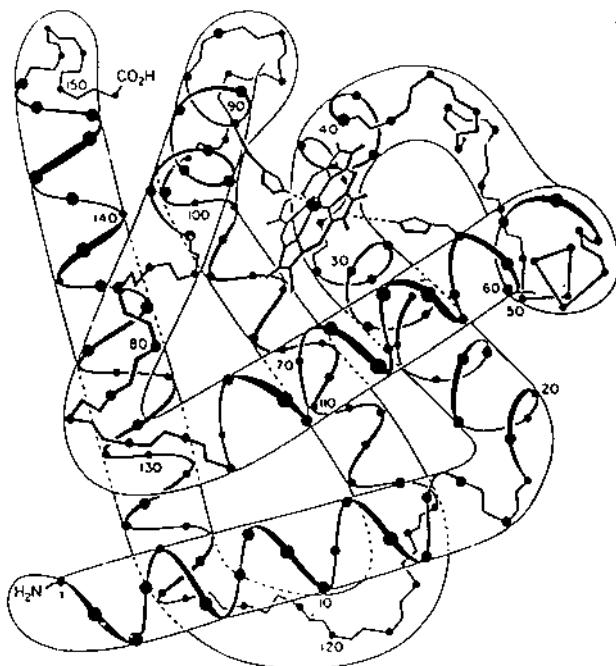

**Figure 11** A proposed mechanism for blood clotting in mammalian plasma in the intrinsic system. The factor on the left side of reaction (proenzyme) is converted to active enzyme by a highly specific proteolysis. PL, phospholipids. (From Ref. 23.)

transglutaminase cross-linking of a glutamyl  $\delta$ -carboxyl group to an  $\varepsilon$ -amino group of a lysyl residue of fibrin to form the final clot. The proenzymes are always found in the blood but the cascade of events, initiated by a cut (for example), takes < 1 min to produce a clot.

After the primary amino acid sequences of proteins are formed, they are posttranslationally modified and then folded to give the secondary and tertiary structures, as dictated by the amino acid sequence. Some proteins, such as hemoglobin, with > 30% hydrophobic amino acid residues on the surface, will form quaternary structures. Figure 12 shows the primary, secondary ( $\alpha$ -helices) and tertiary structures of myoglobin.

### C. In Vivo Turnover of Proteins

Do proteins last forever, once synthesized? The answer is no in all except one case. Table 9 shows a few exam-

**Figure 12** Schematic drawing of the primary, secondary, and tertiary structures of myoglobin as determined by x-ray crystallography. Only the  $\alpha$ -carbons are shown. The heme is located in the upper center part of the molecule. (From Ref. 24.)

ples of turnover rates for proteins. Ornithine decarboxylase has a half-life of 10 min, while lactate dehydrogenase isoenzyme LDH<sub>5</sub> has a half-life of 16 days. Hemoglobin has a half-life of  $\sim$  40 days. Elastin is thought to be stable for a lifetime.

Many studies have been done on how a protein molecule is targeted for replacement. Factors to consider include the equilibrium between native and reversible denatured protein, the state of glycosylation,

**Table 9** Rates of Intracellular Turnover of Some Selected Proteins

Protein	Half-life
Ornithine decarboxylase	10 min
$\delta$ -Amino levulinate synthetase	60 min
Catalase	1.4 d
LDH <sub>5</sub>	16 d
Hemoglobin	$\sim$ 40 d
Mitochondria protein as whole	4–5 d
Rat protein, 70%	4–5 d
Cultured cells	1–2 h

Source: Ref. 25.

types of damage caused by metabolic events and to cofactors of enzymes. Cellular protein turnover occurs primarily in the lysosomal organelles found in the cytoplasm of cells. (See Refs. 26 and 27 for a review of in vivo protein turnover. This chapter is limited to that of protein biosynthesis.)

## V. COMMERCIAL UTILIZATION OF KNOWLEDGE FROM IN VIVO PROTEIN BIOSYNTHESIS

This chapter closes with a brief and incomplete look at why detailed knowledge of the pathway of protein biosynthesis is commercially important.

There is first, and foremost, the health reason for being able to potentially “fix” some 600 or so diseases and defects of humans caused by defective genes. Now that the entire human genome has been elucidated, how, and should, the defective genes be repaired in order to prolong and improve the quality of life? At what cost, in privacy, dollars, and ethical considerations?

The opportunity to use nature as an excellent “chemist” promises many rewards. Organisms, especially microorganisms, can be “reprogrammed” to concentrate most of their energy in making proteins, enzymes, and health products needed by humans and other animals. The biological process is less polluting and requires less energy and much less time, and the products are stereospecifically those that can be used by other organisms, including humans. DNA shuffling and enhanced plasmid expression of a gene may lead to higher yields at faster rates than wild-type organisms can do. The change in one or a few codons may lead to more product, or a product with better properties. The Bt gene inserted into corn, cotton, and soybeans, for example, eliminates the need for highly toxic and polluting chemical pesticides.

There are several recombinant gene approaches that may be used to modify the properties of enzymes and proteins: (a) plasmid amplification; (b) selective changes in one or more nucleotides of a gene so as to modify one or a few amino acid residues in wanted proteins; (c) addition of new amino acids at the C- or N-terminal end of proteins to increase ease of purification; (d) anti-sense sRNAs to inhibit translation of specific genes in organisms; (e) mRNA–protein fusions to make new or modified functions (28); (f) ribosome displays to produce larger libraries for genetic cloning and improvement via combinatorial chemical techniques (28); and (g) DNA family shuffling [molecule breeding (29, 30)].

Stemmer et al. (29) are leaders in DNA family shuffling of genes. DNA shuffling can be used to great advantage for directed evolution of plants, animals, and microorganisms, in that it can select for useful mutations among similar genes from different species. Libraries of chimeric genes can be generated by random fragmentation, via specific restriction enzymes, of a pool of related genes, followed by reassembly of the fragments in a self-priming polymerase reaction. Template switching during translation causes crossovers in areas of sequence homology. Unlike traditional breeding techniques, molecular breeding by shuffling can efficiently mix gene sequences from different species of organisms. The most common uses of DNA shuffling to date are to increase specific activities of enzymes and hormones, increase stability of proteins, or improve specificity of enzymes, hormones, or drugs (29).

Some of the many examples illustrating the promise of DNA shuffling are (a) making pharmaceuticals and vaccines to target specific cells (31, 32); (b) improving starch metabolizing enzymes (33); (c) improving thymidine kinase for AZT phosphorylation (34); (d) developing humanized antibodies to ganglioside GM<sub>2</sub> (35); and (e) improving the specific activity and specificity of enzymes (33, 36). Specific activity increases of 50- to 150-fold have been reported in some cases.

Table 10 lists a few reasons why directed protein biosynthesis of genetic engineering of organisms has merit.

**Table 10** How Can Molecular Biology Be Used for Industrial and Laboratory Purposes?

- 
- |  |
|--|
| To produce needed enzymes in large, relatively pure amounts    |
| To make needed proteins in large, relatively pure amounts      |
| To suppress production of unwanted <i>in vivo</i> enzymes      |
| To enhance production of desired <i>in vivo</i> enzymes        |
| To identify and classify microorganisms                        |
| To determine amino acid sequences of proteins and enzymes      |
| To enhance nutritional quality of food proteins                |
| To modify proteins to improve functional properties            |
| To increase stability of enzymes at higher temperature and pH. |

## Nucleic Acid Biosynthesis

**Dominic W. S. Wong**

*U.S. Department of Agriculture, Albany, California, U.S.A.*

### I. INTRODUCTION

Biosynthesis of DNA is a biochemical process of high complexity, tightly controlled by a wide range of regulatory mechanisms. At least 30 proteins are required to replicate the chromosome of *Escherichia coli*. The overall pattern of DNA replication is semiconservative as unequivocally proved by Meselson and Stahl (1) using  $^{15}\text{N}$ -labeling techniques. At the same time, the biochemistry and enzymology of the process of DNA replication has become the focus, since Kornberg and colleagues (2) isolated DNA polymerase I from *E. coli*. Four decades later, the general picture of DNA replication is fairly well understood, although many details remain to be filled. This chapter is not an overview of the replication process, but an attempt to describe the enzymology of the process, with emphasis on a number of relatively well-characterized enzymes critical to various stages of DNA replication in prokaryotes.

In simple genomes, DNA replication is initiated by the formation of a nucleoprotein complex formed by the association of multiple DnaA proteins with the recognition sequence at the replication origin. In *E. coli*, the origin of replication consists of a sequence of 245 bp that contains four binding sites to which DnaA can bind and initiate the stepwise assembly of all the proteins and enzymes to form a replisome necessary for replication (3). The binding of multiple DnaA proteins to the replication origin promotes denaturation of the DNA strands in an A + T-rich region adjacent to the nucleoprotein complex. In eukaryotic cells,

the origin of replication consists of a core component (including an origin recognition element, a DNA-unwinding element, and an A + T-rich element) and one or more auxiliary components flanking the *ori* core, that are binding sites for the activation by transcription factors (4). The opening of the strands allows several events to occur at the replication fork, each requires a unique enzyme or enzyme complex: (a) DNA helicase for progressively unwinding the parental duplex DNA; (b) primases for the synthesis of primer RNAs needed for the initiation of polymerization; (3) DNA polymerase for the continuous  $5' \rightarrow 3'$  synthesis in the leading strand, and the synthesis of Okazaki fragments in the lagging strand in a discontinuous manner.

### II. UNWINDING

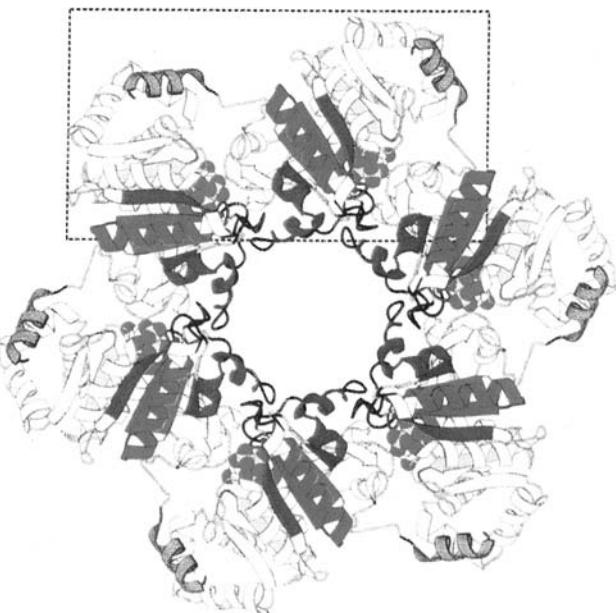

Helicases are a family of enzymes essential to many aspects of DNA metabolism, including DNA replication, recombination, transcription, and repair and, for RNA translation, splicing and ribosomal assembly. Comparison of amino acid sequences suggests that helicases can be classified into two superfamilies, SF1 and SF2, and a smaller family consisting of DnaB-like helices (5). In the latter family, *E. coli* DnaB, RuvB, Rho, RepA, and bacteriophage T7 gp4 and T4 gp41 are helicases with a hexameric ring structure (6). This family of helicases is defined by five conserved regions. The *E. coli* DnaB and the bacteriophage T7 gp4 are the

most extensively studied replicative helicases that catalyze strand separation at the replication fork. Both are 5'-3' helicases which exhibit a conformational flexibility. The hexameric DnaB has been shown to exist in two different forms, with a threefold symmetry (a trimer of dimers), or sixfold symmetry, and a range of intermediate states (7). The T7 gp4 also likely involves stable dimer, trimer, and higher oligomer species (8). The functional implication of these conformations is not clear. The T7 gp4 protein, unlike DnaB, is bifunctional, consisting of a helicase domain and a primase domain, collectively known as helicase-prime.

### A. Molecular Structure

The primary structure of DnaB helicase, deduced from the DNA sequence, contains 470 amino acid residues with a calculated MW of 52,265. In the mature protein, the N-terminal methionine residue is removed in vivo, leaving Ala as the N-terminal residue (9). The protein is proteolytically cleaved in a two-stage process (10). The N-terminal 14 amino acid residues are removed initially, resulting in a 50-kDa polypeptide (Fragment I), which is subsequently cleaved into two separate segments: a C-terminal 33-kDa Fragment II which contains the active site for nucleotide binding proteins, single-stranded DNA binding, DNA-dependent ATPase activity, and oligomerization to hexameric structure, and an N-terminal 12-kDa Fragment III which is essential for protein interaction with DnaC and primase in priming DNA replication in the primosome. The crystal structure of Fragment III consists of a central helix ( $\alpha$ 1) wrapped around by five  $\alpha$ -helices (11).

The crystal structure of the helicase domain of the bacteriophage T7 gp4 protein has been determined (68). The T7 helicase domain has a sixfold symmetric ring with a central hole of 35 Å, that can accommodate a single-stranded DNA. The structural core is a nucleotide-binding fold consisting of a central parallel  $\beta$  sheet flanked by helices (Fig. 1). Four of the five motifs (H1, H1a, H2, and H3), which are conserved in the DnaB-like family, are located at the C-terminal ends of the  $\beta$  strands. The binding of nucleotide lies at the interface between subunits, involving interactions of residues within the four motifs. The subunits are joined with stabilization by hydrophobic and electrostatic interactions over the length of helix A intertwining between adjacent domains. Several conserved residues at the NTP binding site have been identified for interactions with the phosphates (12). Lys318 interacts with the  $\beta$  phosphate and also serves to stabilize

**Figure 1** Ring-shaped hexamer of bacteriophage T7 gp4 helicase, with the outer diameter of 120 Å and a central hole diameter of 35 Å. The N-terminal helix of each subunit packs against the neighboring subunit of the hexamer in a swapping arrangement. (Reprinted from Ref. 68, Copyright 1999, with permission from Elsevier Science.)

the transition state during hydrolysis. Arg522 is in contact with the  $\gamma$  phosphate, which is linked to residues in the ssDNA binding site (located in motif H4) via His465. This arrangement may provide a switch coupling ATP hydrolysis to DNA binding. Both  $\beta$  and  $\gamma$  phosphates are coordinated by a Mg<sup>2+</sup> ion that ligands to Ser319 and Asp424 sidechains.

### B. NTP Binding and ATP Hydrolysis

For the unwinding of double stranded DNA, cooperative NTP binding and hydrolysis are required to induce conformational changes necessary to promote DNA binding and translocation of helicase along the DNA (13). Studies on *E. coli* DnaB suggests that all nucleotides bind with high affinity to three sites, followed by a second phase of low-affinity binding, with a negative cooperativity (14). For the bacteriophage T7 gp4, nucleotide binding at the three high-affinity sites exhibits positive cooperativity (15). The T4 helicase shows a preference with dTTP, and one to two NTPs per hexamer is sufficient for the interaction between helicase and DNA. Crystallographic studies on the T7 gp4 helicase domain indicate that NTP binding results in the

rotation of the subunits of the ring with a 15° distortion from a sixfold symmetry (12). This conformational change gives rise to the negative cooperativity of NTP binding; binding at one site confers a negative effect on the binding of the subsequent site. A model has been proposed in which the binding sites can exist in either of two conformational states—R (relaxed) when the site is filled by ADP, P<sub>i</sub>, and T (tense) when ATP is bound to the site. Conformational changes from R to T and vice versa with each cycle of ATP binding and hydrolysis, involves three NTP binding sites at any one stage of the cycle (13). In a two-site sequential model, one catalytic NTPase site and one site for ADP + P<sub>i</sub>, alternating among the six subunits. It is also as likely that active hydrolysis occurs at only one site in any one cycle. Nucleotide hydrolysis is mediated by Mg<sup>2+</sup> coordination of the phosphates for nucleophilic attack. The metal ion also serves to stabilize the developing negative charge of the transition site. The energy released is the driving force for the helicase to unwind DNA duplex and processively translocate along the nucleic acid lattice.

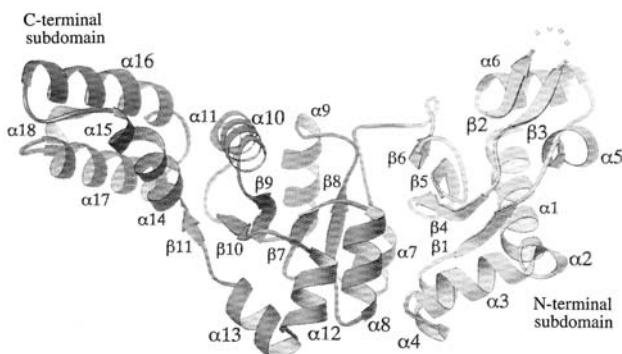

### C. DNA Binding

The T7 gp4 helicase, like most hexameric helicases, binds ssDNA with a much higher affinity than dsDNA. The helicase binds a 10-mer and 30-mer with a K<sub>d</sub> value of 10 nM, and a second strand 50-fold lower in affinity (16). Similar results have been observed for *E. coli* DnaB (17). Most DNA helicases show preferences, at least in vitro, for unwinding duplex DNA with ssDNA flanking at either 5' or 3' ends. The *E. coli* DnaB and the T7 gp4 helicase require a forked DNA, with ssDNA primers attached to both 5' and 3' ends of each complementary strand (18). In the unwinding process, T7 gp4 helicase encircles the lagging strand whereas the 3'-5' ssDNA strand (leading strand) is excluded from the central cavity (19). In this model, the helicase translocates unidirectionally along the single-stranded DNA in the direction of the DNA duplex, facilitated by ATP hydrolysis. Alternatively, an active mechanism has been proposed for the *E. coli* Rep protein, in that the helicase binds to the dsDNA at the duplex–primer junction, and plays a direct role in destabilizing the base pairs in each catalytic step (20). A recent study showed that T4 helicase can unwind unnatural substrates having the displaced DNA strand replaced by a peptide nucleic acid mimic, at similar rates as DNA-DNA substrate, indicating that unwinding is insensitive to the chemical nature of the displaced strand (21).

### III. PRIMING

DNA polymerases are unable to initiate de novo polymerization, and require the priming of DNA synthesis by RNA transcription. The process involves replication-priming RNA polymerases, called primases, that synthesize short RNA primers to provide a 3'-OH onto which the first nucleotide is added. In *E. coli*, the primase, DnaG, is produced separately from the DnaB helicase, whereas in bacteriophage T7, primase and helicase activities are found in separate domains of the gp4 protein. The priming step occurs once for the leading strand, but multiple times for DNA synthesis in the lagging strand. The *E. coli* DnaG participates in protein–protein interactions with DnaB (helicase), single-stranded DNA binding protein (SSB), and DNA polymerase III holoenzyme, for cooperative synthesis of DNA. Association of primase with the replication fork is mediated by protein–protein interaction with the DnaB helicase (22), with the binding site located at the C-terminal domain of ~16 kDa (23). Mutations on the surfaces of interaction between the two proteins significantly reduce primer synthesis (24). The DnaG primase synthesizes primers predominantly 10–12 nucleotides in length, starting with a purine (25). This (p)ppApPu-rich sequence at the 5' end of the primer RNAs is structurally similar to some of the eukaryotes. The primase remains stably bound to the primer RNA site via contact with the single-strand DNA-binding protein (SSB), and must be displaced before the DNA polymerase holoenzyme can attach to the DNA duplex–primer junction. It has been suggested that the  $\chi$  subunit of the  $\gamma$  complex in the holoenzyme competitively binds to the SSB to disrupt the primase–SSB interactions, resulting in the displacement of the primase from the primer (26).

The *DnaG* gene sequence contains a coding region of 1740 nucleotides, corresponding to 580 amino acids, with the first 14 residues cleaved off in the mature protein (27). A sequence comparison of several bacterial primases reveals a conserved zinc-finger motif in the N-terminus where the catalytic domain is located, and a conserved basic region that shares with RNA polymerase large subunits (28). That the catalytic function is located in the N-terminus has been confirmed by a study on a partial proteolytic digestion of the protein, and analysis of biochemical properties of the major fragments (29). The DnaG primase is a cashew-shaped molecule consisting of three domains: an N-terminal  $\alpha/\beta$  fold, a central five-stranded  $\beta$  sheet sandwiched by six  $\alpha$ -helices, and a C-terminal antiparallel, three-helix bundle (Fig. 2) (30). The active site is located at a

**Figure 2** Structure of *Escherichia coli* DnaG primase, showing the N-terminal, central, and C-terminal subdomains from right to left. (Reprinted from Ref. 30, Copyright 2000, with permission from American Association for the Advancement of Science.)

shallow, wedge-shaped cleft formed at the interface between the N-terminal and central domains. The invariant carboxylic acids, Glu265 and Asp309, from the side formed by the central domain serve as ligands for  $Mg^{2+}$  coordination. The side covered by the N-terminal domain provides an electrostatically positive ridge for surface interaction with the template phosphodiester backbone.

#### IV. ELONGATION

Two modes of action are introduced in the elongation process, because of the antiparallel arrangement of the DNA duplex, and the fact that DNA polymerase can only synthesize DNA in the  $5' \rightarrow 3'$  direction. DNA synthesis in the leading strand occurs in the same direction as the replication fork progress, and consequently only a single priming event is needed and DNA is synthesized continuously by DNA polymerase III holoenzyme. The leading strand synthesis is highly processive at a rate of 1000 bp/sec, owing to the action of a “sliding clamp” ( $\beta$  subunit) that tethers the enzyme to the DNA template. Processivity (average number of bases inserted in a single event of association, polymerization, and dissociation of the DNA polymerase on the DNA template) of 5000 (31) to even 500,000 (32) has been reported. Elongation of the lagging strands, however, consists of the formation of short DNA fragments of 1–2 kb in length, in a discontinuous process requiring repeated RNA primer synthesis, DNA extensions, primer removal, DNA repair, and gap filling. The DNA polymerase enzyme complex adapts to these various conditions by partial

disassembly and reassembly of the holoenzyme structure during the synthesis of each Okazaki fragment (33, 34).

#### A. DNA Polymerase III

DNA polymerase III holoenzyme is a large enzyme complex ( $> 1$  MDa) composed of 10 subunits (35), with four distinct functional components: (a) the polymerase core— $\alpha$  (132 kDa),  $\varepsilon$  (27 kDa), and  $\theta$  (10 kDa); (b) the  $\beta$  subunit (38 kDa), which acts like a “sliding clamp” that confers processivity (36); (c) the  $\gamma$  complex ( $\gamma_2\delta_1\delta'_1\chi_1\psi_1$ , 47 kDa) which assembles the  $\beta$  subunit onto the DNA in an ATP-dependent process (37, 38); and (d) the linker protein,  $\tau$  (71 kDa), which dimerizes two polymerase cores and one  $\gamma$  complex. The core subunits,  $\alpha\varepsilon\theta$ , are tightly bound and can only be dissociated by denaturation. The  $\alpha$  subunit contains polymerase activity, while the  $\varepsilon$  subunit carries the editing function of  $3'-5'$  exonuclease activity (39). In contrast, DNA polymerase I consists of both polymerase and  $3'-5'$  exonuclease activities, located in the C-terminal Klenow fragment of the enzyme molecule (40).

DNA polymerases are classified into three major families—A, B, and C—based on the alignment of DNA sequences with *E. coli* polymerases (41). Family A enzymes are named for their homology to the product of the *polA* gene encoding *E. coli* DNA polymerase I; Family B enzymes are named for homology to *polB* gene encoding *E. coli* DNA polymerase II; and Family C for their homology to the *polC* encoding *E. coli* DNA polymerase II  $\alpha$  subunit. *E. coli* DNA polymerase III contains 1160 amino acid residues with a calculated MW of 129,920 daltons, and a pI of 4.93 (42). The widely investigated *E. coli* DNA polymerase I consists of 928 amino acids with a calculated MW of 103,117 and a pI of 5.37 (43, 44). Mild proteolysis of DNA polymerase I at Thr323-Val324 produces a large (Klenow) fragment of 605 amino acid residues with a MW of 68,064, and a smaller fragment of 323 amino acid residues.

#### B. Molecular Structure

The crystal structures of several DNA polymerases have been published, including *E. coli* DNA polymerase I Klenow fragment (40), HIV-1 reverse transcriptase (45), rat DNA polymerase  $\beta$  (46), *Thermal aquaticus* DNA polymerase (47), bacteriophage T7 DNA polymerase (48), bacteriophage RB69 DNA

polymerase (49), *Thermococcus gorgonarius* DNA polymerase (50), and Archaeon *Thermococcus* sp. 9°N-7 polymerase (51).

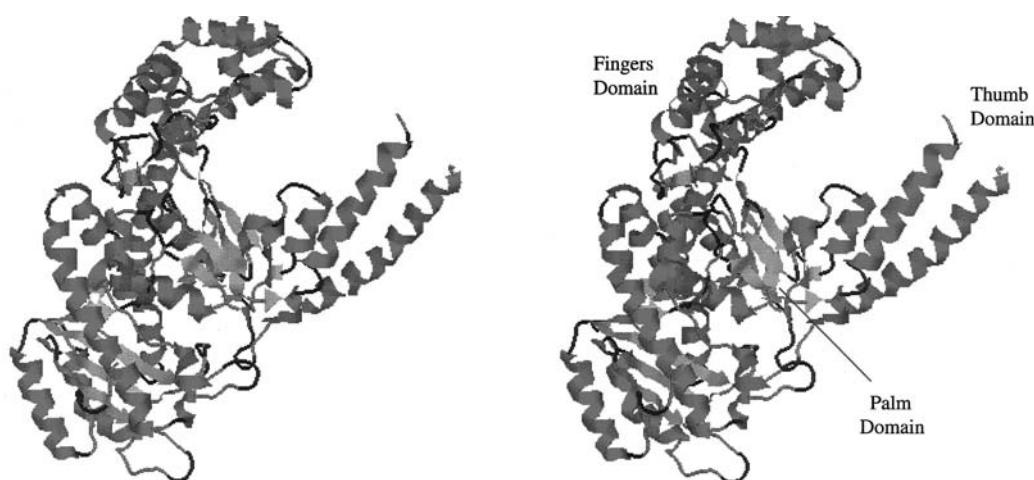

The overall structure of *E. coli* polymerase I Klenow fragment consists of a large C-terminal (polymerase) domain that has a handlike shape built by the palm, fingers, and thumb subdomains, and a smaller globular N-terminal (3'-5' exonuclease) domain that forms a central, mostly parallel  $\beta$ -pleated sheet with  $\alpha$  helices on both sides (Fig. 3) (40).

The general architecture of the polymerase domain is shared by all known polymerases. The palm subdomain contains a six-stranded antiparallel  $\beta$  sheet that forms the bottom of the cleft about 20–24 Å wide and 25–35 Å deep, which can accommodate  $\sim 8$  bp of duplex DNA. The fingers subdomain contains all  $\alpha$  helices that form one side of the wall surrounding the cleft. The other side of the wall consists of primarily two long  $\alpha$  helices, projecting out and hanging over the cleft like a thumb. The palm subdomain is the most conserved structure among all polymerases. This is the catalytic center that contains the binding sites for the 3' terminus of the primer and the substrate dNTP. The active site contains a cluster of three carboxylate side chains of Asp705, Asp882, and Glu883, which are ligands for two metal ions. The fingers subdomain binds the DNA template strand and directs it in a productive orientation for interactions with the primer. The thumb subdomain functions to control the accessibility of the active site to substrate binding and product release. The thumb  $\alpha$  helices, together with numerous other protein–DNA interactions, may act

as a clamp to position the template primer relative to the polymerase active site.

The small (3'-5' exonuclease) domain contains a central mostly parallel  $\beta$  sheet with  $\alpha$  helices on both sides (40). A divalent metal ion is coordinated to the carboxylate groups of Asp355, Glu357, and Asp501, and to the 5' phosphate of dTMP, with a water molecule (or hydroxide ion) as a fifth ligand. A second metal ion at site B is observed only when dNMP is bound to the protein molecule. The meal  $Mg^{2+}$  is coordinated to the carboxylate of Asp355, Asp424, and two of the 5' phosphate oxygens of dNMP, and three water molecules hydrogen bonded to the carboxyl oxygens of Asp424 and to backbone amides (52).

The polymerase domain and the exonuclease domain have separate DNA binding sites and can function independently. The Klenow fragment, with the polymerase active site filled by a duplex DNA, can bind and cleave a second DNA substrate at the exonuclease active site (53). Based on the crystallographic study of the Klenow fragment bound to duplex DNA (54), the duplex DNA (primer strand base-paired to the template strand) is in contact with the thumb subdomain, the single-stranded template strand beyond the site of DNA synthesis is in contact with the fingers subdomain, and the 3' end of the primer strand lies near the carboxylates groups of the three catalytic residues in the active site. In the editing mode, the 3' end of the primer strand is dissociated from the duplex and lies in the active site of the exonuclease domain. This particular arrangement of the substrate binding allows an interactive mechanism of DNA synthesis and

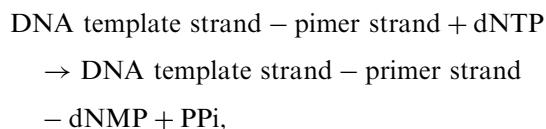

**Figure 3** Schematic illustration of *Escherichia coli* DNA polymerase I Klenow fragment, showing the N-terminal, central, and C-terminal subdomains. Arrows indicate  $\beta$  sheet; tubes represent  $\alpha$  helices (From PDB id: 1kfd).

proofreading (or editing) by virtue of allowing the 3' end of the primer strand to shuttle between the two active sites, when a mismatch at the 3' terminus occurs (55). It involves a competition between these two sites for synthesis and editing.

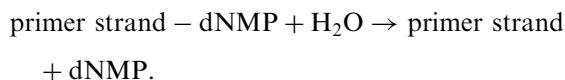

In *E. coli* DNA polymerase III holoenzyme, the polymerase and 3'-5' exonuclease activities reside in separate subunits,  $\alpha$  and  $\epsilon$  respectively, rather than in two domains of the same subunit as in the case of DNA polymerase I described above (39). The  $\epsilon$  subunit plays a significant role in replication fidelity by controlling the editing activity of the holoenzyme. Proofreading by DNA polymerase III depends on the cooperative interaction of the polymerase and exonuclease subunits. The efficiency and substrate specificity of the 3'-5' exonuclease activity are markedly affected when the subunit is complexed in the polymerase core. Compared with that of the free  $\epsilon$  subunit, the activity in an  $\alpha\epsilon$  complex increased 10 to 80-fold, indicating the involvement of the  $\alpha$  subunit in proofreading and contribution to the fidelity of DNA replication (56).

### C. Reaction Mechanism

The chemical reaction at the core of DNA replication is the DNA polymerase-catalyzed nucleotidyl transfer reaction, depicted as follows:

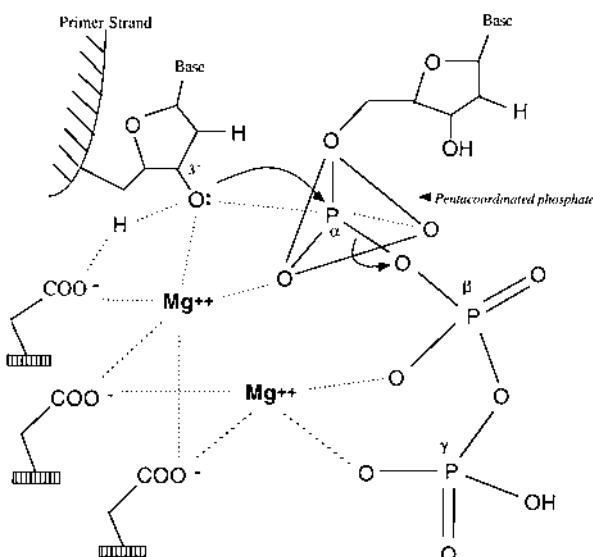

where dNTP represents one of the four deoxynucleotides and dNMP corresponding deoxyribonucleoside 5'-monophosphate. The 3'-5' exonuclease reaction removes the dNMP from the single-stranded primer by hydrolysis as follows:

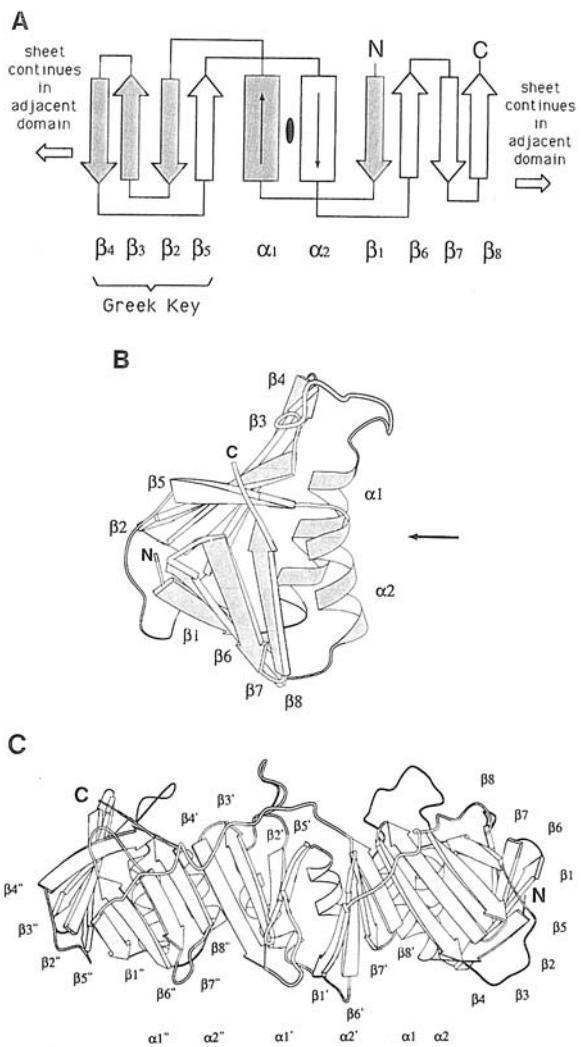

In the polymerase reaction, at least two carboxylic acid residues (Asp705 and Asp882 in DNA polymerase I Klenow fragment) serve to anchor the two metal ions which play a major role in catalysis. The  $\text{Mg}^{2+}$  at site A activates the primer's 3'-OH with one of the Asp ligands as the proton acceptor (57–59). This facilitates a nucleophilic attack on the  $\alpha$ -phosphate of the incoming dNTP which assumes a pentacoordinate transition state stabilized by both  $\text{Mg}^{2+}$  ions at sites A and B. The  $\text{Mg}^{2+}$  at site B also functions to stabilize the negative charged  $\beta$  and  $\gamma$  phosphates (Fig. 4). The high

fidelity of polymerization is achieved by a large reduction in the rate of phosphodiester bond formation for incorrect nucleotides by an induced-fit conformational change, in conjunction with editing by the 3'-5' exonuclease (60, 61). DNA polymerases have typical base substitution errors ranging from  $10^{-4}$  to  $10^{-7}$ . The discrimination against a wrong nucleotide insertion has been attributed to hydrogen bonding between a DNA template base and a dTNP substrate base, and more recently, to geometric selection where insertion is strongly favored by substrates with bond angles and distances that conform to the Watson-Crick model (62).

Structural and kinetic studies of 3'-5' exonuclease reveal that phosphoryltransfer is mediated by a two-metal ion phosphoryltransfer mechanism (52, 55). One of the metal ions (site A), acting as a Lewis acid, facilitates a nucleophilic attack by a water molecule on the phosphorous atom of the terminal nucleotide, from a position opposite the 3'-OH leaving group. Metal ion B stabilizes the resulting pentacoordinate transition state and facilitate the leaving of the 3' oxyanion. Three carboxylic acid residues—Asp355, Asp501, and Glu357—serve to coordinate the metal ions and, together with Tyr497, to position the single-strand primer DNA and the  $\text{H}_2\text{O}$  molecule essential for catalysis.

(C) Ribbon diagram of one monomer, consisting of three structural domains of similar architecture. (Reprinted from Ref. 63, Copyright 1992, with permission from Elsevier Science.)

#### D. Possessivity

*E. coli* DNA polymerase III holoenzyme belongs to a group of replicative polymerases which also include phage T4 DNA polymerase, and eukaryotic DNA polymerase  $\delta$ . These polymerases replicate DNA processively along the entire length of the DNA template, utilizing a “sliding clamp.” In *E. coli* DNA polymerase holoenzyme, the  $\gamma$  complex acts as a clamp loader in an ATP activation to load a  $\beta$  subunit (“clamp”) onto

the primer terminus at the single-strand/double-strand junction (or nicked duplex DNA). The association of the  $\beta$  clamp increases the processivity of polymerase III from polymerization of  $\sim 10$  nucleotides to  $> 50,000$  nucleotides per binding event, with  $\sim 35$ -fold increase in the overall rate of polymerization (32). The crystal structures of the  $\beta$  subunit of *E. coli* DNA polymerase III holoenzyme, and the corresponding processivity factors of T4 bacteriophage (gp45, gene 45 protein), and eukaryotic DNA polymerase (PCNA, proliferating cell nuclear antigen) have been determined (63–65). The  $\beta$  subunit exists as a dimer with a ring structure and a central cavity that can accommodate a DNA duplex (63). Each monomer of 366 amino acid residues consists of three domains of identical topology, each with a  $\beta$  sheet supporting two  $\alpha$ -helices in a twofold symmetry (Fig. 5). A dimer formation results in 12  $\alpha$ -helices lining the inner surface of the ring with the  $\beta$  sheets on the outer layer, with an overall structure of a star-shaped ring. Once loaded by the  $\gamma$  complex, the  $\beta$  subunit ring can move freely along duplex DNA. The  $\beta$  subunit ring acts as a sliding clamp for the polymerase core to enable the enzyme for DNA synthesis in a processive manner. The mechanism regarding how the  $\beta$  dimer ring slips onto the DNA, and eventually leaves at the end of the template is not fully understood, but some involvement of breaking and closing of the ring must occur. It has been proposed that the  $\delta$  subunit in the  $\gamma$  complex plays a major role in binding the  $\beta$  dimer during the loading process (66).

## Protein Modification to Optimize Functionality Protein Hydrolysates

**Ton Kunst**

*Quest International, Naarden, The Netherlands*

### I. INTRODUCTION

Proteins are used abundantly in the food industries because of their nutritional value and functional properties such as emulsification, foaming, gelation, hydration, and textural properties. These functional properties of proteins are related to their molecular structures and their ability to interact with other components in the food matrix. The recently published book "Functionality of Proteins in Food" (1) reviews the results of > 50 years' extensive research to understand the factors affecting protein functionality and to develop methods to improve functionality.

Ideally, food proteins should possess a broad range of functional properties. Most commercial food proteins, however, have a limited functionality or have limitations with respect to their use in food systems. A better knowledge about structure-function relations and interactions allows the selection and/or development of optimal performing ingredients and results in the final food products with improved properties. **Figure 1** schematically shows the structure-function relations in foods. Individual ingredients are combined and are processed into a final food product. The perception of the final product is determined by its sensory properties, and these are affected by the functional properties of the ingredients in the food matrix. The functional properties in turn are deter-

mined by the molecular structures and the molecular interactions of the ingredients; they are affected by the process conditions.

Food research is focused on building up knowledge on the relations between process conditions, structural properties, functional properties, and the properties of the final food product. Food product development is often based on a definition of the required properties or perception of the final products. The individual components are selected on basis of the required property in the final product and what is (often empirically) known about the properties of the individual ingredients. To modify the perception of the final product, normally one parameter in the food matrix (e.g., concentration or pH) or in the process (e.g., temperature) is altered and the effects are studied. If this does not result in the required food product, a new ingredient has to be developed on the basis of a specific functional requirement.

Food scientists can use many methods to broaden the functionality range and to improve specific functional properties of food ingredients. In case of proteins, both chemical and enzymatic methods can be applied to improve the functionality (2–5). The present review focuses on the partial enzymatic hydrolysis of proteins to make peptides with improved solubility and improved foaming, emulsifying, and nutritional properties. Aspects of both the production process and the application will be discussed.

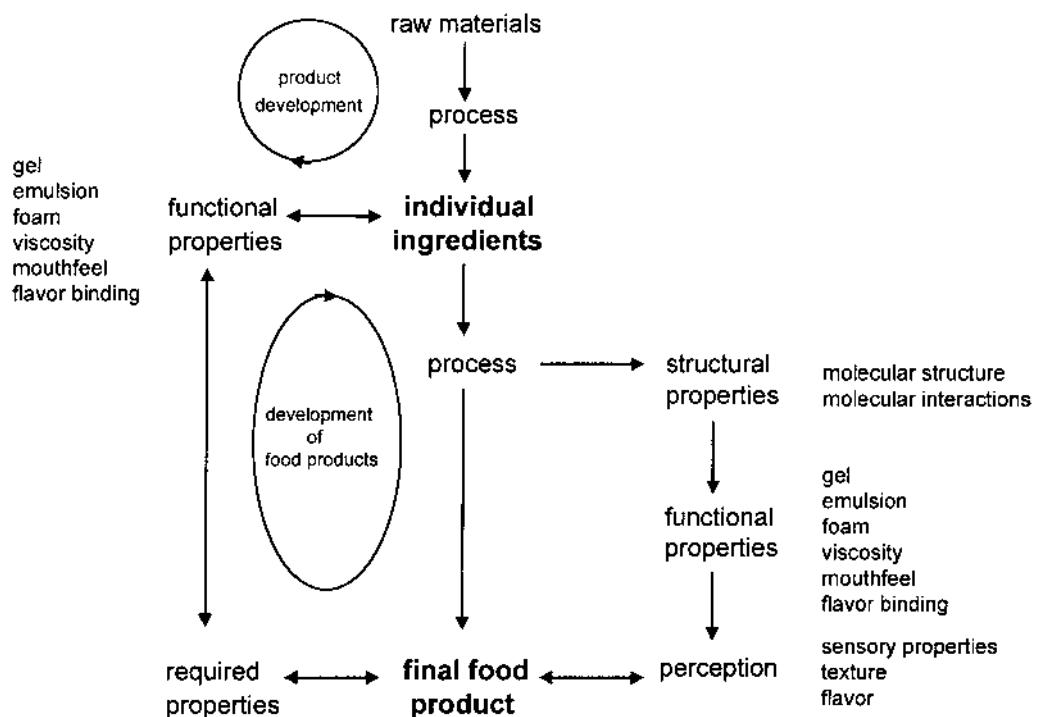

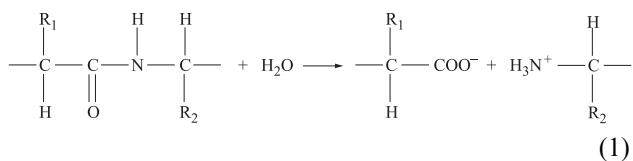

Figure 1 Structure–function relations in foods.

## II. PROTEINS, PROTEIN HYDROLYSIS, AND PROTEIN HYDROLYSATES

Proteins are linear polymers of amino acids that are covalently linked via a peptide bond. The hydrolysis of proteins involves the hydrolytic degradation of this peptide bond using alkali, acid or enzyme [Eq. (1)].

Acid hydrolysis has traditionally been used to produce flavor products (hydrolyzed vegetable protein or HVP). Most of the literature on the production of protein hydrolysates with acids is published in the form of patents. A short summary and review is given by Dave et al. (6). Today the use of acid hydrolysis of proteins is limited owing to the risk of the formation of chloropropanols during the hydrolysis.

Alkali hydrolysis of proteins has long been used to produce foaming agents to substitute egg proteins or to produce fire extinguisher foams. Also, for the alkali hydrolysis most of the literature is published in the form of patents (7, 8).

Neither alkali nor acid hydrolysis is very specific; the rate of hydrolysis of the peptide bond is mainly determined by the side chain of the amino acid residue of the peptide bond (9). In addition, a number of amino acids, e.g., cystine, serine, and threonine, are destroyed and undesired components such as lysinoalanine may be formed (10). Racemization of amino acid residues also occurs during alkali hydrolysis (4).

Enzymatic hydrolysis is much milder than acid or alkali hydrolysis and does not lead to the destruction of amino acids. It also is much more specific. By selection of the proper enzymes the cleavage of specific peptide bonds is possible. The enzymatic hydrolysis of proteins has extensively been studied by Adler-Nissen (11).

One of the key parameters in protein hydrolysis is the degree of hydrolysis (DH). This is defined as the percentage of peptide bonds cleaved. The DH is usually approximated by the AN/TN ratio in which AN is the amount of amino nitrogen and TN is the amount of total nitrogen as determined via the Kjeldahl method. There are different methods to determine the number of amino-nitrogen groups in the hydrolysate. Well-known and often applied methods are the Formol titration (12), the determination of

free amino groups by the reaction with o-phthalic anhydride in the OPA method (13), and the determination of free amino groups by the reaction with 2,4,6-trinitrobenzene sulfonic acid in the TNBS method (14). The actual properties of a protein hydrolysate are determined by the chain length of the peptides. The average peptide chain length (PCL), given as the number of amino acids in the peptide, can be approximated from the degree of hydrolysis via  $PCL = 100/DH$ .

More important and more informative, however, than the average peptide chain length is the peptide chain length distribution. This can be approximated by gel filtration techniques, and can be determined by methods involving mass spectrometry or by a procedure involving the Edman degradation technique (15).

### III. PRODUCTION OF ENZYMATIC PROTEIN HYDROLYSATES

#### A. General Aspects

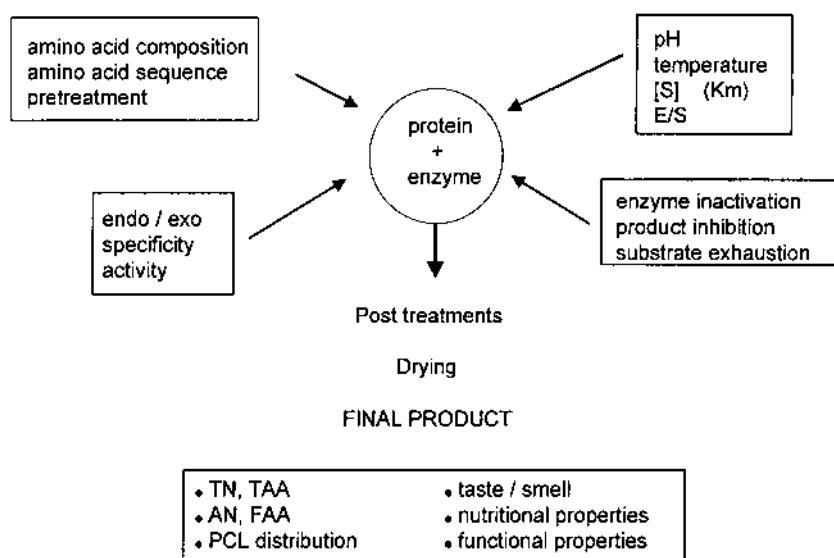

For the production of protein hydrolysates with enzymes, a wide variety of endo- and exopeptidases are available as well as a great number of downstream processing techniques. A schematic overview is shown in [Figure 2](#). A protein with a certain amino acid composition and sequence is hydrolyzed by one or more enzymes each with a certain specificity and activity. Prior to hydrolysis the protein raw material can be pretreated. The hydrolysis reaction depends on the

pH, the temperature, and the concentrations of substrate and enzyme.

In industrial practice the reaction in general is carried out in batch form and takes a few hours (16). During hydrolysis the degree of hydrolysis increases and phenomena such as enzyme inactivation and product inhibition start to play a role. After hydrolysis the enzyme is inactivated (e.g., by heat treatment). The obtained hydrolysate can be subjected to a number of posttreatments such as centrifugation or (membrane) filtration to remove insoluble components or larger peptides. Finally a dried product is obtained with specific nutritional and functional properties that are determined by physicochemical properties such as the amino nitrogen (AN), the total nitrogen (TN), the free and total amino acid profile (FAA and TAA), and the peptide chain length distribution. Knowledge about the relations between the final product properties and the process conditions allows control of the reaction and makes it possible to produce hydrolysates that are optimally suited for their application.

#### B. The Enzymes

It will be clear that the selection of a proper enzyme is crucial for the final results. The choice of the enzyme is determined by parameters such as the required amount of free amino acids and the required degree of hydrolysis. An enzyme with a broader specificity in general results in a higher DH.

**Figure 2** Production of protein hydrolysates.

**Table 1** Industrially Relevant Endopeptidases

Enzyme	EC number	Preferential cleavage
Serine proteases	3.4.21	
Chymotrypsin	3.4.21.1	tyr-, trp-, phe-, leu-
Trypsin	3.4.21.4	arg-, lys-
Subtilisins	3.4.21.12	mainly hydrophobic
Cysteine proteases	3.4.22	
Cathepsin B	3.4.22.1	arg-, lys-, phe-X-
Papain	3.4.22.2	arg-, lys-, phe-X-
Ficin	3.4.22.3	phe-, tyr-
Bromelain	3.4.22.4	lys-, arg-, phe-, tyr-
Aspartic proteases	3.4.23	
Pepsin	3.4.23.1	aromatic-, leu-, asp-, glu-
Chymosin	3.4.23.4	cleaves phe <sub>105</sub> -met <sub>106</sub> bond in $\kappa$ -casein
Metallo proteases	3.4.24	
Thermolysin	3.4.24.27	ile-, leu-, val-, phe-
Neutral proteinase	3.4.24.28	leu-, phe-, and others

There are a number of different peptidases, which can be subdivided into endo- and exopeptidases. There are four classes of endopeptidases or proteases, which differ in the nature of their catalytic center. Examples of some industrially relevant enzymes and their specificity are given in Table 1.

The exopeptidases can be subdivided into a number of classes. Important exopeptidases are the aminopeptidases and the carboxypeptidases. The carboxypeptidases are subdivided according to their catalytic center. Exopeptidases are generally not commercially available in purified form but often are used in the form of a crude extract of microorganisms such as yeast or lactobacilli or of extracts of gland materials such as pancreatin. In Table 2 some of the more important exopeptidases are listed.

### C. Protein Raw Materials

The protein raw materials commonly used to produce protein hydrolysates on an industrial scale are milk proteins, meat proteins, and a number of vegetable proteins such as soy and gluten. More recently, rice protein and pea protein (17) are also being used. Fish proteins are also frequently hydrolyzed but their main application is animal feed (18).

The amino acid profile of the protein raw material not only determines the nutritional properties of the final hydrolysate, but also affects to what extent and

**Table 2** Examples of Exopeptidases

Enzyme	EC number
leu-aminopeptidase	3.4.11.1
lys-peptidohydrolase	3.4.11.15
gly-leu dipeptidase	3.4.13.11
di-peptidyl-peptide hydrolase	3.4.14.4
gly-pro aminopeptidase	3.4.14.5
Carboxypeptidase C or Y	3.4.16.1
Glycine carboxypeptidase	3.4.17.4
Alanine carboxypeptidase	3.4.17.8
Carboxypeptidase S	3.4.17.9

how easily it can be hydrolyzed by a given peptidase. It has been shown that proteins with a higher content of hydrophobic amino acids were more easily hydrolyzed by an enzyme that preferably cleaves after a hydrophobic amino acid (11). The structure of the protein raw material, its solubility, and its state of denaturation all affect the hydrolysis process.

In its simplified form the hydrolysis of a protein proceeds according to the scheme originally proposed by Linderstrøm-Lang (19). It assumes that the native and denatured (reversibly unfolded) state are in equilibrium and that only the (partly) unfolded form can be hydrolyzed by an enzyme into an intermediate form which then is hydrolyzed to the final products. Basically two types of reactions can be distinguished but real hydrolysis processes will be intermediates of these two types. In the *one-by-one* type of reaction the overall rate of hydrolysis is determined by the first step in the process (the reversible unfolding of the molecule). The equilibrium lies strongly on the native side but once a native protein molecule (partly) unfolds and a peptide bond can be cleaved, the molecule becomes unstable and further unfolds; more peptide bonds are exposed and the intermediate product can be degraded rapidly into many small peptides. Since the equilibrium lies strongly on the native side, the protein molecules will be degraded one by one; no significant amounts of intermediate products will be present but only native protein and end product. In the *zipper* type of reaction, the proteins are rapidly converted into the intermediate forms. The rate-limiting step is the slow degradation into the end products.

For those hydrolysis processes that proceed according to the one-by-one reaction the denaturation of the protein (e.g., by heat treatment) will shift the equilibrium of the first step to the "denatured side," and the initial reaction rate will increase (11). Extensive denaturation, however, impairs the solubility of the protein

owing to molecular aggregation, and this slightly decreases the hydrolysis rate.

#### D. Reaction Conditions

The reactions conditions such as pH, temperature, hydrolysis time, and concentration of enzyme and substrate are selected on basis of the required degree of hydrolysis (DH) of the final product and the pH and temperature optimum of the enzyme. To control the hydrolysis reaction it is necessary to monitor the DH during the reaction. This can be done with a number of methods of which the most common are the pH stat, the measurement of the increase in solubilization, the measurement of the osmolarity, and the determination of the amount of amino nitrogen formed.

##### 1. pH Stat

Upon hydrolysis of the peptide bond a free carboxyl and a free amino group are formed that are ionized depending on the pH of the reaction mixture [see Eq. (1)]. At pH values  $> 6$  the carboxyl group will release a  $\text{H}^+$  ion and the pH of the reaction mixture will drop. At pH values  $< 5$  the carboxyl group will take up a  $\text{H}^+$  ion and the pH of the reaction mixture will rise. In the range of 5–6 the pH will not vary much. Above pH 9,  $\text{H}^+$  are released from the ammonium group of the peptide.

When the hydrolysis reaction is carried out at pH values outside the range of pH 5–6 and is kept constant during hydrolysis, the amount of alkali or acid required to maintain the pH is a measure of the amount of hydrolyzed peptide bonds. This so-called pH stat method was originally developed by Jacobsen et al. (20). A more detailed description of how to use it to determine the DH during hydrolysis is given by Adler-Nissen (11). It is an important tool in laboratory-scale experiments. On a production scale it has the disadvantages of technical difficulties and the extra minerals that are introduced into the reaction mixture.

##### 2. Osmometry

Upon hydrolysis soluble peptides are liberated. As a consequence the freezing point of the reaction mixture is lowered. The freezing-point depression can be correlated with the DH (11). For each set of reactions, however, the osmometer has to be calibrated by a separate determination of the amount of liberated amino nitrogen (via TNBS, Formol titration, or OPA). Although it is not a continuous method it can be carried out

quickly. However, the method only takes solubilized peptides into account and consequently the observed DH may be lower than the actual DH.

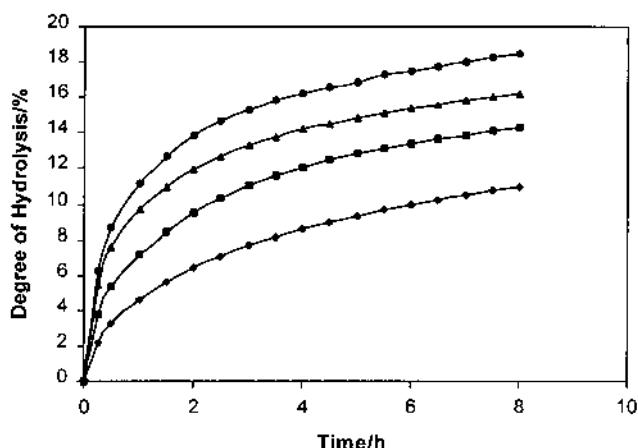

#### 3. Determination of the Amount of Amino Nitrogen

The increase in the number of amino nitrogen groups can be monitored by taking samples and analyzing them as described earlier (OPA, Formol titration, TNBS). These methods also have the disadvantage of not being continuous in most laboratories; continuous measurements, however, can be done with currently available automated equipment.

Knowledge and understanding of the relationship among hydrolysis time, enzyme amount, and degree of hydrolysis allow the control of the hydrolysis reaction. Despite many attempts, however, it is still not possible to give quantitative descriptions of the hydrolysis process. This is related to the complexity of the reactions in terms of specificity and substrate composition. With 20 different amino acids, 400 different peptide bonds can be formed, for each of which the enzyme will have a different affinity and rate of hydrolysis. First the peptide bonds for which the enzyme has the highest affinity will be cleaved, followed by those for which the affinity is lower. In addition, some peptide bonds are buried inside the tertiary structure and need to be exposed to be hydrolyzed.

In kinetic studies in general only the first few minutes are taken into account to calculate parameters such as  $K_m$  and  $V_{max}$  or  $k_{cat}$ . The production of protein hydrolysates on an industrial scale, however, can take many hours. Figure 3 shows a typical relation among process time, enzyme/protein ratio, and DH as measured by the pH stat technique. The steepest increase in DH takes place in the first 30 min of the reaction. Thereafter the reaction rate slows down. Longer hydrolysis time and the use of more enzyme result in a higher DH. A number of studies are reported in the literature in which an empirical model for the hydrolysis of proteins has been developed. These models are based either on the amount of solubilized protein (21) or on the degree of hydrolysis (11, 22, 23).

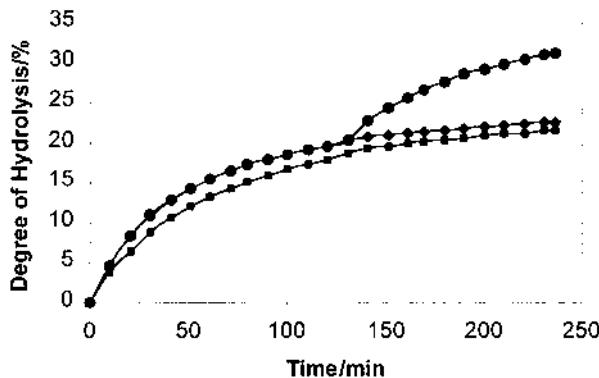

From the literature data it can be concluded that substrate limitation does not play a role in industrial protein hydrolysis processes. The data in Figure 3 show that with increasing enzyme concentrations the degree of hydrolysis increases. When substrate limitation is the rate-limiting factor it is expected that the degree of hydrolysis at the end of the process is the same for all enzyme concentrations. This is clearly

**Figure 3** Relation among DH, time, and enzyme concentration. Hydrolysis conditions: temperature, 50°C; pH, 8.0; protein—soy protein, 40 g/L; enzyme—alcalase 2.4 L; enzyme concentrations—0.2 g/L (◆), 0.4 g/L (■), 0.8 g/L (▲), or 1.2 g/L (●).

not the case. In industrial protein hydrolysis processes the substrate concentrations are high so that substrate saturation most likely prevails throughout most of the hydrolysis reaction (11).

The data in Figure 4 show the time course of three different hydrolysis experiments in the pH stat. Under the hydrolysis conditions as applied, enzyme inactivation was found not to be important. In the presence of 10 g/L substrate, 97% of the enzyme was still active after 48 h at 50°C. In general, enzyme inactivation does not seem to be very important provided enough

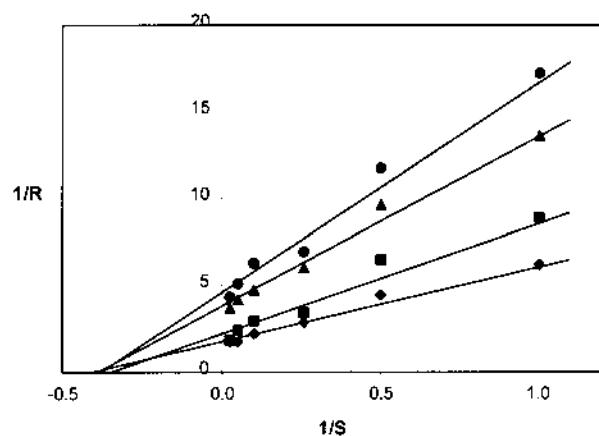

**Figure 4** Product inhibition during hydrolysis. Hydrolysis conditions: temperature, 50°C; pH, 8.0; protein—potato protein, 40 g/L; enzyme—alcalase 2.4 L, 1.6 g/L. (◆) control. (●) At  $t = 135$  min 20 g/L fresh substrate is added. (■) At  $t = 0$  min 20 g/L peptide cocktail is added.

substrate is present (to prevent autohydrolysis of the enzyme) and the temperature is not too high (to prevent thermal denaturation).

The control hydrolysis curve in Figure 4 levels off as expected. In the second experiment, fresh substrate was added after 135 min and it was found that the rate of hydrolysis increased. In the third experiment a peptide cocktail was added at the start of the hydrolysis. This peptide cocktail was obtained by hydrolyzing the protein for 20 h, inactivating the enzyme, and removing the insolubles. It can be seen that the initial rate of hydrolysis is clearly lower than that of the control. Similar results were reported by Adler-Nissen (11), Krause et al. (24), and Haque and Antill (25). Also, the addition of fresh enzyme was found to result in an increase in the rate of hydrolysis (21, 23).

From these results it can be concluded that product inhibition is an important parameter in protein hydrolysis. The addition of fresh substrate and fresh enzyme causes a shift in the equilibrium; the addition of peptides inhibits the reaction. Adler-Nissen (26) measured the initial hydrolysis rates using hydrolysates with different DHs as substrates. It was found that the  $K_m$  was more or less independent of the DH but that  $V_{max}$  decreased with increasing DH. Similar results were obtained by Snijder and Kunst (27) as shown in Figure 5. From these results it is concluded that mixed inhibition or noncompetitive inhibition occurs (28).

**Figure 5** Effect of peptide size on enzyme kinetics. Hydrolysis conditions: temperature, 50°C; pH, 8.0; substrate—peptides obtained from potato protein. ## **E. Downstream Processing**

After the actual hydrolysis process the enzyme is inactivated via e.g. a heat treatment. The hydrolysate can be subjected to further processing steps such as separation, filtration, or treatments with charcoal or ion exchange resins (16). Charcoal nonselectively removes both high- and low-molecular-weight organic compounds and can be applied to remove off-color material and to achieve slight reductions in off-odor and bitterness. Products for patients suffering from phenylketonuria (PKU) are treated with charcoal and/or ion exchange resins to remove phenylalanine from hydrolysates (29, 30). The treatments, however, also remove tyrosine and reduce the amounts of other hydrophobic amino acids.

Filtration or separation of hydrolysates is generally applied to remove insoluble components in order to improve the clarity of the hydrolysate. Membrane filtration is often used to remove larger peptides and undigested protein fragments that are potential antigenic materials. This results in a product with a reduced allergenicity. Membrane filtration is also applied to reduce the level of endotoxins in the hydrolysate; this is important when the hydrolysate is applied in parenteral formulae or in tissue culture media. The final process step usually is drying of the hydrolysate.

## **F. Membrane Bioreactors**

Membrane bioreactors combine the hydrolysis step and the membrane filtration step (31). The advantages of a membrane bioreactor are that the enzyme is retained (which saves costs), that the peptide size is controlled, and that peptides that inhibit the enzyme are continuously removed after formation.

The disadvantage is that the insoluble fraction in the hydrolysate is concentrated, which results in flux reduction and reduced productivity. With prolonged operation times microbiological spoilage also may become a problem; not only the insoluble protein material is retained, but also all microorganisms. Especially, the more thermophilic microorganisms may give rise to uncontrolled hydrolysis reactions. It is for these reasons that membrane bioreactors are currently not applied on an industrial scale for the production of protein hydrolysates. Further research is required to optimize the process.

## **G. Immobilized Enzymes**

The immobilization of enzymes, including proteolytic enzymes, has been extensively studied (see Chapters 22–24 in this book). The advantage of the use of immobilized enzymes is the possibility to reuse the enzyme (which saves costs) and the possibility to produce hydrolysates in a continuous way. The application of immobilized proteolytic enzymes to produce protein hydrolysates on an industrial scale up to now is limited, however. When the immobilized enzyme is applied in a batch reactor it must be separated from the hydrolysate via e.g. a crude filtration step. The costs involved in this isolation can be higher than the savings obtained by reuse of the enzyme.

In laboratory experiments immobilized enzymes have been used in columns. Packed columns easily get blocked by the insolubles in the raw material or by the insolubles formed during hydrolysis (see Sec. IV.B.3). Expanded bed columns, therefore, have to be used. With the recently developed beads very good expanded bed columns can be made that can be applied at a production scale for adsorption of proteins from particulate-containing feedstocks (32). These beads can be used also to immobilize enzymes on the surface of the beads. The costs involved are considerable, however, and limit their application as carrier for immobilized enzymes.

In addition it is difficult to control the microbiological quality of the hydrolysate because microorganisms tend to build up on the carrier material. This requires operation at elevated temperatures, which increases the risk of protein denaturation and insolubilization. The application of immobilized enzymes in expanded bed columns thus requires a delicate balance between microbiological constraints on the one hand and protein insolubilization at the other; further research is required to establish the best conditions.

## **IV. APPLICATIONS**

Intact, native proteins generally have well-defined three-dimensional structures that affect their functional properties. Peptides are much smaller, the molecular structure is more random, and a tertiary structure is rarely observed (33). For the secondary structure of proteins, the  $\alpha$ -helices and the  $\beta$ -pleated sheets are the most important structures. Peptides in general do not have sufficient length to have enough H bonds to stabilize the helix. Upon hydrolysis of proteins the hydrophobic areas, which are normally buried inside the

folded molecule are exposed and as a consequence the properties of a protein hydrolysate strongly differ from those of the original protein.

Enzymatically hydrolyzed proteins have a wide range of both food and nonfood applications, which relate either to their nutritional or to their functional properties. Larger peptides (2–5 kDa) are mainly used as functional ingredients (aeration) or in personal-care products. Medium-size peptides (1–2 kDa) are used in clinical nutrition (34) and sports nutrition (35, 36). Smaller peptides (< 1 kDa) are used in infant food products requiring a reduced allergenicity (15) and for fermentation and tissue culture media (37).

## A. Nutritional Properties

### 1. Nutritional Value

The nutritional value is primarily determined by the amount of essential amino acids in the protein hydrolysate and mainly depends on the amino acid composition of the protein raw material. Under some conditions a specific amino acid composition is required. For example, products for patients suffering from phenylketonuria (PKU) should be very low in phenylalanine. These products are produced from highly hydrolyzed proteins and are subjected to specific downstream processing such as treatments with charcoal or adsorption chromatography resins to remove phenylalanine (29, 30). Another example is hydrolysates with a high glutamine content. Glutamine is regarded as a conditionally essential amino acid that is required in periods of physical stress such as severe trauma, surgery, infection, starvation, or heavy training (38). Peptides rich in glutamine are also increasingly used for cell nutrition (37). In general such products are produced from wheat gluten, which contains ~ 27% glutamine.

With respect to sports nutrition it has been shown that protein hydrolysates stimulate recovery after prolonged intensive exercise (39). During high-intensity exercise, athletes use up their glycogen reserves, and the time needed to restore their muscle glycogen levels determines the time needed to recover from fatigue (40). Although the insulin release is stimulated primarily by carbohydrates, the release of insulin is further stimulated by proteins and peptides (41), resulting in an increased uptake of glucose from the blood, an increased glycogen synthesis rate, and thus an enhanced recovery after prolonged intensive exercise. Contrary to proteins, peptides are heat stable and can be applied in pasteurized, ready-to-use drinks. Furthermore, peptides are soluble over a wide pH

range, which allows them to be used in refreshing drinks (36).

Not only is the nutritional value determined by the amino acid composition, but also the peptide chain length distribution seems to be an important factor. Some lactic acid bacteria for instance prefer di- and tripeptides over free amino acids (42, 43). Also, in the human small intestine most of the dietary proteins are absorbed as small peptides. There are specific carriers for small peptides that are separate from the carriers for uptake of free amino acids (44). These small peptides are more adequately absorbed in the small intestine than the equivalent free amino acids. This allows the formulation of products for enteral nutrition that gives less intestinal discomfort, as less amino acids are available for bacterial fermentation in the large intestine.

### 2. Reduced Allergenicity

Food allergenicity is a complex topic, and the manifestations of disease and the diagnostic methods are highly variable (45). In the majority of allergic responses a specific immunoglobulin (IgE) mediates the immediate hypersensitivity reaction. Immunoglobulins (also called antibodies) are produced by the body in response to invasions of foreign compounds such as proteins. Materials that elicit antibody production (other than IgE) in an organism are called antigens. An antigen may contain multiple antigenic determinants (epitopes), which are small regions of the antigen molecule that specifically elicits the production of antibodies to which the antigen binds. In case an antigen elicits an IgE response, the antigen is called an allergen. In order to initiate a clinical manifestation of allergenic responses, it is required that the IgE form a bridge between two epitopes; the allergen thus should have at least two epitopes at a certain distance from each other. Destroying the molecular structure of the allergen or antigen forms the basis of the application of protein hydrolysates in the control of food allergies. Decreasing the size of the molecules via hydrolysis reduces the number of protein molecules with two epitopes (and may even destroy epitopes) and will reduce the antigenicity (46).

There is, however, no definite molecular weight below which peptides are nonallergenic or above which they are allergenic. In general there appears to be a limit for antigenicity for peptides with 10–15 amino acids (47). The first products, which were marketed ~ 40 years ago, comprised > 70% free amino acids and peptides up to 8 amino acid residues long.

More recently developed products have < 10% free amino acids and peptides up to 15 amino acid residues long (15). These developments are based on a better understanding of the physiology of the small intestine (see Sec. IV.A.1).

### 3. Bioactive Peptides

It has long been known that proteins can be the source of bioactive peptides. Especially the milk proteins have been extensively studied (48). The main problem is how to isolate them in a commercially attractive manner. As of now only casein phosphopeptides can be manufactured on an industrial scale using a process involving ion exchange chromatography (49) or a process involving an aggregation step and an ultrafiltration step (50). Possible applications of casein phosphopeptides, which relate to their mineral binding capacity, are in the treatment of caries (51) or as mineral carriers to promote  $\text{Ca}^{2+}$  uptake (52, 53). Further research is required to design enzymes that allow the specific liberation of those sequences that are known to have a biological activity.

## B. Functional Properties

Proteins and peptides are more than just a source of essential nutrients. They also have functional properties allowing them to contribute to the sensory properties of the final food product (54). Table 3 shows some functional and organoleptical properties of protein hydrolysates. The surface properties of peptides are especially important. To understand the role of protein hydrolysates it is necessary to have a general under-

**Table 3** Important Functional and Organoleptical Properties of Protein Hydrolysates

General property	Specific property

Organoleptic	Taste Smell Flavor binding Color Mouth feel

standing of the physicochemical background of foams and emulsions. More detailed information can be found in recent reviews and textbooks on this subject (1, 55, 56).

### 1. Surface Properties

During the formation of emulsions or foams, energy is applied to disperse, deform, and break up oil droplets or air bubbles in an aqueous phase. To form a good foam or a good emulsion it is required that the newly formed air bubbles or oil droplets not (re)coalesce and that once the energy input has stopped, the obtained foam or emulsion is stable for some time. To meet these requirements surface-active agents have to be used. Surface-active agents are adsorbed at the oil-water interface (in emulsions) or air-water interface (in foams) and lower the interfacial tension. Different aspects, however, play a role in the formation on the one hand and stabilization of foams and emulsions on the other hand.

a. *Formation of Foams and Emulsions.* During the formation of emulsions or foams, the oil droplets or air bubbles are subjected to shear stresses and they break up when the stress exceeds the Laplace pressure difference. The Laplace pressure difference ( $\Delta p$ ) is given by  $\Delta p = 2\gamma/R$  in which  $\gamma$  is the surface tension and  $R$  is the radius of the oil droplet or the air bubble. From this it follows that for a given energy input smaller oil droplets or air bubbles are formed when the surface tension is lower. The (re)coalescence is prevented when the surface-active agent in the interface prevents the aggregation of oil droplets or air cells by electrostatic or steric repulsion.

The most important property for surface-active agents during the formation of foams and emulsions is the ability to quickly reduce the interfacial tension (57, 58). In the case of a protein or a peptide this requires that the molecule rapidly adsorb at the interface and rapidly unfold to maximize the reduction of the interfacial tension.

*Movement to and adsorption at the interface.* Much of the current knowledge on the movement to and adsorption of proteins at interfaces is collected in diffusion-driven static systems. It is important to realize that emulsification and whipping processes are highly agitated and that in such systems convection is more important. The time of movement of the protein or peptide molecule to a newly formed interface is in the order of ms. After arrival at the interface, proteins and peptides can be adsorbed. The major driving force for

adsorption is the reduction in contact area between non-polar groups and water. This reduces the free energy of the system and thus the interfacial tension. The adsorption of proteins at an interface is positively correlated with their surface hydrophobicity (55, 59).

*Unfolding of the molecule and formation of films.* A protein molecule that is adsorbed at an interface can unfold. The thermodynamic environment of the interface differs from that of the bulk phase, and unfolding results in a reduction of the free energy. The driving force for unfolding probably is the hydrophobic effect (56).

The surface tension of a clean air–water interface is  $72 \text{ mNm}^{-1}$ , which is sufficient to overcome the activation energy barrier for protein unfolding. The structure will rearrange such that the nonpolar segments are predominantly located in the gas phase and the hydrophilic parts in the aqueous phase. The foaming power is related to the rate and extent of unfolding and this depends on the flexibility of the molecule. The flexibility of the molecule is determined by the strength of the forces maintaining the structure such as S-S bridges, electrostatic interactions and repulsions, and the average hydrophobicity (59).

The surface tension of a clean oil–water interface is only  $\sim 30 \text{ mNm}^{-1}$ , which most probably is not enough to overcome the activation barrier for protein unfolding (55). Consequently for emulsions the surface hydrophobicity is more important than the average hydrophobicity (4, 60).

*b. Stability of Emulsions and Foams.* Once an emulsion or a foam is formed, its lifetime in part depends upon the viscoelastic properties of the adsorbed protein layers and their resistance to rupture. Both foams and emulsions are thermodynamically unstable systems and are subjected to various types of instabilities:

*Drainage (foams) or creaming (emulsions).* Drainage and creaming are caused by density differences between the phases. This process can be retarded by increasing the viscosity of the continuous phase or by gelation of the continuous phase.

*Disproportionation (Ostwald ripening).* This occurs when the dispersed phase is soluble in the continuous phase; it therefore only plays a role in foams. The Laplace pressure difference is greater in smaller bubbles, and as a consequence gas diffuses from small bubbles (which shrink) to large bubbles (which grow). This process is retarded when the bubbles have a uniform size and when the surface elasticity  $E_d$  exceeds  $\gamma/2$  (61).

The surface elasticity increases when the molecules in the interface have more intermolecular interactions.

*Aggregation or flocculation.* In this process air bubbles or oil droplets stick together. This process is retarded when there is more electrostatic repulsion or more steric repulsion.

*Coalescence.* After the aggregation of air bubbles or oil droplets the thin film separating them may break and they can flow together. The stability to coalescence can be improved by increasing the surface viscoelasticity by an increase of the intermolecular interactions.

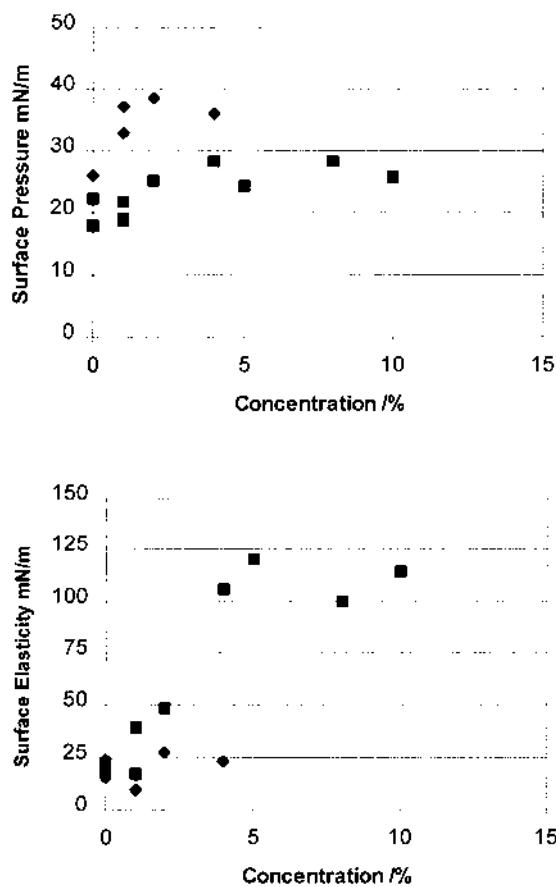

*c. General Requirements.* The most important properties for a good emulsifying or foaming agent thus are the ability to rapidly reduce the interfacial tension and the ability to form a viscoelastic film that is resistant to rupture. These two properties, however, are related as can be seen for  $\beta$ -lactoglobulin and  $\beta$ -casein.

$\beta$ -Lactoglobulin is a globular protein that slowly adsorbs and unfolds at the interface, but it can form strong films. It performs rather poorly in the formation of emulsions and foams but it has good stabilization properties.  $\beta$ -Casein, on the other hand, is a random coil molecule that quickly adsorbs at the interface; it cannot, however, form very strong films. It has good emulsification and foaming properties but poor stabilization properties.

Modifications of (globular) proteins via limited hydrolysis or by rupture of intramolecular disulfide bridges in general will result in more unfolding of the molecule. This will increase the flexibility and improve the ability to quickly reduce the interfacial tension and improve the foaming and emulsifying properties, but it will reduce the ability to form a coherent film and reduce the stabilization properties.

Figure 6 shows the interfacial properties of intact protein and protein hydrolysate on an air–water interface. The intact protein gives a surface pressure of  $\sim 30 \text{ mNm}^{-1}$ . The peptides obtained after hydrolysis gives a significantly higher surface pressure indicating a higher foaming capacity. The surface elasticity, which is a measure for the amount of interactions in the surface, however, is much larger for the intact protein than for the peptides. This indicates that the protein contributes more to the stability of a foam.

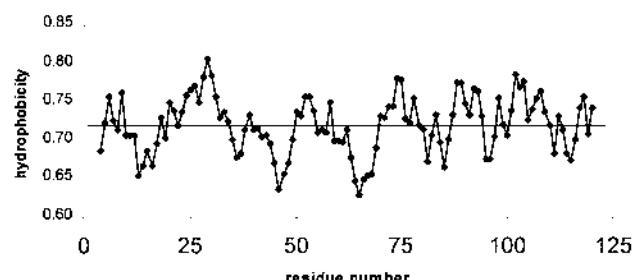

For good interfacial properties a peptide should have clustered hydrophobic and charged areas and a molecular weight above a certain minimum to allow this distribution (62, 63). The distribution of charge and hydrophobicity can be derived from the amino

**Figure 6** Surface properties of proteins and protein hydrolysates. The surface properties have been measured in a ring trough at ambient temperature. (a) Surface pressure. (b) Surface elasticity. Pea protein hydrolysate: ◆; intact pea protein: ■.

acid sequence of the protein or peptide (64, 65). An example of the distribution of the hydrophobicity in  $\alpha$ -lactalbumin is given in Figure 7. It will be clear that hydrolysis with different enzymes will give peptides with different charge and hydrophobicity distributions, and this explains the importance of enzyme selection in the production of surface-active peptides.

Both foaming properties and emulsifying properties are strongly related to the size of the peptides. Literature reports that the optimum peptide size generally lies in the range of 15–35 amino acid residues. This corresponds to a DH of typically 3–6% (17, 66). Chobert et al. (67) and Turgeon et al. (62) report minimum peptide sizes of  $\sim$  2000 daltons. Also, Caessens (63) reported that smaller hydrophilic peptides have poor foam and emulsion stabilizing properties.

**Figure 7** Hydrophobicity pattern of  $\alpha$ -lactalbumin. The hydrophobicity is calculated using the hydrophobicity data given by Rose and Dworkin (65). The protein parts that have a hydrophobicity  $> 0.72$  will be buried in the structure.

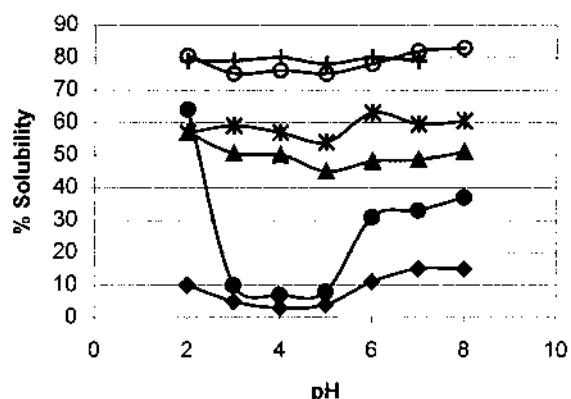

## 2. Gelation and Water Binding

The formation of a gel requires large protein molecules that can form crosslinks in all three dimensions. The strength and hardness of a gel are related to the size and shape of the molecule rather than to the amino acid composition. A very good correlation between the average molecular weight and the gel hardness was found (68). Hydrolysis of proteins, which reduces the size of the molecules, is therefore expected to reduce the ability to form a gel.

However, it has been shown that the hydrolysis of whey protein (69) or casein (70) can lead to the formation of aggregates and the formation of a gel. Electron microscopy showed that these gels have a particulate type of structure. The aggregates in the whey protein hydrolysates consist of a number of peptides with molecular weights of 2000–6000 daltons which are held together by noncovalent interactions. It is hypothesized that a limited hydrolysis causes the protein to unfold after which exposed hydrophobic areas can interact intramolecularly to form aggregates (71). The aggregates from the casein hydrolysates were found to have a higher proportion of hydrophobic amino acids. It is likely that the phenomenon of aggregate formation is sometimes misinterpreted as a plastein reaction. At this moment the potential for improvement of the texture of food products is not clear and further research will be required.

## 3. Solubility

Partial hydrolysis of proteins is often used to improve the solubility of a protein (Fig. 8). For optimal solubilization of soy protein a DH of  $\sim$  8% or higher is required (66). A 100% solubility, however, is never achieved; this is related partly to peptide-peptide inter-

**Figure 8** Effect of DH on solubility at various pH values. Intact protein (●), DH 1.0% (◆), DH 3.2% (▲), DH 5.1% (\*), DH 7.7% (+), DH 8.3% (○). The hydrolysates were obtained by hydrolyzing soy protein with alcalase 2.4 L. The solubility was measured in a 1% protein dispersion in 0.2 M NaCl. (From Ref. 66.)

actions and partly to the presence of compact structures in the protein that cannot be hydrolyzed. Further research will be required to elucidate these limiting factors and to develop methods or new enzyme preparations that allow the degradation of these compact structures.

Although peptides as such may be soluble, in a final application insoluble complexes can be formed due to interactions with other ingredients in the food matrix. In drinks, for example, peptides may associate with polyphenols or caramels, and the formed complexes can precipitate. In drinks also the concentration of the hydrolysate can be important; for soy protein hydrolysates it has surprisingly been found that at low pH the solubility is better at higher concentrations (11).

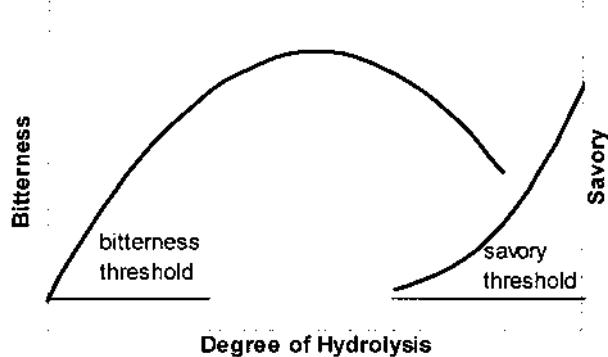

### C. Organoleptic Properties

In food applications taste and smell are very important parameters. When food proteins are hydrolyzed a bitter taste and a savory taste usually develop. In addition, protein hydrolysates frequently carry the taste and smell characteristics of the raw material from which they are derived. The savory taste and smell are related to the presence of very small peptides and free amino acids. The bitterness is related to the size and the average hydrophobicity of the peptides (72). This can be calculated using the hydrophobicity values of the individual amino acids as reported in the literature (11).

Individual peptides will each have a different average hydrophobicity but also different threshold values and different bitterness intensity. The conformation of a peptide and how well it fits in the bitter receptor in the mouth will affect this. Peptides with a hydrophobic residue at the C-terminus are reported to be more bitter (73). Hydrophobic peptides are more bitter when there is another amino acid on both the N- and the C-side of the hydrophobic residue(s). Bitterness is the major limitation of the use of protein hydrolysates, and the reduction, prevention, or removal of the bitterness of protein hydrolysates has been studied extensively.

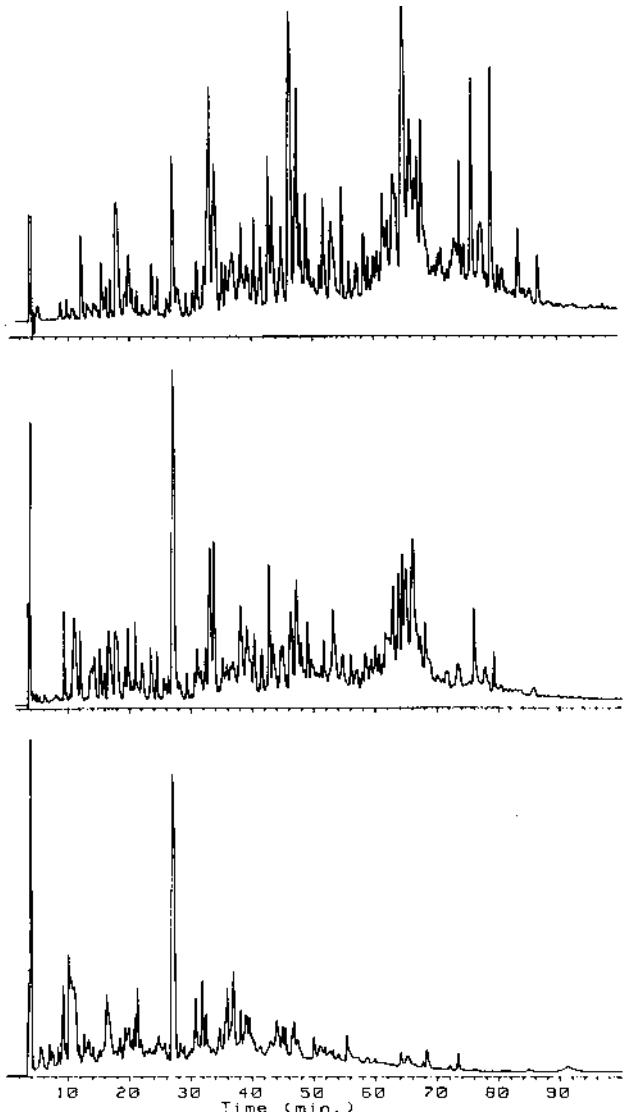

In an intact globular protein the majority of the hydrophobic side chains is hidden in the interior of the molecule and cannot interact with the taste receptors. Upon hydrolysis the protein molecule unfolds and is degraded into smaller peptides. The hydrophobic amino acids now are exposed to the solvent and can interact with the taste receptors. As the hydrolysis process proceeds, more hydrophobic amino acids are exposed and the bitterness increases. When the hydrolysis process proceeds further, the number of hydrophobic amino acids which have another amino acid at both the N- and the C-side decreases and the bitterness will pass through a maximum. At very high degrees of hydrolysis, however, a high amount of free amino acid will also be present and this will induce a savory flavor. **Figure 9** shows the general relation among DH, bitterness, and savory flavor.

To reduce the bitterness, methods involving specific enzymatic treatments, selective separations, and masking can be applied (74). The bitterness of a hydrolysate can also be affected via the specificity of the enzyme. Endopeptidases that give peptides with nonpolar amino acids at the C-terminus were found to result

**Figure 9** General relation between DH and organoleptical properties.

in hydrolysates with a relatively high bitterness (75). The application of both aminopeptidases (76) and carboxypeptidases (77) was found to reduce the bitterness of hydrolysates. Figure 10 shows the effect of using

**Figure 10** Reversed-phase patterns of casein hydrolysates. (Top) Casein hydrolyzed with an endopeptidase (Neutrase, NOVO). (Center) Casein hydrolyzed with an endopeptidase (Neutrase, NOVO) and a carboxypeptidase (obtained from autolyzed yeast). (Bottom) Casein hydrolyzed with an endopeptidase (Neutrase, NOVO) and an enzyme mixture containing both carboxypeptidase and aminopeptidase (BioProtease P23, Quest International). The casein hydrolysates were analyzed on a C<sub>18</sub> reversed-phase column using a gradient of 0.1% TFA in water to 0.1% TFA in acetonitrile as eluent.

exopeptidases on the reversed-phase HPLC chromatogram of the hydrolysates. With increasing elution time, the hydrophobicity increased. The bitterness was found to be strongly correlated with the amount of material eluting after 50 min (78, 79). The neutral protease hydrolysate contains much hydrophobic material and is very bitter. When exopeptidases are used, less hydrophobic material is present and the bitterness is reduced. It should be realized, however, that the savory taste will increase owing to increased levels of free amino acids. Because of this increased level of free amino acids the osmolarity of the hydrolysate also increases. When applied in enteral feeding this may result in an influx of water into the intestine, which can cause diarrhea.

Another method to reduce the bitterness is the plastein reaction (80). The original idea behind it is that the molecular weight is increased via a protein resynthesis but later it was thought that transpeptidation is giving the effect (81). As a result of the reduction insoluble components are formed, which are not perceived as bitter. However, it is also possible that the formation of aggregates of hydrophobic peptides (see Sec. IV.B.2) results in a reduction of the number of exposed hydrophobic side chains and consequently also results in a reduced bitterness.

Murray and Baker (82) found that treatment with activated carbon lowered bitterness. This procedure suffers from the disadvantage that the protein losses can be high (83) and that the selective removal of hydrophobic peptides negatively affects the nutritional properties (66).

Next to processing and selective separation methods, several methods to mask the bitter taste of protein hydrolysates via the addition of specific components have been reported. Polyphosphates, glycine, gelatin, gelatinized starch, cyclodextrins, glutamine, and asparagine were found to mask bitterness (74).

## V. CONCLUDING REMARKS

Enzymatic hydrolysis is a valuable and flexible tool to modify and improve the functional properties of proteins. To be able to produce a specific hydrolysate it is necessary to have: (a) a detailed knowledge about the relations between process conditions and the properties of the hydrolysate obtained from a given protein and enzyme in combination, and (b) a detailed knowledge about the relations between the physicochemical properties of the hydrolysate and their functional properties.

Protein hydrolysates are complex mixtures of peptides, and this makes the task to acquire the required knowledge highly challenging. In recent years our knowledge on the kinetics of the hydrolysis reaction and the relations between structural and functional properties has increased tremendously. Information about the primary structure of proteins is very useful and for this reason in many studies on protein hydrolysis milk proteins have been used as model substrates.

With the new genetic modification techniques it will be possible to create new enzymes on the basis of increased understanding of the enzyme mechanism. This will offer new possibilities for further optimization and fine-tuning of protein hydrolysates.

## Production and Modification of Acylglycerides

**Rob M. M. Diks**

*Unilever Research and Development, Vlaardingen, The Netherlands*

### I. INTRODUCTION

Acylglycerides are important ingredients of a wide variety of food products, especially those consisting of emulsions of water and oil. Acylglycerides consist of a glycerol backbone with one, two, or three fatty acid chains attached to it, thus giving a mono-, di-, or triglyceride molecule. The delicate balance between the apolar hydrophobic fatty acids and the polar OH groups in the molecule, as well as the type of fatty acid involved, determines the physical behavior of the acylglyceride and hence its specific function in the food product.

Triglycerides can well be considered the most important class of acylglycerides. Being the major component of edible oils and fats, they serve many functions in daily food products. Apart from being an energy source, they are nutritionally important for their dietary supply of essential fatty acids, as well as fat-soluble vitamins and antioxidants. Furthermore they significantly contribute to product characteristics such as spreadability, mouth feel, and the flavor release during consumption.

Diglycerides are used generally as emulsifiers, often in a mixture with monoglycerides. However, they are also known to act as crystal habit modifier in triglyceride mixtures (1, 2), and could act as a building block for the organic synthesis of, e.g., drug and phospholipids (3).

Having only one apolar fatty acid chain and two polar hydroxy groups, monoglycerides are the most

surface-active type of acylglycerol. They are widely applied to stabilize water-in-oil as well as oil-in-water emulsions such as those present in spreads, dressings, and cosmetic creams (4).

In general, the physical behavior of an acylglyceride, and hence its commercial value, is related to its fatty acid composition. Hence the ability to specifically modify its composition allows the production of tailor-made acylglycerols. Using conventional organic synthesis many acylglycerols are being produced on a larger scale. These processes are generally carried out at relatively high temperatures and pressures, using rather unspecific catalysts if not fully random catalysts. As a result, complex multistep processes are required to obtain the desired product. Moreover, toxic byproducts can be formed as well as off-flavor and colors, again requiring substantial posttreatment and downstream processes, especially when food applications are concerned.

As opposed to this, enzymes are highly specific and can operate under mild conditions of temperature, pressure, and pH. In recent years much attention has therefore been focused to the exploitation of enzymes, especially lipases, for lipid modification.

In this chapter various aspects of the use of lipases for the modification of acylglycerols will be highlighted. Firstly, the general functioning of lipases, their specificities and the importance of water in lipase-catalyzed reactions are discussed. Secondly, some process engineering aspects of lipase catalyzed processes are covered. This comprises the immobiliza-

tion of lipases, reactor design, and modeling as well as the operational stability of the biocatalyst. Finally, examples of glyceride modification processes are reviewed. Though the production of monoglycerides and diglycerides is covered, the main focus in this chapter will be on the modification and processing of triglycerides, being the most important processes applied on an industrial scale.

## II. LIPASES

### A. General Properties

Probably the most important class of enzymes studied in general are lipases, i.e., glycerol ester hydrolases (EC 3.1.1.3), especially those that are obtained from microbial sources. In living organisms the function of lipases is to hydrolyze oils and fats into free fatty acids, a mixture of partial glycerides (mono- and di-) and glycerol. The latter products are taken up by the organism to provide energy and growth intermediates. The industrial equivalent of this process is widely employed in detergent systems for laundry cleaning (5).

In the early 1980s it was shown that under very dry conditions, such as in organic solvents, lipases remain active and sometimes even show novel characteristics such as improved stability (6). Over the years it has been shown that lipases in organic media are capable of carrying out all major reactions important for acylglycerol modification, e.g., hydrolysis, esterification (Fig. 1), and trans- or interesterification reactions (Fig. 2).

Several extensive reviews on the subject have recently been published (7, 8). It should be realized that when referring to organic media, this also covers liquid oils, i.e., solvent-free systems. For certain applications, especially those aimed at food product ingre-

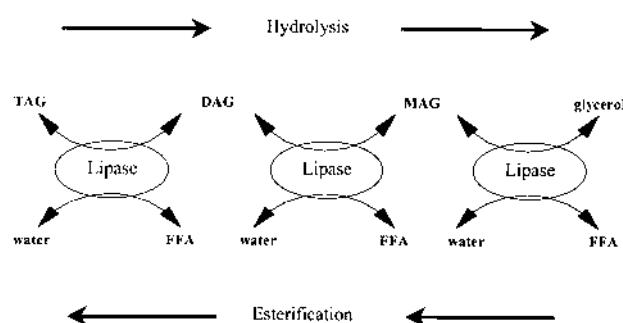

dients, this is sometimes an important benefit. Apart from the requirement of food grade solvents, its absence prevents the need for solvent removal and recovery, thus reducing processing costs.

The ability of lipases to catalyze fatty acid exchange reactions on acylglycerols results from two major characteristics. Firstly, the construction of the “active site” of this class of enzymes. It consists of three amino acids forming a so-called catalytic triad (16). In close interaction, they cause the lipase to split, e.g., a triglyceride molecule in a covalent lipase–fatty acid complex and a diglyceride (Fig. 1). In a second reaction step a water molecule comes in, thereby releasing the fatty acid and returning the lipase to its native state, thus completing a full hydrolysis cycle (9). This two-substrate (triglyceride and water) two-step model is generally referred to as the Bi-Bi, Ping-Pong model (59).

In a similar manner a new ester bond can be established when a new diglyceride molecule reacts with the existing lipase–fatty acid complex, forming a new triglyceride molecule. This scheme highlights the importance of diglycerides as intermediate in trans- and interesterification reactions and hence the necessity of a minimum degree of hydrolysis to start the interesterification reaction.

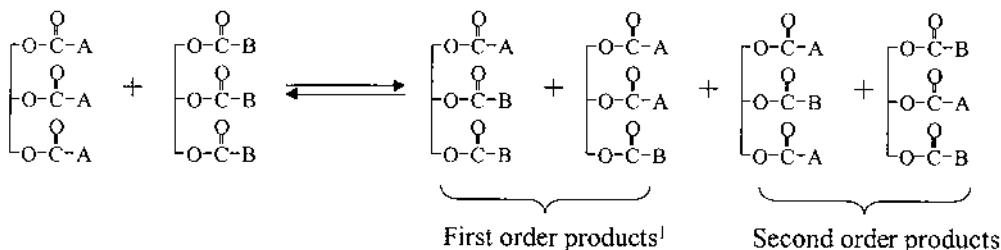

Secondly, lipases are characterized by a phenomenon called *interfacial activation* (10, 11). The entrance to the active site is covered by a lid or flap when dissolved in water. However, when in contact with an interface between water and apolar phase, i.e., oil, or being dispersed in organic solvent, the flap opens, allowing substrates to enter the active site. Thus in a system of a polar and an apolar phase, lipases are highly active on substrates present in the apolar phase, whereas their activity toward water-soluble substrates is rather low. As a result of the activation in the presence of an organic phase, lipases, individually fixed on an inert carrier by adsorption, also show their activity in organic solvents and vegetable oil. In fact, the lipases here are located at the interface between the organic medium and the solid carrier material.

Though lipases are generally considered true catalysts—substances that accelerate the reaction rate but do not affect the equilibrium composition—the above-described phenomenon should be taken into account when operating in a biphasic system. For example, using *Candida rugosa* lipase for triglyceride hydrolysis > 90% free fatty acids will be formed (12), whereas ~ 90% degree of esterification is obtained when using fatty acids and long-chain alcohols (> C<sub>12</sub>) (13) or sterols as substrates (14, 15). The latter result represents actual thermodynamic equilibrium composition.

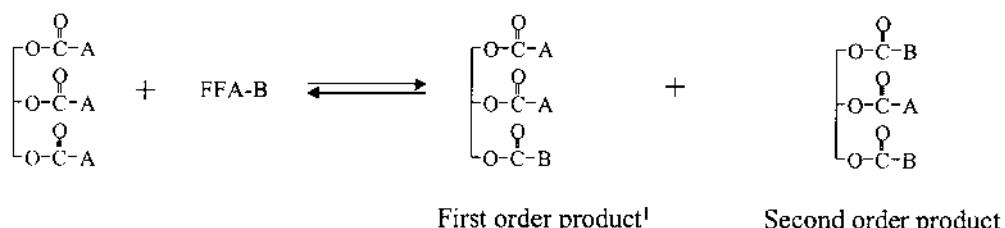

**Figure 1** Reactions on acylglycerides catalyzed by lipases.

## Interesterification

## Acidolysis (transesterification)

**Figure 2** Interesterification and acidolysis of triglycerides with 1,3-specific lipases. The first-order products always comprise two 1,3-isomers.

However, in the former case the synthesis reaction is blocked by the fact that glycerol is strongly diluted in the aqueous phase and cannot effectively enter the active site of the lipase.

### B. Lipase Specificities

Though the catalytic triad principle mentioned above is true for all lipases, the active site of lipases comes in different shapes and sizes (16, 17). This restricts the way in which acylglycerols can bind, or slows down and even prohibit certain acylglycerols from binding at all. The result is a preference of the lipase to react on certain acylglycerols or positions within, e.g., a triglyceride molecule. This is often addressed as the selectivity or specificity of a lipase.

Three major types of specificity can be distinguished (Table 1). The first type involves positional or regioselectivity, most lipases being either 1,3-specific or fully random (nonspecific). The 1,3-specificity is the most common and is displayed by, e.g., human gastric lipases, as well as microbial lipases such as from *Rhizomucor miehei*, *Thermomyces* sp., and various *Rhizopus* sp. As a result of a trough-shaped active site, triglycerides can bind only in specific positions allowing lipases to modify acylglycerols on the sn-1 and sn-3 positions, both in hydrolysis and inter- or transesterification.

It should be noted that for the *Rhizomucor miehei* lipase a surprising phenomenon was reported in that the lipase showed a preference for the sn-1 position when operating under very dry conditions (18). This property could allow for stereospecific synthesis to be carried out. As opposed to this regiospecificity, lipases, such as that from *Candida rugosa* and the one from *Geotrichum candidum*, are random and hence can modify the fatty acids on all positions of the acylglycerols.

The second type of specificity relates to the type of fatty acid being involved. For example, certain *Cuphea* lipases show a distinct selectivity for short chain fatty acids. Another important example is *Geotrichum candidum* lipase B. Though being non regiospecific, it shows a strong selectivity for fatty acids with a *cis*- $\Delta$ -9 double bond (20, 21). Both this lipase and that from *Candida rugosa* display a strong selectivity against long-chain polyunsaturated fatty acids. This property is probably related to the tunnel shape of the fatty acid binding site of both lipases (22).

The easiest way of exploiting these fatty acid selectivities in product purification or fatty acid enrichments is in single-stage reactions such as hydrolysis or esterification, in combination with a physical means of separating the desired end product and the residual unwanted fatty acid fraction (see section on fatty acid enrichment).

**Table 1** Exploitation of Lipase Specificities for Acylglycerol Modification

Specificity	Lipases	Application
Regiospecificity sn-1, sn-3 specific	<i>Rhizomucor miehei</i> <sup>a</sup> <i>Rhizopus oryzae</i> <i>Rhizopus arrhizus</i> <i>Rhizopus delemar</i> <i>Rhizopus niveus</i> <i>Porcine pancreatic lipase</i>	Triglycerides interesterification/acidolysis synthesis by esterification Diglycerides triglyceride hydrolysis/glycerolysis (directed) fatty acid esterification Monoglycerides triglyceride hydrolysis/glycerolysis fatty acid esterification
Nonspecific	<i>Candida rugosa</i> <i>Chromobacterium viscosum</i> <i>Pseudomonas fluorescens</i> <i>Pseudomonas cepacia</i>	Fatty acid production by hydrolysis Mono- and diglycerides by directed glycerolysis Fatty acid production by hydrolysis Mono- and diglycerides by directed glycerolysis
Fatty acid specificity Short-chain fatty acids	<i>Cuphea</i> sp.	Production of fatty acid concentrates by selective hydrolysis
Long-chain poly-unsaturated acids	<i>Geotrichum candidum</i>	Production of enriched glycerides by selective hydrolysis or enriched fatty acids by esterification
<i>Cis</i> -Δ9 unsaturated fatty acids	<i>Candida rugosa</i>	Production of enriched glycerides by selective hydrolysis or enriched fatty acids by esterification
<i>Geotrichum candidum</i> B		Production of enriched glycerides by selective hydrolysis or enriched fatty acids by esterification
Partial glyceride specific Monoglycerides	Potato acylhydrolase (patatin)	Monoglycerides by fatty acid esterification
Mono- and diglycerides	<i>Penicillium camembertii</i> <sup>b</sup> <i>Penicillium cyclopium</i> <sup>b</sup>	Mono- and diglycerides by fatty acid esterification Mono- and diglycerides by fatty acid esterification

<sup>a</sup>sn-1 specific under semi-dry operating conditions (18).

<sup>b</sup>The selectivity for monoglycerides over diglycerides varies with the water activity (114, 115).

The third major lipase specificity is that for certain types of acylglycerols. *Penicillium camembertii* lipase is known to act upon mono- and diglycerides only, whereas other *Penicillium* lipases are reported to hydrolyze only triglycerides. Patatin, a potato acyl hydrolase, is even more specific, almost exclusively producing monoglycerides in synthesis (23). Unfortunately, details on its active site are not yet available.

### C. Effect of the Thermodynamic Water Activity

Apart from being a substrate, water also has a vital function in maintaining the three-dimensional conformation of the enzyme and hence its intrinsic activity (24, 25). This effect is most conveniently expressed in

terms of the thermodynamic water activity maintained in the reaction medium. It allows comparison of results of enzymatic reactions in various organic solvents, even though absolute water concentrations are significantly different (26).

It has been shown that the form of this relationship is rather lipase specific. For example, *Rhizomucor miehei* lipase has an optimum water activity ~ 0.5 and still retains 40% of its maximum activity at water activities close to zero (27, 28). On the other hand, the lipases from *Candida rugosa*, *Humicola*,\* and *Pseudomonas cepacia* not really showed a maximum, their activity

\**Humicola lanuginosa*, currently known as *Thermomyces lanuginosus*.

continuously increasing with the water activity up to saturation level (29). The relationship is rather independent of the type of reaction catalyzed by the lipase (30), the carrier material of the lipase (28) as well as the type of solvent applied (27). However, in polar solvents interactions with the solvent molecule itself may affect the enzyme activity (31), which may explain the low activity of certain lipases in such solvents (32).

The existence of an optimum water activity urges proper control of the water activity throughout a reaction. In fact several methods have been developed which allow accurate control of the water activity in batch as well as continuous reactor systems: e.g., vacuum, controlled air sparging (33), membrane pervaporation (34), and equilibration with concentrated salt systems (35, 36). These techniques have been shown adequate to obtain optimum performance of biocatalysts in ester synthesis.

In some cases water activity control during the process is not relevant at all. For example, in the synthesis of esters from hydrophobic fatty acids and hydrophobic alcohols degrees of synthesis in the range of 90% can easily be reached, even in the presence of free water (13, 14). Moreover, this is independent of the type of lipase applied (13).

A more general case is the interesterification or acidolysis of oils and fats. Starting with a pure triglyceride (acylglycerol) mixture, the thermodynamics of the system will cause nearly all water initially present to be used for hydrolysis (26). Though this reaction does create the diglyceride intermediates required for the interesterification reaction to proceed, it simultaneously results in a significant reduction of the water activity. Moreover, the latter may easily drop below the optimum of the lipase applied. Adding extra water to the system to increase the  $a_w$  is no solution as it will only result in further hydrolysis and hence decreased product (modified triglyceride) yield (37).

Thus, quickly losing water by hydrolysis, the major part of the interesterification reaction will proceed at a very low equilibrium water activity (38–42). As a result of this drying process, the initial water activity of the catalyst itself is of less importance, especially in a continuous reactor system. Instead, the supply of water via the feed stream to a reactor is essential in order to establish a low but constant water activity in the system, thereby preventing exhaustive drying of the catalyst and providing for fresh intermediates to keep the interesterification reaction going. It is therefore generally accepted that in interesterification reactions, the water content in the feed steam should be close to saturation (41, 43, 44).

### III. REACTOR ENGINEERING ASPECTS

#### A. Efficiency of Free Lipases

Using free lipases in organic media, one problem to overcome is the low activity of crude enzyme powders. High lipase input obviously reduces the economic viability of the system and is hence not feasible. Both physical and chemical modification of free lipases have been developed, describing increased lipase solubility and activity.

In most cases chemical modification involves the covalent coupling of a wide variety of hydrophobic molecules onto lysine amino acid residues on the lipase (45, 46). This generally results in an enhanced activity and stability of the catalyst. It was shown that in certain cases these effects are due to an increased porosity of the lipase-aggregate structure obtained after lyophilization of the lipase (47). A similar phenomenon may explain the enhanced activities reported after physical modification of lipases. This technique often involves drying of a lipase in the presence of hydrophobic compounds, often lipids (48, 49).

An alternative “modification” method, referred to as *in situ* immobilization, is based on the conversion of an emulsion of a lipase solution in oil into a dispersion of solid particles. The latter is achieved by drying the system under reduced pressure. The intensity of mixing during the drying stage determined the average particle size of the biocatalyst thus obtained (50). Despite these developments, dispersion of the dried modified lipase preparations in hydrophobic media remains essential but difficult, especially when highly viscous oils are involved. Moreover, recovery of the suspended lipase from the reaction medium for reuse may require significant catalyst handling and operational cost.

#### B. Immobilization of Lipase on Inert Carriers

The use of macroscopic inert carrier materials to immobilize lipase is important, as it allows easy catalyst handling and reuse after separation of the catalyst by sedimentation or filtration. A vast amount of literature has been published on the immobilization of lipases on solid surfaces or inert carrier materials. The methods described cover covalent coupling, precipitation, entrapment, and adsorption. Moreover, many different carrier materials have been used over the years such as hydrophilic powders (celite), ion exchange resins, and hydrophobic polymers, either in the form of particles or as membranes. Extensive overviews on the details of these techniques can be found elsewhere (8).

The most widely used technique is the adsorption of lipases onto porous carrier materials. Such materials provide a huge internal surface area to immobilize individual lipase molecules from solution with high efficiency. The carrier materials should fulfill a number of criteria to deliver a proper biocatalyst (51, 52). Obviously the material should allow efficient lipase immobilization and an appropriate pore size to allow diffusion of the lipase ( $> 50$  nm) (52). Furthermore, particle size is important in order to minimize the risk of substrate mass transfer limitations (40). However, to be able to use the biocatalyst in a packed-bed reactor, a minimum particle size ( $> 500 \mu\text{m}$ ) should be accounted for to keep the pressure drop over the packed bed within reasonable limits.

Carrier materials such as ion exchange resins (e.g., Duolite ex Rohm-Haas, Germany (53)) and polypropylene particles (Accurel EP-100, ex Akzo-Nobel, Germany) (54, 55) are most widely used for lipase adsorption. Especially the latter material has proven to be a suitable carrier, as the immobilization of a wide variety of lipases has been shown to be very efficient and reproducible (54). Though easily immobilized on the carrier, it was reported that certain lipases gave activities much lower than could be expected based on their loading. This phenomenon is attributed to conformational changes in the structure of the lipase and hence a loss of lipase activity upon adsorption of lipase molecules onto the carrier surface. Precoating of the carrier with dummy, nonlipase protein before adsorption of the lipase has proven a reliable technique to overcome the reduction of the activity of the immobilized lipase (54, 56).

It should be noted that immobilization is mentioned as a technique to enhance the stability of lipases. Fundamental studies have revealed that indeed the flexibility of enzymes immobilized onto solid surfaces is considerably reduced (24). However, data actually comparing one and the same type of reaction with both the free and immobilized versions of one lipase are rather scarce (57). Often research measures the temperature optima of the free and immobilized enzymes in different reaction systems; for example, hydrolysis in an emulsion system for the free lipase, and an (inter)esterification in a solvent system for the immobilized lipase. However, considering effects of mass transfer, substrate solubility, and water activity as described above, comparison of results from different assays can be rather tricky, and hence the impact of immobilization itself should be evaluated with care.

### C. Packed-Bed Reactor Setup

One of the major advantages of immobilization is the potential to run a continuous process with maximum exploitation but minimum handling of the biocatalyst. The simplest design of a continuous reactor is a packed-bed reactor, consisting of a cylindrical column holding a fixed bed of catalyst particles containing immobilized lipase. The reaction medium, being either liquid oil or organic solvent containing the substrates, is simply pumped through this bed of catalyst particles. During its pass through the bed the substrates are converted into the desired end-products within the pores of the catalyst. The degree of conversion is simply controlled by the time allowed in the column, i.e., the residence time. The latter is determined by the height of the fixed bed and the flow rate of the reaction medium (see Sec. III.D).

An important design parameter for a packed-bed reactor is catalyst particle size, which generally is in the range of 200–1000  $\mu\text{m}$ . Too-small particles result in an unacceptable pressure drop over the packed bed, whereas too-large particles will introduce mass transfer limitation effects, thereby decreasing the efficiency of the catalyst. The latter especially holds for high-viscosity systems such as vegetable oils. Applying organic solvents as the reaction medium, pore diffusion limitation, i.e., internal mass transfer resistance, can generally be neglected (40).

External mass transfer generally is not an issue, especially when using organic solvents (40, 58). The completion of the reaction requires residence times in the packed bed from half an hour to several hours, depending on the activity of the biocatalyst applied. The oil flow rates applied are generally above the range in which external limitations become important. A detailed study of mass transfer effects in packed-bed reactors can be found elsewhere (39, 49).

### D. Process Modeling

Many models have been developed to describe lipase-catalyzed reactions. The simplest models generally involve Michaelis-Menten kinetics or similar type of rate expressions describing, e.g., substrate or product inhibition. These types of models are often used to describe single reactions such as hydrolysis and esterification (59).

Acidolysis (transesterification) and interesterification of triglycerides are much more complex. Being multistep and multisubstrate reactions a full-kinetic description is highly complicated. Several models

have been developed which are based on true kinetics of the multistep process. With varying degrees of detail, these models easily contain up to five or six reaction parameters, depending on the reaction mechanism assumed (9, 42, 58). However, to limit the complexity of such a model the number of reacting species is generally reduced by assuming only two fatty acids to be involved, e.g., the one present in the triglycerides before the reaction and the fatty acids to be incorporated (9).

A second class of models lacks any mechanistic background and only describe the change in the composition of the triglyceride fraction during acidolysis and interesterification (39, 60, 61). They neglect the initial phase of the process in which water present in the starting mixture is being used for hydrolysis, thereby generating free fatty acids and diglycerides. This starting point is valid, considering the fact that the rate of hydrolysis is at least an order of magnitude faster than the rate of interesterification. As a result the hydrolysis phase is short compared to the total time required for full triglyceride conversion, and once completed, the overall glyceride composition of the mixture remains constant (38, 40–42).

The simplest approach is to consider the fatty acid exchange reactions between the triglyceride species as a purely statistical process approaching the equilibrium end composition (Sec. IV.A) for the triglyceride mixture concerned. In chemical engineering terms such a process is generally referred to as a pseudo-first-order process. Mathematically this is represented by the following one parameter equation:

$$X = 1 - e^{-k \cdot \tau} \quad (1)$$

in which  $X$  is the relative degree of conversion;  $k$  is the pseudo-first-order activity constant of the biocatalyst; and  $\tau$  is the incubation (batch) or average residence time (continuous) in the system.

The degree of conversion is based on the change in the composition between the start and the end of the reaction. The latter is generally characterized by the absence or presence of certain characteristic substrate or product triglycerides:

$$X = \frac{TAG_{t=1} - TAG_{t=0}}{TAG_{eq} - TAG_{t=0}} \quad (2)$$

The composition of the product triglycerides at equilibrium can be calculated from analytical data on the overall composition of the sn-1,3 and sn-2 positions in the starting triglyceride mixture (see Sec. IV.A).

When dealing with the incorporation of specific fatty acids in triglycerides, such as in an acidolysis

reaction, the first-order model can still describe the change in the composition of the triglyceride fraction. However, the models fail to describe the change of the composition of the free fatty acid fraction, as well as the effect of the initial acid/oil ratio on the apparent catalyst activity. In this case a second-order model is often applied (42, 60, 62). It should be noted that the latter models can generally only describe the process for a limited number of fatty acids (61), similar to the kinetic models referred to above.

## E. Stability of Immobilized Lipases

Decisive for the application of any process on industrial scale is variable cost and hence productivity of the biocatalyst. The latter is determined by the activity as well as the longer-term stability of the biocatalyst. In principle, deactivation is an inherent characteristic of any enzyme in which especially temperature is important. Also the presence of water is important as fundamental studies showed that water is involved in many enzyme deactivation reactions. This may explain the improved stability of enzymes in nonaqueous organic media (63). However, the role of water is much more complicated, as it was also reported that some water is required to sustain the enzyme activity over time in a continuous system (41, 125).

Another important mechanism causing deactivation is poisoning of the enzyme by a physical or chemical interaction with impurities in the reaction medium. A number of papers have shown that the stability of lipases in oils is related to the intrinsic quality of the feed oil (41, 43, 44, 53). More specifically, it has been shown that primary and secondary products from triglyceride auto-oxidation, such as hydroperoxides and their degradation products, may reduce the activity of the biocatalyst (64–66).

Deactivation is generally described as a first-order process with time (39, 43, 62), given by the following equation:

$$k = k_0 \cdot e^{-k_d \cdot t} \quad (3)$$

in which  $k$  is the catalyst activity at any time;  $k_0$  is the catalyst activity at the start;  $k_d$  is the deactivation constant [1/time]; and  $t$  is the incubation time.

The specific deactivation constant ( $k_d$ ) is actually a lump parameter, comprising all deactivation mechanisms taking place, such as the thermal deactivation and poisoning phenomena mentioned above. This parameter thus is a complex function of the reaction conditions, e.g., temperature and water activity, the

"quality" of the reaction medium, and the type of lipase involved. This complex nature of the problem generally suggests that it is rather difficult to predict the performance of a chosen lipase in a certain application and hence substantial testing is required each time a new process is being developed. This is confirmed by literature data showing half-life times varying between a few days and several months, depending on specific reaction system studied (7).

#### IV. MODIFICATION OF TRIGLYCERIDES

##### A. Modifying the Fatty Acid Composition

Chemical interesterification is one of the major modification techniques and basically involves a random rearrangement of the sn-1, sn-2, and sn-3 fatty acids over the triglycerides present in the mixture (Fig. 1). A similar result can be obtained when using a random lipase such as that from *Candida rugosa*\* (38, 67), *Pseudomonas fluorescens* (68), or *Pseudomonas cepacia* (69). Using a 1,3-specific lipase, only the fatty acids on the outer positions of the triglyceride molecules will be randomized. In this case the sn-2 position remains intact, which implies that a different triglyceride mixture will result, as compared to the random process.

In both cases the rearrangement process can be regarded as a statistical process, and hence the final, equilibrium composition of the product can be easily calculated. For example, assuming only three fatty acids—X, Y, and Z—present in a TAG mixture, the molar concentration of an individual types of triglycerides follows from:

$$\text{Random process: } \begin{aligned} XYZ &= 6 \cdot x \cdot y \cdot z \\ X_2Y &= 3 \cdot x \cdot x \cdot y \\ X_3 &= x \cdot x \cdot x \end{aligned}$$

$$\begin{aligned} \text{1,3-specific process: } XYZ &= 2 \cdot x_{1,3} \cdot y_2 \cdot z_{1,3} \\ XYX &= x_{1,3} \cdot y_2 \cdot x_{1,3} \end{aligned}$$

in which x, y, z = the molar fractions of X, Y and Z in overall fatty acid composition of the triglyceride mixture; 6, 3, 1 = the number of ways in which three, two, and one type of fatty acids, respectively, can be distributed over the sn-1, sn-2, and sn-3 positions;  $x_{1,3}, z_{1,3}$  = the molar fractions of X and Z on the sn-1 and sn-3 positions;  $y_2$  = the molar fraction of fatty

acid Y on the 2-positions; and 1, 2 = the number of ways the two and one type of fatty acids, respectively, can be distributed over the sn-1 and sn-3 positions in the triglyceride mixture.

The overall- and 2-position fatty acid composition in a triglyceride mixture can be obtained by conventional HPLC or GC analysis. The 1,3-position composition then follows by calculation. Though the above presented rules specifically refer to interesterification of triglycerides, they also apply to acidolysis—i.e., the reaction between triglycerides and fatty acids or single fatty acid esters. However, in this case the overall 1,3-positional fatty acid composition follows from the 1,3-positional fatty acid composition in the triglyceride fraction, the free fatty acid composition, and the molar ratio of free fatty acids to triglycerides.

##### B. Melting Properties of Triglycerides

Triglycerides are the basis for the production of spreads such as margarine and butter, as well as confectionery fats and chocolate. An important triglyceride property in this type of product is their melting behavior and contribution to product texture. The latter is easily recognized in product properties as softness, spreadability, and mouth feel.

The melting behavior of oils and fats is the result of complex interactions among large numbers of triglycerides, all different in the type and position of the fatty acids they contain. Thus modification of the fatty acid composition or distribution will result in a change in the melting behavior.

Chemical interesterification using a sodium alkoxide catalyst is widely being applied for oils and fats modification (70, 71). However, a growing interest exists for its enzymatic equivalent. This process runs under mild operating conditions of temperature and pressure. Moreover, exploiting the specificity of lipases, more specific triglyceride mixtures are obtained which cannot be produced by the random, chemical process.

To date, the main application of enzymatic TAG modification is probably the production of cocoa butterfat equivalents. Cocoa butterfat has a very special melting behavior, which is characterized by a rapid melting within a narrow temperature range. This behavior is related to its high content of POSt- and StOSt-type triglycerides (P = palmitic; O = oleic; St = stearic acid). The latter are not commonly present in vegetable oils, but can be produced by enzymatic modification of e.g. palm midfraction (a palm oil fraction rich in POP) and stearic acid. Using the 1,3-specific lipase from

\**Candida rugosa*, formerly referred to as *Candida cylindracea*.

*Aspergillus niger* in petroleum ether at 40°C, a POSt- and StOSt-rich mixture was thus obtained after 16 hours (38). Alternatively methylesters (72) or ethylester (73) have been used as stearic donor, using a 1,3-specific lipase such as *Rhizomucor miehei*, *Candida antarctica* B (74), or *Rhizopus japonicus* lipase (60).

Other liquid oils, e.g., olive oil, have also been evaluated for the production of cocoa butter equivalents. However, in this case the acidolysis product will also contain less functional tri- and di-oleyltriglycerides such as POO and StOO (75), which requires further separation of the POSt and StOSt fraction by conventional fractionation (38).

An improvement of the melting behavior has also been reported for butterfat being interesterified with a lipase. Using the 1,3-specific *Rhizopus arrhizus* lipase on Accurel interesterification during 96 h at 40–60°C resulted in significantly softer products with improved melting profiles, especially when interesterifying butter fat with canola oil (76–78). It was shown that chemical randomization yielded even more pronounced effects on fatty acid composition and spreading properties. The latter can also be obtained using a random lipase—e.g., that from *Pseudomonas fluorescens* (68).

Improved melting properties were also reported after the modification of fully vegetable oil blends. Starting with a 60/40 mixture of palm stearin and soybean oil, it was shown that the solid-fat content dropped after interesterification during 16 h using the 1,3-specific *Mucor miehei* lipase at 70°C (53). Similar results were reported for other fat blends consisting of palm stearin with coconut oil (43), palm kernel oil, and blends of palm with coconut or palm kernel oil (79). In all cases the 1,3-specific rearrangement of the fatty acids resulted in a decrease of the solids content at all temperatures.

### C. Structured Triglycerides

In the last few decades it has become clear that the fatty acid composition of dietary fats has important implications for human health. Moreover, in certain cases also the position of the fatty acids, i.e., the triglyceride structure, is important (80). Much research has therefore been devoted to the production of so-called structured lipids, which are enriched in TAGs of a very specific structure and/or in a certain type of fatty acid. It is especially in this area that the selectivities of lipases become of particular interest.

Acidolysis using a 1,3-specific lipase is most commonly applied to produce structured triglycerides. A

good example of such a process is the production of Betapol, an additive for infant formulas (81). This product predominantly consists of OPO, which is a major triglyceride in human milk fat (82). Hydrolysis of OPO by human pancreatic lipase will result in free oleic acid and 2-monopalmitin, which are both easily absorbed. As opposed to this, vegetable oils in infant formulas generally contain the POO-type triglycerides, the hydrolysis of which results in free palmitic acid. The latter will form insoluble calcium soaps, thereby preventing absorption of both the palmitic acid and the calcium (83).

Another example is the MLM triglycerides (M = medium-chain C<sub>6</sub>–C<sub>12</sub>; L = long-chain), preferably with an unsaturated fatty acid at the 2-position. Because of the improved digestibility of these types of triglycerides (84, 85), they are of interest for individuals suffering from pancreatic deficiency and other fat malabsorption disorders (86, 87).

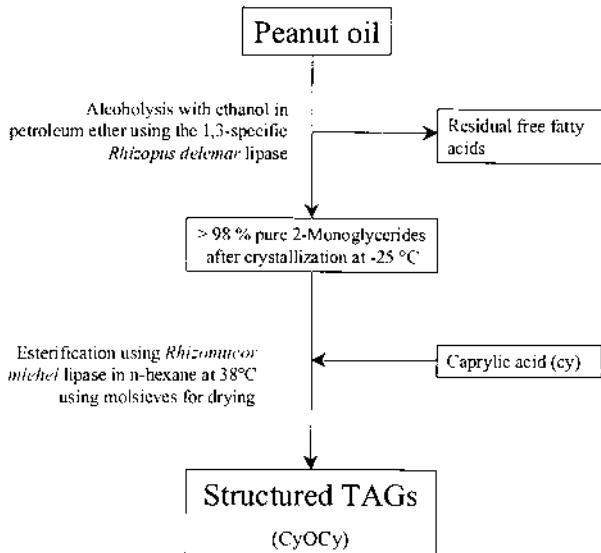

Starting from liquid oils such as sunflower or soybean (88) or peanut oil (89), the desired TAGs are obtained by 1,3-specific acidolysis with a medium fatty acid donor, e.g., free fatty acids. This reaction can be carried out in batch as well as a packed-bed reactor (90).

However, in this one-step acidolysis process, MLM is not the only product. As the process is purely statistical the final mixture will also contain MLL- and LLL-type triglycerides. The concentrations of all TAG types depends on the molar excess of the fatty acids and the equilibrium composition can be calculated using the principles described above.

MLM concentrates were obtained in a two-step enzymatic process. In the first step nearly pure 2-monoglycerides were produced by ethanolysis (reaction with ethanol) of e.g. triolein or cotton seed oil using the 1,3-specific *Rhizopus delemar* lipase (Fig. 3). This reaction was carried out in organic solvent (ethers) at 40°C and 0.75 water activity. After purification by crystallization these 2-monoglycerides were reesterified with caprylic acid at 38°C in hexane using immobilized *Rhizomucor miehei* lipase. This process yielded ~90% MLM (89).

### D. Fatty Acid Enrichment

Nutritionally interesting triglycerides can also be obtained by enrichment or removal of certain fatty acids from a TAG mixture, independent of the TAG structure involved. Especially in this area the fatty acid selectivity of certain lipases is rather important.

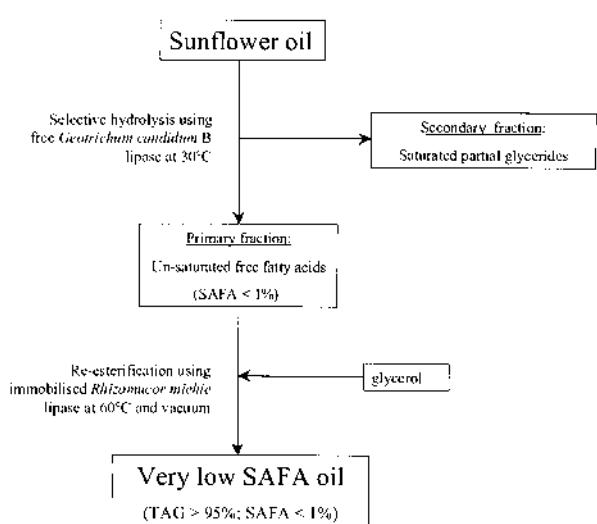

**Figure 3** Two-step synthesis of structured triglycerides. (Adapted from Ref. 89.)

### 1. Low-Saturate Oils

The first example is the production of a low-saturate oil. For many decades the lowering of blood cholesterol by changing the dietary fat consumption has been a hot issue. Nowadays it is recommended to limit the intake of total fat and especially from saturated fat (127), and hence there is considerable interest in low-saturate fat products.

A two-step enzymatic process was described, exploiting the high selectivity of *Geotrichum candidum* lipase B for cis- $\Delta$ -9 unsaturated fatty acids (20, 21). In the first step of the process this lipase was used to preferentially hydrolyze oleic and linoleic acid from sunflower oil at 40°C. This resulted in > 99% unsaturated fatty acids in the free fatty acid fraction (91). After separation of the free fatty acids by conventional distillation, reesterification with glycerol was carried out using immobilized *Rhizomucor miehei* lipase (Fig. 4). Running the process at 60°C under continuous removal of water, > 95% w/w triglycerides were thus obtained with a saturated fatty acid content < 1%.

Now *Rhizomucor miehei* lipase is the most distinct 1,3-specific lipase, and hence the high yield of triglycerides in this reesterification reaction may seem rather surprising. However, whenever dealing with partial glycerides, acylmigration should be accounted for. At temperatures > 40°C monoglycerides (92) as well as diglycerides (93, 94, 126) undergo acylmigration.

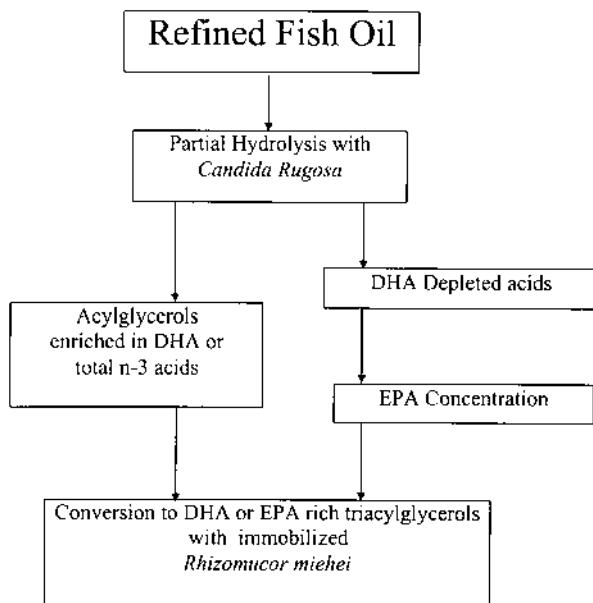

**Figure 4** Fatty acid enrichment via selective hydrolysis: the production of a low-saturate oil via selective hydrolysis and nonselective enzymatic reesterification. (From Ref. 91.)

Thus the primary esterification products—i.e., (1,3)-monoglycerides and 1,3-diglycerides—are converted to their 2-position isomer. Subsequent esterification will result in the formation of 1,2-diglycerides and finally triglycerides (95, 96, 103). Research has shown that the presence of ionic enzyme carriers (94) and the use of apolar solvents (97) also promote acyl migration.

### 2. Enrichment of Long-Chain Polyunsaturated Fatty Acids

The second example of fatty acid enrichment is the production of TAGs enriched in long-chain polyunsaturated fatty acids (LPUFA). These fatty acids are now recognized to play an essential role in the human diet and have important biomedical properties. Marine oils are an important source for LPUFAs such as eicosapentaenoic acid (C20:5; EPA) and docosahexaenoic acid (C22:6; DHA). However, their individual levels are generally rather low and involve a mixture of different fatty acids. Thus enrichment and separation of these fatty acids is widely being investigated. Because of the high susceptibility of LPUFAs to oxidation, especially in this area low-temperature enzymatic processing can be a powerful tool (Fig. 5).

Glycerides enriched in LPUFAs can be produced by selective hydrolysis using the positionally nonselective but chain length-specific lipase from *Candida rugosa*

**Figure 5** Production scheme for the enrichment of fish oil. (From Ref. 103.)

(Table 1). Starting with marine oils such as sardine or cod liver oil (98) or tuna oil (99, 100), partial glycerides with LPUFA levels between 45% and 65% were obtained.

It should be noted that the LPUFAs accumulate in the partial glyceride fraction because of the selectivity of the lipase against, i.e. discrimination against, these fatty acids. Using *Geotrichum candidum* lipase similar overall enrichment results were obtained. However, this lipase appears even more selective than *Candida rugosa*, as it is able to discriminate between EPA and DHA (101).

Another option for enrichment of oils is selective esterification of fish oil free fatty acids, using the conventional 1,3-specific lipases. Being also selective against LPUFAs but active in the esterification reaction, as compared to hydrolysis, reaction with simple alcohols results in free fatty acids enriched in the LPUFAs. These can be purified from the unwanted ester fraction by distillation (100, 102).

One interesting feature about the selective hydrolysis is the level of triglycerides as high as 75% in the residual glyceride mixture, even at degrees of hydrolysis as high as 70% (99, 103). This result is probably due to the ability of the *Candida rugosa* lipase to discriminate against triglycerides with a rising number of long-chain fatty acids in their structure. A model study revealed that triglycerides containing three DHA

chains were hardly hydrolyzed, whereas the rate of hydrolysis increased with two or only one DHA chain in the TAG molecule (104). The phenomenon being less strong for diglycerides and absent for monoglycerides, triglycerides will always become the major compound in the product mixture.

It should be noted that processes similar to those discussed in this paragraph have been used for the enrichment of other interesting fatty acids—e.g., conjugated linoleic acid (CLA) (105), arachidonic acid (AA) (106),  $\gamma$ -linoleic acid (GLA) (107–109), and erucic acid (EA) (110).

## V. PARTIAL GLYCERIDE PRODUCTION

### A. Monoglycerides

Monoglycerides are widely applied as emulsifiers or surfactants and are normally produced by high-temperature glycerolysis using an inorganic catalyst (4). The product is a mixture of mono- and diglycerides (1:1 w/w) and residual triglycerides. Moreover, because of the reaction conditions applied, the crude product is often dark in color and has a burnt flavor. Obviously, this requires extensive purification during further downstream processing, generally involving molecular distillation. Because of the ambient reaction temperatures applied, lipase catalyzed processing has widely been investigated as the more “natural” process, with fewer byproducts and lower energy consumption.

Producing monoglycerides from oils and fats by hydrolysis would be the simplest route. It has been shown that the use of Celite immobilized porcine pancreas lipase at 40°C in a solvent-free system did result in 2-monoglyceride levels as high as 68% w/w in the residual glyceride fraction (111). This result corresponds to 67% of the theoretical molar yield. An even better result was obtained in organic solvent using *Rhizopus arrhizus* lipase at 35°C. A molar conversion of > 95% to 2-monoglycerides was obtained (89, 112). Despite this higher molar conversion, obviously the process route implies a low conversion efficiency.

Starting from free fatty acids and glycerol production of monoglycerides (predominantly the 1(3)-isomer) is much more efficient. Using the monoglyceride-specific enzyme patatin, an acylhydrolase from potato tubers (113), does offer an opportunity for a “natural” process. At temperature < 50°C this lipase was shown to produce > 95% monoglycerides in a solvent-free system (23). Though very specific, the enzyme is not commercially available.

Another option is the use of *Penicillium camembertii* lipase (lipase G), which is a mono- and diglyceride specific lipase and not able to react upon triglycerides. Moreover, it was shown that the selectivity to produce monoglycerides over diglycerides is determined by the water activity applied during the reaction. The lower the  $a_w$ , the more monoglyceride-specific the lipase. Thus at a water activity of approximately 0.1, > 90% pure monoglycerides were produced with 76% degree of conversion (114).

Even higher degrees of conversion were obtained by lowering the reaction temperature, such that the product starts to crystallize. This process is generally referred to as "directed synthesis," referring to the fact that crystallization shifts the equilibrium towards preferential synthesis of the desired solid product. Using this approach it was shown that at 40°C even solid palmitic acid could be converted to pure monoglycerides. Using *Penicillium cyclopium* lipase, nearly pure monoglycerides were produced at > 90% degree of conversion (115). It should be noted that the rate of this "solid-to-solid" conversion process is determined by the rate of diffusion of the reactants and hence the process is rather slow. Consequently the process may take 10–15 days to complete.

Similar results were reported using free lipase from *Pseudomonas fluorescens* or *Chromobacterium viscosum*. Monoglyceride yields between 70% and 90% were obtained, starting from various oils and fats (116, 117). It was shown that the high monoglyceride yield could be obtained simply by reducing the reaction temperature below a certain "critical temperature" (118). However, the latter appeared strongly dependent on the type of triglycerides involved (saturation level).

## B. Diglycerides

For diglycerides processes have been developed similar to those described above, the only difference being either the optimum composition of the starting mixture, the lipase applied, or the processing conditions. Again, directed processes, i.e., applying temperature programming, have been shown to be an important tool for high purity and yield diglyceride production. Thus stepwise decreasing the reaction temperature from 62°C to 48°C, glycerolysis of hydrogenated beef tallow yielded ~ 90% diglycerides using a free *Pseudomonas* lipase (119).

The glycerol/triglyceride ratio was shown to affect the product purity, i.e., the level of monoglycerides

formed. Optimum diglyceride yield was obtained at a glycerol/triglyceride molar ratio equivalent to its stoichiometric value for diglyceride production, i.e., 1:2 (119).

Directed esterification is another efficient means of diglyceride production. Using the 1,3-specific lipases from *Rhizomucor miehei* (116, 120) or *Rhizopus arrhizus* (94, 115), diglyceride yields of 65–85% were obtained. Applying continuous removal of water (116) during the process, yields > 90% were reported.

Comparable results were reported using the partial glyceride-specific lipase from *Penicillium camembertii*. As described above, at high water activity it loses its selectivity for monoglyceride production, yielding 60–85% diglycerides (114, 115).

It should be noted that the "directed synthesis" routes for mono- and diglyceride production prefer the use of free lipases to minimize the rate of mass transfer. Still reaction times are rather long. Moreover, recovery of the free lipase remains rather difficult if the use of solvents is to be avoided. Allowing solvents in the system, recovery of the biocatalyst obviously is much easier. Immobilizing the lipase on nonporous inorganic powders, the catalyst can be recovered after the (solvent-free) process by filtration, having dissolved the reaction medium in acetone (121). Carrying out the whole process in organic solvents, mass transfer is not an issue. For such systems other means of selective product removal also have been developed, such as in-line adsorption (122), crystallization in a separate vessel (123), and extraction (124).

## VI. FUTURE PERSPECTIVE

As shown in this chapter, the use of lipases can be an important tool in the synthesis of a wide range of acylglycerides. Maximum production of a desired product can be obtained by carefully selecting the right lipase with the right selectivity under the right conditions for the process involved. Both the lipase selectivity and the relatively low reaction temperatures are important advantages over conventional organic synthesis, resulting in less byproduct formation and allowing single-step syntheses.

Despite these advantages, only a few of the processes described above are actually applied in industry at full scale. This is mainly due to the prohibitively high cost of most enzymes, as well as the relatively low operational stability encountered in certain applications. However, using modern biotechnology the cost of

enzymes is expected to decrease. Moreover, improved lipase selectivity and stability may further enhance the interest for the applications of enzymes in industry.

## Significance of Indigenous Enzymes in Milk and Dairy Products

**Patrick F. Fox**

*University College, Cork, Ireland*

### I. INTRODUCTION

About 60 indigenous enzymes have been reported in normal bovine milk (1); with the exception of  $\alpha$ -lactalbumin, most of these have no obvious physiological role. The indigenous enzymes are constituents of the milk as excreted and arise from three principal sources: (a) the blood via defective mammary cell membranes; (b) secretory cell cytoplasm, some of which is occasionally entrapped within fat globules by the encircling fat globule membrane (MFGM); and (c) the MFGM itself, the outer layers of which are derived from the apical membrane of the secretory cell, which in turn originates from the Golgi membranes; this is probably the principal source of the enzymes. Thus, most enzymes enter milk owing to peculiarities of the mechanism by which milk constituents, especially the fat globules, are excreted from the secretory cells. Milk does not contain substrates for many of the enzymes present, while others are inactive in milk owing to unsuitable environmental conditions such as pH.

The following abbreviations are used: MFGM, milk fat globule membrane;  $\beta$ -CN,  $\beta$ -casein;  $\alpha_{s2}$ -CN,  $\alpha_{s2}$ -casein; LPL, lipoprotein lipase; UHT, ultra high temperature; HTST, high temperature short time; LTLL, low temperature long time; PE, pasteurization equivalent; HML, human milk lysozyme; BML, bovine milk lysozyme; EWL, egg white lysozyme; NAGase, N-acetyl- $\beta$ -D-glucosaminidase; GGTP,  $\gamma$ -glutamyl transpeptidase; LPO, lactoperoxidase; XO, xanthine oxidase; SO, sulfhydryl oxidase; SOD, superoxide dismutase.

Many indigenous milk enzymes are technologically significant from five viewpoints:

1. Deterioration (lipase [potentially the most significant enzyme in milk], proteinase, acid phosphatase and xanthine oxidase) or preservation (lactoperoxidase, sulfhydryl oxidase, superoxide dismutase) of milk quality.
2. As indices of the thermal history of milk; these include alkaline phosphatase,  $\gamma$ -glutamyl transpeptidase, lactoperoxidase, and perhaps others.
3. As indices of mastitic infection; the concentration of several enzymes increases on mastitic infection, especially catalase, N-acetyl- $\beta$ -glucosaminidase and acid phosphatase.
4. Antimicrobial activity, such as lysozyme and lactoperoxidase (which is exploited as a component of the lactoperoxidase-H<sub>2</sub>O<sub>2</sub>-thiocyanate system for the cold pasteurization of milk).
5. As commercial source of enzymes; these include ribonuclease and lactoperoxidase.

With a few exceptions (e.g., lysozyme and lactoperoxidase), the indigenous milk enzymes do not have a beneficial effect on the nutritional or organoleptic attributes of milk, and hence their destruction by heat is one of the objectives of many dairy processes.

The technologically significant indigenous enzymes in milk and their catalytic activities are listed in [Table 1](#). All these enzymes have been isolated and well characterized. Other enzymes that have been isolated and characterized but which have little or no significance in milk are listed in [Table 2](#). Enzymatic

**Table 1** Technologically Significant Indigenous Enzymes in Milk

Enzyme	Reaction	Significance
Lipase	Triglycerides + H <sub>2</sub> O → fatty acids + partial glycerides + glycerol	Off flavor in milk; flavor development in blue cheese
Proteinase (plasmin)	Hydrolysis of peptide bonds, particularly in β-casein	Reduced storage stability of UHT products; cheese ripening
Alkaline phosphomonoesterase	Hydrolysis of phosphoric acid esters	Index of pasteurization
Acid phosphomonoesterase	Hydrolysis of phosphoric acid esters	Cheese ripening; reduced heat stability of milk;
Lysozyme	Hydrolysis of mucopolysaccharides	Bacteriocidal agent
γ-Glutamyl transpeptidase	Transfer of γ-glutamyl residues	Index of heat treatment
N-Acetylglucosaminidase	Hydrolysis of glycoproteins	Index of mastitis
Xanthine oxidase	Aldehyde + H <sub>2</sub> O + O <sub>2</sub> → Acid + H <sub>2</sub> O <sub>2</sub>	Pro-oxidant; cheese ripening
Sulphydryl oxidase	2RSH + O <sub>2</sub> → RSSR + H <sub>2</sub> O <sub>2</sub>	Amelioration of cooked flavor
Superoxide dimutase	2O <sub>2</sub> • + 2H <sup>+</sup> → H <sub>2</sub> O <sub>2</sub> + O <sub>2</sub>	Antioxidant
Catalase	2H <sub>2</sub> O <sub>2</sub> → O <sub>2</sub> + 2H <sub>2</sub> O	Index of mastitis; pro-oxidant
Lactoperoxidase	H <sub>2</sub> O <sub>2</sub> + AH <sub>2</sub> → 2H <sub>2</sub> O + A	Index of pasteurization; bactericidal agent; index of mastitis; pro-oxidant

activities that have been detected in milk but which have not been isolated and have no known significance in milk are listed in **Table 3**; it is possible that some of these enzymes are secreted by contaminating bacteria in milk.

The indigenous enzymes in milk have attracted the attention of researchers for > 100 years, mainly because of their potential to cause defects in milk and dairy products, especially lipase, and their usefulness as indicators of the thermal treatment of milk. More recently, they have assumed importance as

indices of animal health and of the mechanisms involved in the synthesis and secretion of milk. A very extensive literature has accumulated. The general topic has been the subject of several general reviews (1–10); in addition, the literature on the principal technologically significant enzymes has been reviewed separately (see below).

In this chapter the occurrence, distribution, isolation, and characterization of the principal indigenous enzymes in bovine milk will be discussed, with emphasis on their commercial significance in milk and dairy

**Table 2** Other Enzymes That Have Been Isolated From Milk and Partially Characterized but Which Are of No Known Significance in Milk

Enzyme		Reaction catalyzed	Comment
Glutathione peroxidase	EC 1.11.1.92	GSH + H <sub>2</sub> O ⇌ GSSH	Contains Se
Ribonuclease	EC 3.1.27.5	Hydrolysis of RNA	Milk is a very rich source; similar to pancreatic RNase
α-Amylase	EC 3.2.1.1	Hydrolysis of starch	
β-Amylase	EC 3.2.1.2	Hydrolysis of starch	
α-Mannosidase	EC 3.2.1.24	Hydrolysis of mannan	Contains Zn <sup>2+</sup>

products. The available information indicates that the milks of other species have an enzyme profile similar to bovine milk, although very considerable interspecies differences exist in the level of certain enzymes, e.g., the very high level of lysozyme in human and equine milks. Human milk and that of other primates contain a bile salts-activated lipase, in addition to the ubiquitous lipoprotein lipase, which is not present in the milk of other species. The indigenous enzymes in human milk have been described by Hamos et al. (11) and Hernell and Lonnerdal (12).

## II. PROTEINASES (EC 3.4.-.-)

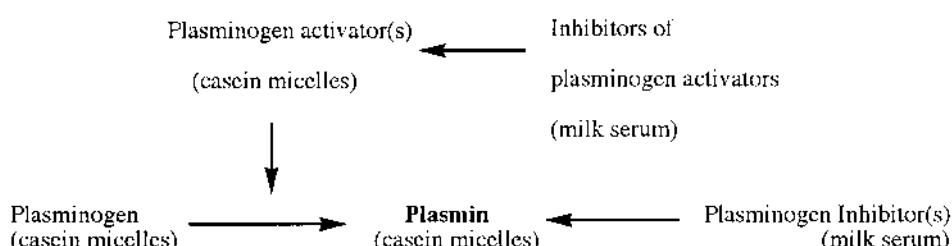

The presence of an indigenous proteinase in milk was suggested by Babcock and Russel in 1897 but because it occurred at a low concentration or had low activity in milk, it was believed until the 1960s that the proteinase in milk might have been of microbial origin. Recent changes in the dairy industry, e.g., improved hygiene in milk production, extended storage of milk at a low temperature at the farm and/or factory, and altered product profile—e.g., UHT processing of milk—have increased the significance of indigenous milk proteinase which has, consequently, been the focus of considerable research.

Milk contains at least two proteinases, plasmin (alkaline milk proteinase) and cathepsin D (acid milk proteinase) and possibly several other proteolytic enzymes, e.g., two thiol proteinases, thrombin, and an aminopeptidase. In terms of activity and technological significance, plasmin is the most important of the indigenous proteolytic enzymes and has been the subject of most attention. The relevant literature has been reviewed by Grufferty and Fox (13) and Bastian and Brown (14).

### A. Plasmin (EC 3.4.21.7)

The physiological function of plasmin (fibrinolysin) is to dissolve blood clots. It is part of a complex system consisting of plasmin, its zymogen (plasminogen), plasminogen activators, plasmin inhibitors, and inhibitors of plasminogen activators (Fig. 1). In milk, there is about four times as much plasminogen as plasmin, and both, as well as plasminogen activators, are associated with the casein micelles, from which they dissociate when the pH is decreased to 4.6; the inhibitors of plasmin and of plasminogen activators are in the milk serum. It has been reported that there is a low level of plasmin activity in the milk fat globule membrane but this appears to be due to the adsorption of plasmin to casein micelles which are adsorbed on the membrane (15). The concentration of plasmin and plasminogen in milk increase with advancing lactation, mastitic infection, and number of lactations. The conversion of plasminogen to plasmin in milk increases with advancing lactation, and there is a positive correlation between plasmin activity and the level of plasminogen activator, which itself is positively correlated with somatic cell count (16). The level of plasmin in milk is also affected by diet and management practices (16). No activation of plasminogen to plasmin is reported (17) to occur during storage of milk at 4°C for 6 days; in fact, plasmin and potential plasmin (plasminogen) activity decreased under these conditions.

Bovine plasminogen contains 786 amino acids with a mass of 88.092 kDa. Its primary structure is arranged in five loops (called kringle), each stabilized by three intramolecular disulfide bonds. Plasminogen is activated in a two-step process: it is first cleaved at Arg<sub>557</sub>-Ile<sub>558</sub> (bovine) by plasmin (a trace of which occurs in blood) to yield Lys-plasminogen which is inactive but undergoes a conformational change

SM = skin milk; FGM = fat globule membrane; P = phosphate.

which exposes the bond Lys<sub>77</sub>-Arg<sub>78</sub> to hydrolysis by urokinase or tissue-type plasminogen activator. Hydrolysis of this bond yields a mature enzyme of ~81 kDa, consisting of two polypeptide chains held together by a single disulfide bond. The five kringle s of plasminogen are retained in plasmin; they are required for activity and are conserved in plasmins from different species. Bovine plasmin is also cleaved at Arg<sub>342</sub>-Met<sub>343</sub> to yield midi plasmin (15). Bovine plasminogen cDNA has been cloned (18).

Plasmin is a serine proteinase (inhibited by di-isopropylfluorophosphate, phenylmethyl sulfonyl fluoride, and trypsin inhibitors) with a high specificity for peptide bonds to which lysine or arginine supplies the carboxyl group. The active site is in the smaller of the two chains and consists of His<sub>598</sub>, Asp<sub>641</sub>, and Ser<sub>736</sub>. It is optimally active at ~pH 7.5 and ~35°C; it exhibits ~20% of maximum activity at 5°C and is stable over the pH range 4–9.

Plasmin is usually extracted from casein by washing with water at pH 3.5 and purified by precipitation with (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and various forms of chromatography, including affinity chromatography. Plasmin is quite heat stable; it is partially inactivated by heating at 72°C for 15 sec, but its activity in milk increases following HTST pasteurization, probably owing to inactivation of the indigenous inhibitors of plasmin or, more likely, inhibitors of plasminogen activators. It partly survives UHT sterilization and is inactivated by heating at 80°C for 10 min at pH 6.8; its thermal stability decreases with increasing pH in the range 3.5–9.2.

The inactivation of plasmin in milk follows first-order kinetics. Arrhenius plots show that inactivation is not linear with increasing temperature. In the temperature range 63–110°C, E<sub>a</sub> for inactivation is 52.75 and 74.44 kJ mol<sup>-1</sup> for low and high somatic cell count (SCC) milk, respectively, while in the range 100–130°C, E<sub>a</sub> is 22.03 and 24.70 kJ mol<sup>-1</sup> for low and high SCC milk, respectively (19). Plasmin is more heat stable to low-temperature treatments, e.g., thermization and HTST pasteurization, in high than in low SCC milk but the reverse is true in the UHT range (19). Milk with a high SCC has high plasminogen activator activity (19).

### 1. Assay of Plasmin Activity

Plasmin activity may be assayed on a wide range of substrates, including proteins, but the most widely used substrate is the synthetic fluorogenic peptide, N-succinyl-L-Ala-L-Phe-L-Lys-7-amido-4-methyl coumarin; the liberated 7-amido-4-methyl coumarin is

quantified by determining the intensity of fluorescence, with excitation at 380 nm and emission at 460 nm (20). The chromogenic substrate, Val-Leu-Lys-*p*-nitroanilide, is also used (16). Plasminogen activity is measured by assaying plasmin activity before and after activation of indigenous plasminogen by an excess of added urokinase (16). Plasminogen activator activity may be assayed by the ability of an ultracentrifugal casein micelle pellet to activate exogenous (added) plasminogen (16).

### 2. Activity of Plasmin on Milk Proteins

β-Casein is the most susceptible milk protein to plasmin action; it is hydrolyzed rapidly at Lys<sub>28</sub>-Lys<sub>29</sub>, Lys<sub>105</sub>-His<sub>106</sub>, and Lys<sub>107</sub>-Glu<sub>108</sub> to yield γ<sup>1</sup> (β-CN f29-209), γ<sup>2</sup> (β-CN f106-209), and γ<sup>3</sup> (β-CN f108-209) caseins and proteose peptone (PP)5 (β-CN f1-105/7), and PP8 slowly (β-CN f29-105/7) and PP8 fast (β-CN f1-29). In vitro (in solution), β-casein is also hydrolyzed fairly rapidly at Lys<sub>113</sub>-Tyr<sub>114</sub> and Lys<sub>183</sub>-Asp<sub>184</sub>, but it is not known if these bonds are hydrolyzed in milk. γ-Caseins normally represent ~3 % of total N in milk but can be as high as 10% in late-lactation milk; as a percent of total N, the value for proteose peptones is about half that of the γ-caseins.

α<sub>s2</sub>-Casein in solution is also hydrolyzed very rapidly by plasmin at bonds Lys<sub>21</sub>-Gln<sub>22</sub>, Lys<sub>24</sub>-Asn<sub>25</sub>, Arg<sub>114</sub>-Asn<sub>115</sub>, Lys<sub>149</sub>-Lys<sub>150</sub>, Lys<sub>150</sub>-Thr<sub>151</sub>, Lys<sub>181</sub>-Thr<sub>182</sub>, and Lys<sub>188</sub>-Ala<sub>189</sub> (see 14), but its hydrolysis in milk has not been characterized. Although less susceptible than α<sub>s2</sub>- or β-caseins, α<sub>s1</sub>-casein in solution is also readily hydrolyzed by plasmin (14) but it does not appear to be hydrolyzed to a significant extent in milk, although it has been suggested that λ-casein is produced from α<sub>s1</sub>-casein by plasmin. Although κ-casein contains several Lys and Arg residues, it appears to be quite resistant to plasmin, presumably owing to a relatively high level of secondary and tertiary structures. The whey proteins are quite resistant to plasmin, probably owing to their compact, globular structures; in fact, β-lactoglobulin, especially when denatured, inhibits plasmin, presumably via sulfhydryl-disulfide interactions which rupture the structurally important kringles.

### 3. Significance of Plasmin Activity in Milk

There is sufficient plasmin in milk to cause very extensive proteolysis, but this is not realized owing to the presence of inhibitors. If the casein micelles are sedimented by ultracentrifugation and redispersed in buffer, very extensive proteolysis occurs on storage since

the inhibitors are removed in the ultracentrifugal serum. According to Guinot-Thomas et al. (17), microbial proteinases cause more proteolysis in milk than plasmin during storage at 4°C for 6 days.

Plasmin and plasminogen accompany the casein micelles on the rennet coagulation of milk and are concentrated in cheese in which plasmin contributes to primary proteolysis of the caseins, especially in cheeses that are cooked to a high temperature, e.g., Swiss and some Italian varieties, in which the coagulant is totally or extensively inactivated (21).  $\beta$ -Casein is the principal substrate and even in low-cooked cheeses (e.g., Cheddar, Gouda), in which the coagulant is the principal primary proteinase, proteolysis of  $\beta$ -casein is due mainly to plasmin action; some hydrolysis of  $\alpha_{s1}$ -casein by plasmin also occurs.

The level of plasmin activity in cheese varies substantially with the variety; Emmental, Parmesan, and Dutch-type cheeses contain about three times as much plasmin activity as Cheddar-type cheeses (22). This is probably due to the greater activation of plasminogen in the former as a result of inactivation of inhibitors of plasminogen activators in high-cooked cheese and their removal from Dutch-type cheese curd on washing (when whey is removed and replaced by water). Plasmin activity is decreased in cheeses made from UF-concentrated milk because of the retention of inhibitors of plasmin and plasminogen activators and  $\beta$ -lactoglobulin in the curd. Proteolysis is less in UF cheeses than in their conventional counterparts; presumably, the lower level of plasmin activity is a contributory factor.

It has been suggested that an elevated level of plasmin activity in late-lactation milk contributes to its poor cheese-making properties; however, an elevated level of somatic cells in milk does not appear to lead to defects in cheese (13). The casein micelles in bovine milk are capable of binding ~10 times as much plasmin as occurs naturally in milk. Exogenous plasmin added to milk is incorporated and uniformly distributed in the cheese curd, in which it accelerates proteolysis and maturation (23). When other exogenous proteinases are added to cheese milk, much of the added enzyme is lost in the whey, increasing cost and creating potential problems for whey processors. The yield of cheese may also be decreased owing to early hydrolysis of casein in the vat. For Cheddar-type cheese, exogenous proteinases may be added to the milled curds at salting, but the enzyme is concentrated at the surface of the curd chips. Activation of indigenous plasminogen by added urokinase also accelerates proteolysis (14, 23a).

Cheese analogues are usually produced from rennet casein which may contain active plasmin. Hydrolysis of  $\beta$ -casein and undesirable changes in the rheological properties of cheese analogs have been attributed to plasmin action (14).

Plasmin activity may contribute to the age gelation of UHT milk produced from high-quality raw milk (which contains a low level of *Pseudomonas* proteinase). The acid precipitability of casein from late-lactation milk is poor, but evidence for the involvement of plasmin is lacking. Reduced yields of cheese and casein can be expected to result from plasmin action in milk since the proteose peptones are, by definition, soluble at pH 4.6 and are not incorporated into acid- or rennet-produced casein curd.

#### 4. Proteinase Inhibitors in Milk

Milk contains several broad-specificity plasma-derived proteinase inhibitors:  $\alpha_1$ -proteinase inhibitor,  $\alpha_2$ -antiplasmin, C1 inhibitor, antithrombin-III,  $\alpha_2$ -macroglobulin, inter- $\alpha$ -trypsin inhibitor, and two inhibitors analogous to human  $\alpha_1$ -antichymotrypsin which possess inhibitory activity against trypsin and elastase, respectively. Inhibitory activity is highly elevated in mastitic milk owing to increased leakage of blood proteins into milk. It has been proposed that trypsin inhibitory activity in milk may be a useful index of mastitis in cows. Bovine colostrum contains colostrum-specific proteinase inhibitors, including trypsin-inhibitory and thiol proteinase-inhibitory activities, which protect immunoglobulins and other biologically active proteins and peptides against proteolysis by gastrointestinal enzymes in the newborn (24, 25).

Apart from the colostrum-specific inhibitors, the plasma-derived inhibitors are present in milk as a result of membrane leakage (mastitis or late lactation) and therefore might be expected to be without significance. However, they are probably quite significant: (a) The level of plasmin in milk is sufficient to cause very extensive hydrolysis of the caseins, as can be readily demonstrated by dispersing ultracentrifugally sedimented casein micelles in buffer (plasmin and plasminogen accompany the casein micelles while the inhibitors are in the milk serum). Plasmin activity is increased by pasteurization apparently because proteinase inhibitors are inactivated by heating. (b) The inhibitors are retained in cheese made from milk concentrated by ultrafiltration (UF) whereas they are lost in the whey during conventional cheese making. Consequently, proteolysis is retarded in UF cheese (14, 25).

Denatured  $\beta$ -lactoglobulin also inhibits plasmin, apparently owing to sulphydryl-disulfide interchange reactions. Since  $\beta$ -lactoglobulin is concentrated by UF, it probably contributes to the inhibition of proteolysis in cheese made from UF-concentrated milk during ripening.

### 5. Plasminogen Activators

There are two types of plasminogen activators, urokinase-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA). Both types occur in milk; uPA is confined to cells in milk while tPA is associated with the casein micelles (26, 27). Both activators have been characterized and cloned (28). Lu and Nielsen (29) reported that there are five plasminogen activators in milk, with molecular weights of 93, 57, 42, 35, and 27 kDa; most were uPA-type activators. PA level increases with mastitic infection and advancing lactation (30), which explains the greater conversion of plasminogen to plasmin in such milks.

### B. Cathepsin D (EC 3.4.23.5)

It has been known for  $\sim$  30 years that milk also contains an acid proteinase (optimum pH  $\sim$  4.0) which is now known to be cathepsin D, a lysosomal enzyme. It is relatively heat labile (inactivated by 70°C for 10 min). Its activity in milk has not been studied extensively, and its significance is unknown. At least some of the indigenous acid proteinase is incorporated into cheese curd; its specificity on  $\alpha_{s1}$ - and  $\beta$ -caseins is quite similar to that of chymosin, but it has very poor milk clotting activity (31). It may contribute to proteolysis in cheese, but its activity is probably normally overshadowed by chymosin, which is present at a much higher level in cheese.

### C. Other Proteinases

The presence of other minor proteolytic enzymes in milk, including thrombin and a lysine aminopeptidase, has been reported (32). In addition to cathepsin D, other proteolytic enzymes from somatic cells are probably present in milk. Verdi and Barbano (33), who studied the degradation of caseins in milk by somatic cells or plasmin, found that somatic cell proteinases and plasmin produced distinctly different peptides, and that the plasmin inhibitor 6-aminohexanoic acid was suitable for studying the action of somatic cell proteinases, without interference from plasmin. Somatic cell proteinases are capable of activating plas-

minogen (34), and this may influence proteolysis in cheese by elevating plasmin levels. Although leucocyte proteinases were more active on  $\beta$ -casein at pH 6.6 than at pH 5.2, their activity at the lower pH was such as to suggest that they may be active in cheese during ripening (35). Suzuki and Katoh (36) found two cysteine proteinases in milk (45 kDa and  $>$  150 kDa). The authors suggested that these proteinases originated in somatic cells and their level increased during mastitic infection.

Grieve and Kitchen (37) compared the action of leucocyte proteinases, plasmin, and some psychotroph proteinases on the caseins. Leucocyte extracts hydrolyzed the caseins in order  $\alpha_{s1} > \beta \gg \kappa$ . Although these authors considered that neutral proteinases from leucocytes (isolated from blood) were unlikely to be important for proteolysis in milk, other authors have found considerably lower proteolytic activity in leucocytes isolated from blood than from milk (34, 35).

Kelly et al. (39), who compared proteolysis in Gouda cheeses made from milks with the same total somatic cell count but different levels of polymorphonuclear (PMN) leucocytes, found more rapid production of  $\alpha_{s1}$ -CN f24-199 and total free amino acids in cheese made from milk with high PMN levels ( $\alpha_{s1}$ -CN is  $\alpha_{s1}$ -casein).

The significance of minor indigenous proteins during mastitic infections was discussed by Fang and Sandholm (40) who investigated the possibility of using specific proteinase inhibitors as therapeutic agents. Although the minor proteinases are probably less significant technologically than plasmin, more work on the subject is warranted.

## III. LIPASES AND ESTERASES (EC 3.1.1.-)

Lipases catalyze the development of hydrolytic rancidity which is a serious defect in milk and some milk products, and, consequently, lipases and lipolysis in milk have been studied extensively. Milk contains three types of esterase: (a) A-type carboxylic ester hydrolase (arylesterase; EC 3.1.1.2), which hydrolyzes aromatic esters, e.g., phenylacetate. It shows little activity on tributyrin, and is not inhibited by organophosphates. (b) B-type esterase (glycerol tricarboxyl esterase, aliphatic esterase, lipase; EC 3.1.1.3). Such enzymes are most active on aliphatic esters although they show some activity on aromatic esters; they are inhibited by organophosphates. (c) C-type esterase (cholinesterase; EC 3.1.1.7; EC 3.1.1.8). These enzymes are most active on choline esters but hydrolyze some

aromatic and aliphatic esters slowly; they are inhibited by organophosphates.

In normal milk, the ratio of A:B:C types of esterase activity is about 3:10:1 but the level of A-esterase activity increases considerably on mastic infection. A and C esterases are of little technological significance in milk. Lipases hydrolyze ester bonds in emulsified esters, i.e., at a water/oil interface, although some may have limited activity on soluble esters. They are usually activated by blood serum albumin and  $\text{Ca}^{2+}$  which bind free fatty acids, which are inhibitory.

Milk lipase was first isolated and characterized by Fox and Tarassuk (41) and Patel et al. (42). The enzyme was optimally active at pH 9.2 and 37°C and was found to be a serine enzyme (inactivated by organophosphates). A lipoprotein lipase (LPL; activated by lipoprotein cofactors) was demonstrated in milk by Korn in 1962 (42a) and isolated by Egelrud and Olivecrona (43). The lipase isolated by Fox and Tarassuk (41) is, in fact, an LPL which is the principal, probably the only, indigenous lipase in bovine milk. It has been the focus of considerable research and has been characterized at the molecular, genetic, enzymatic, and physiological levels (44).

Under optimum conditions, the  $k_{\text{cat}}$  for milk LPL is  $\sim 3000 \text{ s}^{-1}$  and milk contains sufficient enzymes (1–2 mg/L; i.e., 10–20 nM) to theoretically cause rancidity in 10 sec. However, this does not occur in practice because the triglycerides are protected by the MFGM while the lipase is naturally associated with the casein micelles. Also, environmental conditions, e.g., pH, are not optimal. However, if the MFGM is damaged by agitation (e.g., by milking machines, bulk tanks, pumps, etc.), homogenization or temperature fluctuations, lipolysis occurs rapidly and rancidity ensues. Milk LPL appears to be derived from blood plasma and hence any condition that increases the permeability of mammary cell membranes, e.g., physiological stress, mastitic infection, or late lactation, increases the level of LPL in milk and hence the risk of lipolysis. Some individual cows produce milk which becomes rancid spontaneously, i.e., without apparent activation. Apparently, spontaneous rancidity occurs when milk contains a high level of lipoprotein (co-lipase) from blood serum which activates the LPL. Normal milk will become spontaneously rancid if blood serum is added, suggesting that "spontaneous milks" contain a higher than normal level of blood serum. Dilution of spontaneous milk with normal milk prevents spontaneous rancidity, which, consequently, is not normally a problem with bulk herd milks. Presumably, dilution with normal milk decreases the

lipoprotein content of the bulk milk to below the threshold necessary for lipase activation. Natural variations in the level of free fatty acids in normal milk and the susceptibility of normal milks to induced lipolysis may be due to variations in the level of blood serum components in milk.

In addition to LPL, human milk contains a bile salts-activated lipase, which probably contributes to the metabolism of lipids by breastfed babies who have limited pancreatic lipase activity. Bovine milk and milks from other dairy animals do not contain this enzyme.

#### A. Assay of Lipolytic Activity

Lipase can be assayed by incubating the sample with an emulsified lipid substrate—e.g., milk fat, olive oil, tributyrin, etc.—extraction of liberated fatty acids with diethyl ether-petroleum ether, and titration with ethanolic KOH. This method is rather tedious and tributyrin agar diffusion assays may be used when rapid screening is required. Chromogenic substrates, e.g.,  $\beta$ -naphthyl- or *p*-nitrophenyl derivatives of fatty acids or fluorogenic substrates, e.g., coumarin derivatives of fatty acids, are very sensitive and satisfactory, especially when the enzyme has been at least partially purified.

#### B. Significance of Lipase

Technologically, LPL is, arguably, potentially the most significant indigenous enzyme in milk. Although LPL may play a positive role in cheese ripening, undoubtedly the most industrially important aspect of milk lipase is its role in hydrolytic rancidity which renders liquid milk and dairy products unpalatable and eventually unsaleable. Lipolysis in milk has been reviewed extensively (45). It appears to occur mainly at the farm level and the problem may be minimized by good management practices on the farm:

1. Proper installation, maintenance, and operation of milking machines.
2. Avoidance of excessive agitation by pumps or agitators in bulk tanks or risers in milk pipelines.
3. Avoidance of freezing on the walls of bulk tanks.
4. Avoidance of cooling and warming cycles in the bulk tank.
5. Culling of cows with high somatic cell counts.

The first three factors damage the MFGM, making the core triglycerides accessible to lipase. Some casein micelles probably adsorb on exposed fat surfaces. Pipeline milking machines cause more damage to the MFGM than hand milking or bucket milking machines. Suction of air at teat cups (which causes foaming), risers, and change of dimensions in the pipeline and the hose connecting the clawpiece to the receiving jar are major potential sites for damage. Homogenization causes total replacement of the natural MFGM by a membrane composed of casein micelles or submicelles and whey proteins. Unless indigenous LPL is inactivated by pasteurization before or immediately after homogenization, rancidity will develop very rapidly. Minimal high temperature short time (HTST; 72°C for 15 sec) pasteurization of milk causes extensive inactivation of LPL but pasteurization at 80°C for 10 sec is required for complete inactivation.

Freezing of milk on the walls of bulk tanks will damage the MFGM, inducing lipolysis. Temperature fluctuations, e.g., cooling to ~5°C, rewarming to ~30°C, and recooling, also activate lipolysis. Such temperature fluctuations may occur if bulk tanks are not completely emptied at each milk collection and warm milk is added at the subsequent milking. The mechanism of thermal activation is not clear, but damage to the MFGM by fat crystals seems likely.

The propensity of milk to lipolysis increases when the producing animals are under any type of stress. The mammary cell membranes become more permeable to blood constituents as a result of mastitic infection in late lactation and as the animal ages. The number of somatic cells in milk is a good index of such stress or damage, and upper limits for somatic cell count (SCC) are now frequently prescribed by milk processors. Although the potential for hydrolytic rancidity always exists in raw milk, the problem can be reduced to insignificant levels by good management practices at the farm.

#### IV. ALKALINE PHOSPHATASES (EC 3.1.3.1)

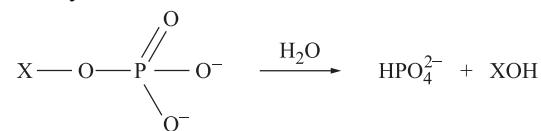

Milk contains several phosphatases, the principal ones being alkaline and acid phosphomonoesterases, which are of technological significance, and ribonuclease, which has no known function or significance in milk. The alkaline and acid phosphomonoesterases have been studied extensively (1, 8, 9).

The occurrence of a phosphatase in milk was first recognized in 1925. Subsequently characterized as an alkaline phosphatase, it became significant when it

was shown that the time-temperature combinations required for the thermal inactivation of alkaline phosphatase were slightly more severe than those required to kill *Mycobacterium tuberculosis*, then the target microorganism for pasteurization. The enzyme is readily assayed, and a test procedure based on alkaline phosphatase inactivation was developed as a routine quality control test for the HTST pasteurization of milk.

##### A. Assay Methods

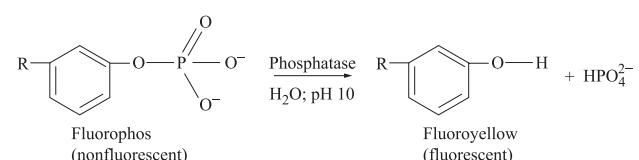

Several major modifications of the original assay have been developed. The usual substrates are phenyl phosphate, *p*-nitrophenyl phosphate, or phenolphthalein phosphate which are hydrolyzed to inorganic phosphate and phenol, *p*-nitrophenol, or phenolphthalein, respectively:

where XOH = phenol, *p*-nitrophenol, or phenolphthalein.

The release of inorganic phosphate may be assayed but the other product is usually determined. Phenol is colorless but forms a colored complex on reaction with one of several reagents, e.g., 2,6-dichloroquinonechloroimide, with which it forms a blue complex. *p*-Nitrophenol is yellow while phenolphthalein is red at the alkaline pH of the assay (~10) and hence these are easily quantified.

A fluorogenic aromatic orthophosphoric monoester, Fluorophos (Advanced Instruments, Needham Heights, MA), has been developed and approved for the determination of alkaline phosphatase in milk and milk products. Hydrolysis of the ester yields a fluorescent compound, Fluoroyellow, the concentration of which is determined fluorometrically (excitation, 439 nm; emission, 560 nm).

Fluorometric methods are about 100–1000 times more sensitive than colorimetric assays. A simple fluorometer has been developed for the analysis (Advanced Instruments). Comparative studies on the fluorometric and the standard colorimetric methods include those of Rocco (46) and Eckner (47).

## B. Isolation and Characterization of Alkaline Phosphatase

Alkaline phosphatase is concentrated in the fat globule membrane and hence in cream. The membrane is released into the buttermilk on phase inversion; consequently, buttermilk is the starting material for most published methods for the purification of alkaline phosphatase. Later methods have used chromatography on various media to give a homogeneous preparation; up to ~7500-fold purification with a yield of ~30% have been reported (1). The characteristics of milk alkaline phosphatase are summarized in Table 4. The enzyme appears to be similar to the alkaline phosphatase of mammary tissue, which is the presumed source of the enzyme in milk.

The enzyme is a dimer of two identical 85-kDa subunits. It contains 4 Zn<sup>2+</sup> per mole which are required for activity; Mg<sup>2+</sup> are also strong activators, and 1 mM Mg<sup>2+</sup> is usually added to the assay mixture. The enzyme is strongly but reversibly inhibited by metal chelators; the apoenzyme is reactivated by Zn<sup>2+</sup>, Mg<sup>2+</sup>, and other metal ions. Reaction of apoenzyme may in fact be used as a sensitive assay for available Zn<sup>2+</sup> in foods. Inorganic orthophosphates are strong competitive inhibitors of the hydrolysis of *p*-nitrophenylphosphate. Alkaline milk phosphatase can dephosphorylate phosphoproteins, including casein, with a pH optimum of 6.5–7.0; however, it does not appear to do so in milk, probably owing to inhibition by the high level of orthophosphate.

**Table 4** Characteristics of Milk Alkaline Phosphatase

Characteristic	Conditions
pH optimum	Casein: 6.8 <i>p</i> -nitrophenylphosphate: 9.9
Temperature optimum	37°C
K <sub>m</sub>	0.69 mM on <i>p</i> -nitrophenylphosphate
Activators	Ca <sup>2+</sup> , Mn <sup>2+</sup> , Zn <sup>2+</sup> , Co <sup>2+</sup> , Mg <sup>2+</sup>
Inhibitors	Metal chelators (EDTA, EGTA, etc.); orthophosphates
Native molecular weights	170–190 kDa
Quaternary structure	2 subunits each of molecular weights 85 kDa
Zn content	4 mol mol <sup>-1</sup> enzyme
Thermal stability:	
D-value at 60°C, pH 9	27.2 min
63°C, pH 9	8.3 min

## C. Reactivation of Phosphatase

Much work has been focused on a phenomenon known as “phosphatase reactivation,” first recognized by Wright and Tramer in 1953, who observed that UHT-treated milk was phosphatase-negative immediately after processing but became positive on standing; microbial phosphatase was shown not to be responsible. Bulk HTST milk never showed reactivation, although occasional individual cow samples did. HTST pasteurization after UHT treatment usually prevented reactivation which was never observed in in-container sterilized milk. Reactivation can occur following heating at a temperature as low as 84°C for milk or 74°C for cream. The optimum storage temperature for reactivation is 30°C, at which reactivation is detectable after 6 h and may continue for up to 7 days. The greater reactivation in cream than in milk may be due to protection by fat, but this has not been substantiated.

A number of attempts have been made to explain the mechanism of reactivation (8). There is evidence that the form of the enzyme which becomes reactivated is membrane bound, and several factors which influence reactivation have been established. Mg<sup>2+</sup> and Zn<sup>2+</sup> strongly promote reactivation; Sn<sup>2+</sup>, Cu<sup>2+</sup>, Co<sup>2+</sup> and EDTA are inhibitory, while Fe<sup>2+</sup> has no effect. Sulfhydryl (SH) groups appear to be essential for reactivation; perhaps this is why phosphatase becomes reactivated in UHT milk but not in HTST milk. The role of -SH groups, supplied by denatured whey proteins, is considered to be chelation of heavy metals, which would otherwise bind to -SH groups of the enzyme (also activated on denaturation), thus preventing renaturation. It has been proposed that Mg<sup>2+</sup> and Zn<sup>2+</sup> cause a conformational change in the denatured enzyme, necessary for renaturation (1).

According to Murthy et al. (48), maximum reactivation occurs in products heated at ~104°C; incubated at 34°C, adjusted to pH 6.5, and containing 0.064 M Mg<sup>2+</sup>; homogenization of products before heat treatment reduces the extent of reactivation. There are reports that raw milk contains three isoenzymes of alkaline phosphatase and that the zymogram patterns of raw and reactivated milk or cream are different (1, 48); however, these different forms probably represent free and bound forms of the enzyme. A mechanism for the reactivation of alkaline phosphatase was proposed by Copius-Pereboom (49); however, this mechanism of reactivation is based on a putative structure of the milk fat globule membrane which is now known to be incorrect. Linden (50)

proposed that reactivation occurs in stages and full reactivation requires  $Zn^{2+}$ ,  $Mg^{2+}$ , inorganic phosphate ( $Pi$ ), and substrate ( $S$ ).

Reactivation of alkaline phosphatase is of considerable practical significance since regulatory tests for pasteurization assume the absence of phosphatase activity. Methods for distinguishing between renatured and residual native alkaline phosphatase are based on the increase in phosphatase activity resulting from addition of  $Mg^{2+}$  to the reaction mixture; various versions of the test have been proposed (48, 51, 52). The official AOAC method (53) is based on that of Murthy and Peeler (52). However, difficulties are experienced in the interpretation of this test applied to cream or butter (54, 55).

#### D. Significance

Alkaline phosphatase in milk is significant mainly because of its use as an index of HTST pasteurization and is used universally for this purpose. However, the enzyme may not be the most appropriate for this purpose (56) becomes (a) reactivation of alkaline phosphatase under certain conditions complicates interpretation of the test; (b) the enzyme appears to be fully inactivated by subpasteurization conditions ( $70^{\circ}C$  for 16 sec); and (c) the relationship between  $\log_{10}\%$  initially activity and pasteurization equivalent (PE) is less linear than the relationship of lactoperoxidase or  $\gamma$ -glutamyl transpeptidase (57).

Although alkaline phosphatase can dephosphorylate casein under suitable conditions, as far as is known, it has no direct technological significance in milk. Perhaps its pH optimum is too far removed from that of milk, especially acid milk products, although the pH optimum on casein is reported to be  $\sim 7$ . It is also inhibited by inorganic phosphate.

Proteolysis is a major contributor to the development of flavor and texture of cheese during ripening (58). Most of the small water-soluble peptides in cheese are from the N-terminal half of  $\alpha_{s1}$ - or  $\beta$ -casein; many are phosphorylated but show evidence of phosphatase activity (i.e., they are partially dephosphorylated) (59–62). In cheese made from pasteurized milk, both indigenous acid phosphatase and bacterial phosphatase are probably responsible for dephosphorylation (which is the more important is not clear), but in raw milk cheese, e.g., Parmigiano Reggiano or Grana Padano, milk alkaline phosphatase appears to be the most important (63, 64). Further work on the significance of indigenous alkaline and acid phosphatases in

the dephosphorylation of phosphopeptides in cheese is warranted.

#### V. ACID PHOSPHOMONOESTERASE (EC 3.1.3.2)

Milk contains an acid phosphatase which has a pH optimum at 4.0 and is very heat stable. (LTLT pasteurization causes only 10–20% inactivation and 30 min at  $88^{\circ}C$  is required for full inactivation; when heated in milk at pH 6.7, the enzyme retains significant activity following HTST pasteurization but it does not survive in-bottle sterilization or UHT treatment.) The enzyme is not activated by  $Mg^{2+}$  (as is alkaline phosphatase), but it is slightly activated by  $Mn^{2+}$  and is very strongly inhibited by fluoride. The level of acid phosphatase activity in milk is only  $\sim 2\%$  that of alkaline phosphatase; activity reaches a maximum 5–6 days postpartum, then decreases and remains at a low level to the end of lactation (65).

#### A. Isolation and Characterization

Acid phosphatase is found free in skim milk, in membrane material in skim milk and in the fat globule membrane. Kitchen (9) appears to believe that a single enzyme is involved and reported that the membrane-bound enzyme is strongly attached and is not released by nonionic detergents. The enzyme has been purified to homogeneity by various forms of chromatography, including affinity chromatography. Purification factors of 10,000 to 1 million have been reported (1). Adsorption onto Amberlite IRC50 resin is a very effective first step in purification. Andrews (65) stated that all the acid phosphatase activity in skim milk is adsorbed by Amberlite IRC50, but this is not indicated in the original papers. In an unpublished study, N.A. Flynn and P.F. Fox found that only  $\sim 50\%$  of the total acid phosphatase in skim milk was adsorbed by Amberlite IRC50 even after reextracting the skim milk with fresh batches of Amberlite, suggesting that skim milk may contain two acid phosphatases. About 40% of the acid phosphatase in skim milk partitioned into the whey on rennet coagulation and this enzyme did not adsorb on Amberlite IRC50. The enzyme was partly purified from whey.

Flynn and Fox attempted to purify the alkaline phosphatase from MFGM by gel permeation chromatography; however, sonication and nonionic detergents failed to disassociate the enzyme from the membrane. The MFGM enzyme, which does not adsorb on

Amberlite IRC50, was much less heat stable than the acid phosphatase isolated from whey or from skim milk by adsorption on Amberlite IRC50. Attempts were made to confirm that the MFGM, whey, and Amberlite-adsorbed enzymes are different by studying the effects of inhibitors, but the results have been equivocal. Overall, it appears that milk contains more than one acid phosphatase. Using a zymogram technique, Andrews and Alichanidis (66) reported that milk from healthy cows contained one acid phosphatase while that from mastitic cows contained two additional acid phosphatases which were of leucocyte origin. It is unlikely that the heterogeneity observed by Flynn and Fox was due to a high proportion of mastitic milk.

The acid phosphatase isolated from skim milk by adsorption on Amberlite IRC50 has been well characterized. It is a glycoprotein with a molecular weight of  $\sim 42$  kDa and a pI of 7.9. It is inhibited by many heavy metals,  $F^-$ , oxidizing agents, orthophosphates, and polyphosphates and is activated by thiol-reducing agents and ascorbic acid. It is not affected by metal chelators. Its amino acid composition indicates a high level of basic amino acids and no methionine (65).

The enzyme is quite active on phosphoproteins, including caseins. It has been suggested that it is a phosphoprotein phosphatase. Although casein is a substrate for milk acid phosphatase, the major caseins, in the order  $\alpha_s$  ( $\alpha_{s1} + \alpha_{s2}$ )  $> \beta > \kappa$ , also act as competitive inhibitors of the enzyme when assayed on *p*-nitrophenylphosphate, probably owing to binding of the enzyme to the casein phosphate groups (the effectiveness of the caseins as inhibitors is related to their phosphate content).

## B. Assay

Acid phosphatase may be assayed, at pH  $\sim 5$ , on the same substrates as used for alkaline phosphatase. If *p*-nitrophenyl phosphate or phenolphthalein phosphate is used, the pH must be adjusted to  $> 8$  at the end of the enzymatic reaction in order to induce the color of the product, i.e., *p*-nitrophenol or phenolphthalein.

## C. Significance

Although acid phosphatase is present in milk at a much lower level than alkaline phosphatase, its greater heat stability and lower pH optimum may make it technologically significant. Dephosphorylation of casein reduces its ability to bind  $Ca^{2+}$ , to react with  $\kappa$ -casein, to form micelles, and its heat stability. As discussed in Section IV.D, several small partially dephosphorylated

peptides have been isolated from Cheddar and Parmigiano Reggiano and Grana Padano cheeses. However, it is not known whether indigenous or bacterial acid phosphatase is mainly responsible for dephosphorylation in cheese made from pasteurized milk. It is claimed (62–64) that alkaline phosphatase is mainly responsible for dephosphorylation in raw milk cheese. Dephosphorylation may be rate limiting for proteolysis in cheese ripening since most proteinases and peptidases are inactive on phosphoproteins or phosphopeptides. It has been suggested that phosphatase activity should be included in the criteria for starter selection.

The acid phosphatase activity in milk increases fourfold to 10-fold during mastitic infection. Three isoenzymes are then present, only one of which is indigenous milk acid phosphatase, the other two being of leucocyte origin (66). The latter isoenzymes are more thermolabile than the indigenous enzyme and are inactivated by HTST pasteurization.

The suitability of acid phosphatase as an indicator enzyme for superpasteurization of milk has been assessed (67, 68). It is not as useful for this purpose as some alternatives, e.g.,  $\gamma$ -glutamyl transpeptidase or lactoperoxidase.

## VI. LYSOZYME (EC 3.2.1.17)

Lysozyme (muramidase, mucopeptide N-acetyl-muramyl hydrolase) is a widely distributed enzyme which lyses certain bacteria by hydrolyzing the  $\beta(1\text{-}4)$  linkage between muramic acid and N-acetylglucosamine of mucopolysaccharides in the bacterial cell wall. Lysozyme activity is normally assayed by the lysis of cultures of *Micrococcus lysodeikticus* measured by a decrease in turbidity.

Lysozyme was isolated from human milk by Jolles and Jolles (69), who believed that bovine milk was devoid of lysozyme. Milks of many species, including bovine, have since been shown to contain lysozyme, and several have been isolated and characterized (70). Human and equine milks are exceptionally rich sources, containing 130 mg/L (3000 times the level of bovine milk) and  $\sim 800$  mg/L, respectively.

The pH optima of human milk lysozyme (HML), bovine milk lysozyme (BML), and egg-white lysozyme (EWL) are 7.9, 6.35, and 6.2, respectively (70). BML has a molecular weight of 18 kDa compared with 15 kDa for HML and EWL. The amino acid composition of BML is considerably different from that of HML or EWL. The amino acid sequence of BML is

highly homologous with that of  $\alpha$ -lactalbumin, a whey protein that is an enzyme modifier in the biosynthesis of lactose. All lysozymes are relatively stable to heat at acid pH values (3–4) but are relatively labile at pH > 7. More than 75% of the lysozyme activity in bovine milk survives heating at 75°C for 15 min or 80°C for 15 sec and is therefore little affected by HTST pasteurization. Low concentrations of reducing agents increase the activity of BML and HML by ~ 330% (70).

Presumably, the physiological role of lysozyme is to act as a bacteriocidal agent. In the case of milk, it may simply be a “spillover” enzyme, or it may have a definite protective role. If the latter is true, then the exceptionally high level of lysozyme in human and equine milk may be significant. Breastfed babies generally suffer fewer enteric problems than bottle-fed babies. While there are many major compositional and physicochemical differences between bovine and human milks which may be responsible for the observed nutritional characteristics, the disparity in lysozyme content may be significant. Fortification of bovine milk-based infant formulae with EWL, especially for premature babies, has been recommended but feeding studies are equivocal on the benefits of this practice, and recent trials failed to demonstrate any beneficial effect due to inactivation of EWL in the human stomach (71, 72).

One might expect that, owing to this bacteriocidal effect, indigenous milk lysozyme would have a beneficial effect on the shelf life of milk. Such effects do not appear to have been reported. Exogenous lysozyme may be added to milk for many cheese varieties, e.g., Gouda, Edam, Emmental, and Parmigiano Reggiano, as an alternative to KNO<sub>3</sub> to prevent the growth of *Cl. tyrobutyricum* which causes late gas blowing and off-flavors. At present, lysozyme is not widely used in commercial cheesemaking (71, 73). Since indigenous milk lysozyme is in the serum phase, very little is incorporated into cheese.

Addition of lysozyme to milk decreases the heat stability of milk, but the level of indigenous lysozyme is probably too low to contribute to the natural variations in the heat stability of milk.

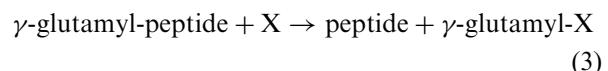

## VII. N-ACETYL- $\beta$ -D-GLUCOSAMINIDASE (EC 3.2.1.30)

N-Acetyl- $\beta$ -D-glucosaminidase (NAGase) hydrolyzes terminal, nonreducing N-acetyl- $\alpha$ -D-glucosamine residues from glycoproteins. It is a lysosomal enzyme which originates principally from mammary gland

epithelial cells and, to a lesser extent, from somatic cells. Consequently, NAGase activity correlates highly with the intensity of mastitis. A field test for mastitis based on NAGase activity has been developed, using chromogenic *p*-nitrophenyl N-acetyl- $\beta$ -D-glucosamine as substrate. Hydrolysis yields *p*-nitrophenol, which is yellow at alkaline pH. NAGase activity is also high in colostrum. NAGase is optimally active at 50°C and pH 4.2 and is inactivated by HTST pasteurization (70–71°C for 15–18 sec). Andrews et al. (68) proposed that NAGase would be a suitable indicator enzyme for assessing heat treatments in the range 65–75°C for 15 sec. NAGase occurs mainly in the whey fraction, from which it has been isolated by various forms of chromatography. Two forms, A and B, differing in molecular weight, 120 and 240 kDa, respectively, and charge were obtained. Each form is dissociated to two dissimilar subunits on treatment with 2-mercaptoethanol and SDS (9, 70).

## VIII. $\gamma$ -GLUTAMYL TRANSPEPTIDASE (TRANSFERASE) (EC 2.3.2.2)

$\gamma$ -Glutamyl transpeptidase (GGTP) catalyzes the transfer of  $\gamma$ -glutamyl residues from  $\gamma$ -glutamyl-containing peptides:

where X is an amino acid.

The enzyme is membrane bound, being found in the membrane material in skim milk (~ 70%) or in the MFGM, from which it can be dissociated by detergents or solvents. The enzyme, which has been purified from the MFGM, has a molecular weight of ~ 80 kDa and consists of two subunits of 57 and 25 kDa, both of which are glycoproteins (74, 75). The enzyme is optimally active at pH 8.5–9 and ~ 45°C and has an isoelectric point of 3.85. It is strongly inhibited by diisopropylfluorophosphate, iodoacetamide, and metals, e.g., Cu<sup>2+</sup> and Fe<sup>3+</sup> (9, 70).

### A. Assay

GGTP is usually assayed using  $\gamma$ -glutamyl-*p*-nitroanilide as substrate; the liberated *p*-NA can be determined by measuring the absorbance at 410 nm or by reaction with naphthylethylenediamine and measuring the absorbance at 540 nm (76).

## B. Significance

GGTP functions in the regulation of cellular glutathione and amino acid transport via the  $\gamma$ -glutamyl cycle; it may be involved in the biosynthesis of milk proteins.

From a dairy technologist's viewpoint, GGTP is of interest mainly because of its heat stability characteristics. As discussed in Section IV.D, alkaline phosphatase is the test enzyme usually used to evaluate the efficiency of HTST pasteurization; however, as discussed, reactivation of this enzyme in UHT-treated products poses problems with the interpretation of the test. Based on a comparative study on the heat stability characteristics of a number of indigenous enzymes in milk, Andrews et al. (68) concluded that GGTP was appropriate for monitoring heat treatments in the range of 70–80°C for 16 sec. This conclusion has been confirmed in pilot-scale studies (77, 78). In whole or skim milk, GGTP is completely inactivated by heating at 78°C for 15 sec (77) or 77°C for 16 sec (76). No reactivation was found under a variety of conditions, and little seasonal variation occurs. As little as 0.1% raw milk could be detected in skim milk or 0.25% in whole milk (76).

Linear models for the thermal inactivation of GGTP and lactoperoxidase (LPO) in a HTST pasteurizer were developed by McKellar et al. (57). The equation for GGTP was:  $\log_{10}\%$  initial activity = 2.004 – 0.281  $\times PE^{0.75}$ . For LPO the equation was:  $\log_{10}\%$  initial activity = 2.122 – 0.096  $\times PE^{0.75}$ .

$$PE = \frac{t}{t_0} = \int e^{\left(\frac{E_a}{R}\right)\left(\frac{1}{T} - \frac{1}{T_0}\right)} dt \quad (4)$$

where  $E_a$  = activation energy;  $R$  = 8.314 J/mol °K;  $T_0$  = 345 K (72°C reference temperature);  $T$  = experimental temperature;  $t_0$  = 15 sec (reference holding time);  $t$  = experimental holding time, sec; and  $PE$  = pasteurization equivalent (71.6°C for 15 sec).

These equations indicate that 1 log decrease in enzyme activity can be achieved with PE values of 5.46 and 2.65 for GGTP and LPO, respectively, indicating that LPO is considerably more heat stable than GGTP. The assay for LPO (using ABTS; see Sec. XIII.A) is subject to greater variation and interference from milk proteins than the GGTP assay. The relationship between  $\log_{10}\%$  initial activity and PE was more linear than the relationship for alkaline phosphatase, possibly due to more than one form of alkaline phosphatase (56). GGTP was about nine times more stable in ice cream mix than in whole milk, which had a much

smaller stabilizing effect on *Listeria innocua* (79). Thus, it appears that GGTP is a suitable enzyme for estimating the intensity of heat treatment in the range 72–77°C for 15 sec to which milk was subjected.

GGTP is absorbed from the gastrointestinal tract, resulting in high levels of GGTP activity in the blood serum of newborn animals fed colostrum or early breast milk. Since GGTP is inactivated by the heat treatment to which infant formulae are subjected, the level of GGTP activity in infants can be used to distinguish breastfed from formula-fed infants (70).

$\gamma$ -Glutamyl peptides have been isolated from Comté cheese (80). Since casein contains no  $\gamma$ -glutamyl bonds, the presence of these peptides in cheese suggests GGTP activity in cheese, but there appear to be no data on this.

## IX. XANTHINE OXIDASE (EC 1.2.3.2)

It has been recognized for ~90 years that milk contains an enzyme capable of oxidizing aldehydes and purines with the concomitant reduction of  $O_2$  to  $H_2O_2$ . The enzyme is now generally referred to as xanthine oxidase (XO). Milk is a very good source of XO, at least part of which is transported to the mammary gland via the bloodstream. A similar enzyme is found in various animal tissues and several bacterial species (8, 9, 70).

### A. Assay

Xanthine oxidase activity can be assayed manometrically (uptake of  $O_2$ ), potentiometrically using a platinum electrode, or spectrophotometrically. This last involves the conversion of the xanthine to uric acid which is quantified by measuring absorbance at 290 nm (75).

### B. Isolation

The enzyme is concentrated in the MFGM, in which it is one of the principal proteins. Therefore, all isolation methods use cream as starting material, using a dissociating agent to liberate XO from membrane lipoproteins and some form of chromatography for purification.

Milk XO has a molecular weight of ~300 kDa and consists of two identical subunits. The pH optimum is ~8.5 and the enzyme requires flavin adenine dinucleotide (FAD), Fe and Mo cations, and an acid-labile sulfur compound as cofactors. Cows deficient in Mo

cations have low XO activity. The amino acid composition of XO has been determined by a number of workers; at least five polymorphic forms have been reported (70).

XO can be converted to an NAD-dependent dehydrogenase by treatment with thiol-reducing agents. The enzyme reverts to an oxidase on aerobic storage, treatment with sulphydryl oxidase, or with sulphydryl oxidizing agents.

### C. Activity in Milk

XO activity in milk varies substantially—2.5-fold (67). Various processing treatments which damage or alter the MFGM affect the XO activity of milk. Activity is increased by ~100% on storage at 4°C for 24 h, by 50–100% on heating at 70°C for 5 min, and by 60–90% on homogenization. These treatments cause the release of XO from the MFGM into the aqueous phase, rendering the enzyme more active. The heat stability of XO is very dependent on whether it is a component of the MFGM or is dissolved in the aqueous phase. Aging and homogenization increase heat susceptibility and explain the inconsistency of early work in which the history of the sample was unknown or unrecorded. XO is most heat stable in cream and least in skim milk. Homogenization of concentrated milk prepared from heated milk (90.5°C for 15 sec) partially reactivates XO, which persists on drying the concentrate, but no reactivation occurs following more severe heating (93°C for 15 sec). Apparently, homogenization releases potentially active, undenatured XO from the MFGM. All the major milk proteins can act as either activators or inhibitors of XO, depending on their concentration, and may have some significance in the activation, inactivation, and reactivation of the enzyme. Studies on the heat stability of XO have been reviewed by Griffiths (67), who investigated its stability in a pilot scale HTST pasteurizer. The enzyme was not completely inactivated after 120 sec at 80°C, and a Z-value of 6.8 was calculated.

### D. Significance of Xanthine Oxidase

#### 1. As an Index of Heat Treatment

The inactivation of XO parallels the conditions necessary for the production of low-heat skim milk powder (82). Andrews et al. (68) considered XO as a suitable indicator of milk heated in the temperature range 80–90°C but Griffiths (67) considered the natural variability in the level of XO activity in milk to be too high for use as a reliable index of heat treatment.

### 2. Lipid Oxidation

XO, which can excite stable triple oxygen ( ${}^3\text{O}_2$ ) to single oxygen ( ${}^1\text{O}_2$ ), is a pro-oxidant. Some individual-cow milks, which undergo spontaneous oxidative rancidity (i.e., without contamination with metals or exposure to light) contain ~10 times the normal level of XO, and spontaneous oxidation can be induced in normal milk by the addition of XO to about four times normal levels. Heat-denatured or flavin-free enzyme is ineffective in oxidation; the susceptibility of unsaturated fatty acids to oxidation increases with the degree of unsaturation (8).

### 3. Atherosclerosis

It has been suggested that XO from homogenized milk enters the vascular system and may be involved in atherosclerosis via oxidation of plasmalogens in cell membranes; this aspect of XO attracted considerable attention in the early 1970s (83). However, the experimental evidence in support of this view is very weak and the hypothesis has been disclaimed (8, 70, 84, 85).

### 4. Reduction of Nitrate in Cheese

Sodium nitrate is added to milk for Dutch, Swiss, and other cheese varieties to prevent the growth of *Clostridium tyrobutyricum* which causes flavor defects and late gas blowing in these cheeses. Xanthine oxidase reduces nitrate to nitrite which is necessary for the bacteriocidal effect of nitrate.

Various oxidation-reduction reactions occur in milk which affect its flavor. Perhaps XO is significant in these reactions, either directly or indirectly.

### 5. Production of $\text{H}_2\text{O}_2$

The  $\text{H}_2\text{O}_2$  produced by the action of xanthine oxidase on oxidation of xanthine, hypoxanthine, or other substrates can serve as a substrate for lactoperoxidase in its action as a bacteriocidal agent (see Sec. XIII.B).

### X. SULPHYDRYL OXIDASE (EC 1.8.3.-)

Milk contains an enzyme, sulphydryl oxidase (SO), capable of oxidizing sulphydryl groups of cysteine, glutathione, and proteins to the corresponding disulfide (for reviews, see 8, 70). The enzyme is an aerobic oxidase which catalyzes the following reaction:

It undergoes marked self-association and can be purified readily by chromatography on porous glass. The enzyme has a molecular weight of ~ 89 kDa, a pH optimum of 6.8–7.0, and a temperature optimum of 35°C. Its amino acid composition, its requirement for iron but not for molybdenum and FAD, and the catalytic properties of the enzyme indicate that sulphydryl oxidase is a distinct enzyme from xanthine oxidase and thiol oxidase (EC 1.8.3.2).

SO is capable of oxidizing reduced ribonuclease and restoring enzymatic activity, suggesting that its physiological role may be the nonrandom formation of protein disulfide bonds, e.g., during protein biosynthesis.

SO immobilized on glass beads has the potential to ameliorate the cooked flavor arising from sulphydryl groups exposed by protein denaturation on UHT processing of milk, but the commercial viability of this system is not known. In any case, sulphydryl groups are effective antioxidants and may serve a beneficial role in UHT milk.

The production of sulfur compounds is believed to be very important in flavor development in Cheddar and other varieties of cheese. Residual sulphydryl oxidase activity may play a role in reoxidizing sulphydryl groups exposed upon heating cheesemilk; the sulphydryl groups thus protected may be reformed during the ripening process.

## XI. SUPEROXIDE DISMUTASE (EC 1.15.1.1)

Superoxide dismutase (SOD) scavenges superoxide radicals,  $O_2^-$ , according to the reaction:

The  $H_2O_2$  formed may be reduced to  $H_2O + O_2$  by catalase, peroxidase or suitable reducing agents. SOD has been identified in many animals and bacterial cells. Its biological function is to protect tissue against oxygen free radicals in anaerobic systems (8, 9, 70).

SOD, isolated from bovine erythrocytes, is a blue-green protein due to the presence of copper, removal of which by treatment with EDTA results in loss of activity which is restored by adding  $Cu^{2+}$ ; it also contains  $Zn^{2+}$ , which does not appear to be at the active site. The enzyme, which is very stable in 9 M urea at neutral pH, consists of two identical subunits of molecular weight 16 kDa held together by one or more disulfide bonds.

Milk contains trace amounts of SOD which is present exclusively in the skim milk fraction. This enzyme

has been isolated and characterized. It appears to be identical to the bovine erythrocyte enzyme. Assay methods for SOD are described by Stauffer (86).

SOD inhibits lipid oxidation in model systems. The level of SOD in milk parallels that of XO (but at a lower level), suggesting that SOD may be excreted in milk in an attempt to offset the pro-oxidant effect of XO. Attempts have been made to correlate the stability of milk to oxidative rancidity with the SOD activity in the milk, but these results have been equivocal. Milk contains several pro- and antioxidants, including exogenous factors such as light, the precise balance of which, rather than any single factor, determines overall oxidative stability. The possibility of using exogenous SOD to retard or inhibit lipid oxidation in dairy products has been considered. A marked improvement in the oxidative stability of milk with a high level of linoleic acid was achieved by adding low levels of SOD.

SOD is more heat stable in milk than in purified preparations. In milk it is stable at 71°C for 30 min (i.e., it is not affected by HTST pasteurization) but loses activity rapidly at even slightly higher temperatures. Slight variations in pasteurization temperature are therefore critical to the survival of SOD in heated milk products and may contribute to variations in the stability of milk to oxidative rancidity.

## XII. CATALASE (EC 1.11.1.6)

An indigenous catalase in milk was first recognized in 1907. The catalase activity of whole milk is associated either with membranes in the skim milk phase or the MFGM. The pellet obtained from buttermilk on centrifugation at 10,000 g is a particularly rich source, from which catalase has been highly purified and crystallized (8, 9, 70).

Milk catalase is a heme protein with a molecular weight of 200 kDa and an isoelectric pH of 5.5. It is stable between pH 5 and 10 but rapidly loses activity outside the range. Heating at 70°C for 1 h at pH 7.0 causes complete inactivation. Like other catalases, it is strongly inhibited by  $Hg^{2+}$ ,  $Fe^{2+}$ ,  $Cu^{2+}$ ,  $Sn^{2+}$ ,  $CN^-$ , and  $NO_3^-$ . Analytical methods for catalase are described by Stauffer (86).

Catalase activity in milk varies with feed, stage of lactation, and especially with mastitic infection, for which it may be used as an index. However, it is not usually used for this purpose, since somatic cell count and N-acetylglucosaminidase activity are superior indices of mastitis. Catalase may act as a lipid pro-

oxidant via its heme iron (i.e., nonenzymatically), but it is probably not very significant.

There is general agreement that cheese made from raw milk ripens more quickly and develops a more intense (although not always a more desirable) flavor than cheese made from pasteurized milk (87). However, for public health reasons and in the interest of producing a consistent product, pasteurized milk is now generally used for cheese making. Many cheeses are still made from raw milk, especially in southern Europe. Many countries require that if raw milk is used for cheese making, the cheese must be ripened for at least 60 days during which it was presumed that pathogens die off, a presumption that is now considered to be invalid. Subpasteurized or thermized milk (e.g., heated at 63–65°C for 16 sec) has been considered as a compromise between raw and pasteurized milk for cheese making. The acceptance of such a practice would require an appropriate validation test, but no suitable test is available at present for identifying thermized milk. The possibility of using the inactivation of catalase as an index of thermized milk was investigated by Hirvi and Griffiths (88). Although catalase was a useful index of thermization of milk (it was almost completely inactivated by heating at 65°C for 16 sec), it was unsuitable as an index of cheese made from thermized milk owing to the production of catalase in the cheese during ripening, especially by yeasts. The thermal inactivation of catalase was also studied by Hirvi et al. (89).

### XIII. LACTOPEROXIDASE (EC 1.11.1.7)

The occurrence of a peroxidase, lactoperoxidase (LPO), in milk was recognized as early as 1881. It is one of the most heat-stable enzymes in milk. Its inactivation was used as an index of flash pasteurization (now very rarely used) and is now used as an index of super-HTST pasteurization, e.g., temperatures > 75°C for 15 sec. LPO was first isolated in 1943; several isolation procedures have since been published (8, 90).

LPO is a heme protein containing ~ 0.07% Fe, with an absorbance peak (Soret band) at 412 nm ( $A_{412}/A_{280} \sim 0.9$ ). The pH optimum is ~ 8.0, its molecular weight is 77.5 kDa, and it consists of two identical subunits. Two principal forms (A and B) occur, each of which exhibits microheterogeneity with regard to amide groups (glutamine and/or asparagine) and carbohydrate content, giving a total of 10 variants.

#### A. Assay of Lactoperoxidase

The principle generally used in assays for peroxidases is the use of a chromogenic or fluorogenic reducing agent, AH<sub>2</sub>, a number of which have been used (86). A highly recommended substrate for lactoperoxidase is 2, 2'-azinobis(3-ethylbenzylthiazoline-6-sulfonic acid) [ABTS] (91).

#### B. Significance

1. As for many other indigenous enzymes, the level of LPO in milk increases on mastitic infection and is therefore a possible index of mastitis; however, it is not well correlated with somatic cell count, and superior methods, including enzyme-based methods (Sec. VII) are available to monitor mastitis.

2. LPO causes nonenzymic oxidation of unsaturated lipids, probably due to its heme group. The heat-denatured enzyme is more active than the native enzyme. Compared with other pro-oxidants, LPO is probably not significant in milk and dairy products.

3. LPO has been used in the Storch test for flash pasteurized milk (67), but this process is not used in modern milk processing. However, the pasteurization of milk at a temperature higher than the HTST minimum, i.e., > 72°C for 15 sec, has recently become quite common. The assay based on the inactivation of alkaline phosphatase is not applicable under such circumstances. Griffiths (67), who evaluated the suitability of several indigenous enzymes as indices of the super-pasteurization of milk, concluded that assay of LPO activity was the most promising method for detecting heat treatments in the order of 76°C for 15 sec. Andrews et al. (68) reported the results of a generally similar study, in which LPO was not included. They conclude that N-acetylglucosaminidase,  $\gamma$ -glutamyl transpeptidase ( $\gamma$ -GGTP), and  $\alpha$ -mannosidase or xanthine oxidase may be the most suitable indicators of heat treatment of 65–75, 70–80, and 80–90°C, respectively. The relative suitability of GGTP and LPO were compared by McKellar et al. (57). The kinetics of the thermal denaturation of LPO was reported by Martin-Hernandez et al. (92).

4. Milk contains bacteriostatic or bacteriocidal substances, referred to as lactenins. One of these is LPO, which requires H<sub>2</sub>O<sub>2</sub> and thiocyanate (SCN<sup>−</sup>) to cause inhibition. The nature, mode of action, and specificity of the LPO-SCN<sup>−</sup>-H<sub>2</sub>O<sub>2</sub> system have been widely studied. LPO and thiocyanate, which is produced in the rumen by enzymatic hydrolysis of thio-

glycosides from Brassicace plants, occur naturally in milk although at variable and probably suboptimal levels. Milk does not contain indigenous H<sub>2</sub>O<sub>2</sub>, which can be generated metabolically by catalase-negative bacteria, or produced in situ through the action of exogenous glucose oxidase on glucose which may be added to milk or produced in situ from lactose by exogenous  $\beta$ -galactosidase or the action of indigenous XO on added xanthine or hypoxanthine, or from added sodium percarbonate or it may be added directly.

Immobilized glucose oxidase has been used to generate  $H_2O_2$  in situ in thiocyanate- and glucose-enriched milk or whey. A self-contained LPO- $H_2O_2$ -SCN<sup>-</sup> system using coupled  $\beta$ -galactosidase and glucose oxidase, immobilized on porous glass beads, to generate  $H_2O_2$  in situ from lactose in milk containing 0.25 mM thiocyanate has been developed.

The bacteriocidal effect of the LPO-H<sub>2</sub>O<sub>2</sub>-SCN<sup>-</sup> system has several applications which have been reviewed extensively (90, 91, 93, 94):

1. Sanitization of immobilized enzyme columns in which LPO is coimmobilized with the enzyme of interest. The requisite  $H_2O_2$  could be generated by immobilized enzymes—e.g., xanthine oxidase, glucose oxidase, or  $\beta$ -galactosidase/glucose oxidase.

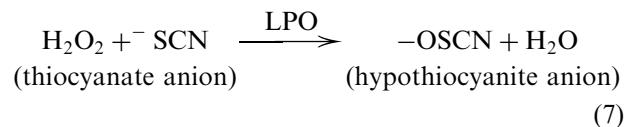

2. As a bacteriocidal agent in toothpaste.
3. In the therapy of mastitis during the non-lactating period.
4. For the preservation of milk in regions lacking refrigeration or pasteurization facilities.

5. To reduce the incidence of enteritis in calves or piglets fed milk replacers. The indigenous LPO is inactivated during the manufacture of these products and LPO isolated from milk or whey is added.

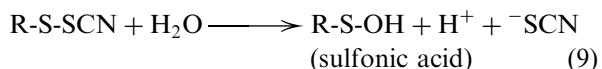

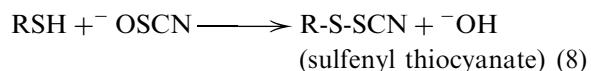

LPO (and lactoferrin) is cationic at the natural pH of milk at which all the principal proteins are anionic. LPO and lactoferrin can therefore be readily isolated from milk or whey by using cation exchange resins. The ion exchangers may be used as columns (95), batchwise (96), or as membranes (97). At least some of these methods are applicable on an industrial scale, making it possible to isolate LPO for use as a food ingredient.

### C. Biochemistry of Lactoperoxidase System

LPO catalyzes the peroxidation of  $\text{SCN}^-$  to products which are nontoxic to mammalian cells but which kill or inhibit the growth of many species of microorganisms. The net reaction is:

Microbial membranes have low permeability for  $\text{^-\text{OSCN}}$  but are quite permeable to HOSCN ( $\text{pK}_a = 5.3$ ). HOSCN or  $\text{^-\text{OSCN}}$  oxidizes sulphhydryl groups:

Any reaction involving a sulphydryl group, e.g., thiol enzymes, will be inhibited by this oxidation. The effect may be reversed by thiol compounds such as glutathione or cysteine.

#### XIV. OTHER ENZYMES

In addition to the enzymes described above, several other indigenous enzymes have been isolated and partially characterized (Table 2) (70). Although a fairly high level of some of these enzymes occurs in milk, they have no apparent function or significance in milk which contains no substrate for many of them. It is possible that some of these enzymes will assume importance in the future as indices of animal health or of product quality. These enzymes will not be discussed further.

Nearly 40 other enzymatic activities have been detected in milk (**Table 3**) but have not been isolated, and only limited information on their molecular and biochemical properties in milk is available (70). Some of these enzymes have been evaluated as indices of the heat treatment of milk (67, 68). Perhaps further study will identify some important or useful attributes of some of these enzymes.

## XV. SUMMARY

Although milk contains ~ 60 indigenous enzymes, only two, lipoprotein lipase (LPL) and plasmin, are really technologically significant. LPL has the potential to cause serious problems but these can be avoided through good milking practices on the farm. The enzyme is relatively heat labile and hence does not cause problems in heat-treated products. Although milk contains considerable potential plasmin, relatively

little is expressed owing to the presence of inhibitors. The significance of plasmin is mainly negative but its action is probably positive in cheese during ripening. Acid phosphatase may be significant in the dephosphorylation of phosphopeptides in cheese. Several oxidoreductases—xanthine oxidase, lactoperoxidase, catalase, superoxide dimutase, and sulfhydryl oxidase—are, at least potentially, significant in milk stability. Lysozyme and lactoperoxidase may have antimicrobial effects in the intestine of the consumer.

Perhaps the most significant and most useful aspect of the indigenous enzymes in milk is as indicators of mastitis, especially N-acetylglucosaminidase, and of thermal treatments. The thermal stabilities of the indigenous enzymes cover quite a wide range of temperatures which make it possible to determine at what temperature milk has been heat-treated in the range 65–90°C for 15 sec. The principal advantage of enzymes compared with other heat-induced changes in analytical applications is the relative ease with which their activity can be quantified.

Most dairy products should undergo no change during storage, and hence the indigenous enzymes capable of causing undesirable changes are inactivated by heating. Cheese is an exception; a very complex series of microbiological, biochemical, and perhaps chemical reactions occur which lead to desirable characteristic taste, aroma, and texture of the finished cheese (98, 99). At least four indigenous enzymes contribute to cheese ripening—plasmin, lipoprotein lipase, acid phosphatase, and xanthine oxidase. Perhaps others contribute, but information is lacking.

Most of the indigenous enzymes in milk remain to be isolated and characterized. As for the principal enzymes, these minor enzymes probably originate from the mammary tissue. Most of these enzymes are unlikely to be technologically significant as milk contains no substrates. However, they may be significant as indicators of animal health or thermal history; if so, they will be isolated and characterized.

## Exogenous Enzymes in Dairy Technology

**Patrick F. Fox**

*University College, Cork, Ireland*

### I. INTRODUCTION

Milk from domesticated animals and products formed therefrom have been components of the human diet for ~10,000 years. Some dairy products are consumed in most or all regions of the world and they are major dietary items in many regions, e.g., Europe, North America, and South America. Total milk production is  $\sim 530 \times 10^6$  metric tons per year, of which ~85% is bovine milk; sheep, goats, water buffalo, camels, and mares are important dairy animals in some regions. Milk is a very perishable commodity and hence there has been a strong incentive to convert it to more stable products, which is facilitated by certain properties of milk. Classically, milk has been preserved by fermentation, usually with salt addition (cheese, fermented milks, butter). Newer preservation methods include drying, pasteurization/sterilization, and freezing. Some characteristics of milk also render it very amenable to modification by enzymes; that milk is a liquid facilitates enzyme addition. Cheese production is probably the oldest, and is still the largest, application of exogenous enzymes in food processing.

Since the principal components of milk are proteins (~3.5%), lipids (~3.6%), and lactose (~4.8%; a disaccharide containing galactose and glucose), the principal enzymes used in dairy technology are proteinases and peptidases, lipases, and  $\beta$ -galactosidase (lactase). However, several oxidoreductases have significant applications.

The principal applications of enzymes in dairy technology will be considered in this review. Earlier reviews include Fox and Grufferty (1), Fox (2), Fox and Stepaniak (3), Brown (4), and Desmazeaud and Spinnler (5).

### II. PROTEINASES

Bovine milk contains ~3.5% proteins which can be resolved into two groups based on solubility at pH 4.6 and 20°C: the caseins, which are insoluble under these conditions and which represent ~80% of the total protein; and the whey (serum) proteins, which are soluble. The casein fraction of bovine milk and that of the other main dairying species comprises four proteins,  $\alpha_{s1}$ -,  $\alpha_{s2}$ -,  $\beta$ -, and  $\kappa$ -caseins, which, although they have certain features in common, e.g., insolubility at pH 4.6, are distinctly different proteins. The whey protein fraction also comprises four main proteins— $\beta$ -lactoglobulin,  $\alpha$ -lactalbumin, blood serum albumin, and immunoglobulins—and several minor proteins, including ~60 indigenous enzymes. Readers are referred to Fox (6) for a detailed description of the milk protein system.

As discussed in Section II.A.1, the colloidal stability of the caseins is extensively changed by limited proteolysis, leading to gelation of the milk system, which is the first step in the production of many cheese varieties. The milk proteins can be easily separated from the other milk constituents and the caseins and whey

proteins readily separated from each other on an industrial scale. Both the caseins and whey proteins have good and diverse functional properties; consequently, milk proteins are the preferred functional food proteins for a wide range of applications (7). Some functional properties can be improved and/or modified by limited proteolysis.

Proteolytic enzymes are the most widely used enzymes in dairy technology and will be discussed below under three headings: cheese manufacture, modification of functional properties, and production of protein hydrolyzates for nutritional and other applications.

### A. Cheese Manufacture

The manufacture of all cheese varieties essentially involves concentrating the protein and fat of milk six-fold to 12-fold, depending on the variety. Concentration is achieved by (a) coagulating the principal milk proteins, i.e., the caseins (if present, the milk fat is occluded in the coagulum); (b) cutting or breaking the coagulum and inducing it to syneresis under the influence of heat and acid; (c) separation of curds and whey; and (d) acidification, pressing, and salting of de-wheyed curd.

Coagulation of the casein is induced by one of three methods:

1. Limited proteolysis by a crude proteinase (rennet), which is exploited in the manufacture of all ripened and some fresh cheeses (~ 75% of total production).

2. Isoelectric precipitation at ~ pH 4.6, used for fresh cheeses, usually by *in situ* production of lactic acid by a culture (starter) of lactic acid bacteria and less frequently by direct acidification with preformed acid, usually HCl, or acidogen, usually gluconic acid- $\delta$ -lactone.

3. Acid plus heat, i.e., acidification to ~ pH 5.2 with acid whey, acid milk, citrus juice, vinegar, or acetic acid at 80–90°C; this method is used to produce a small number of relatively minor varieties, e.g., Ricotta.

Concentration of the total colloidal phase of milk (i.e., fat and total protein) to the level present in cheese, i.e., to a “pre-cheese,” by ultrafiltration is now used commercially for the manufacture of several cheese varieties. Additions of rennet and starter to the concentrate are still necessary for texture and flavor development.

### 1. Enzymatic Coagulation of Milk

The principal gastric enzyme of neonatal ruminants is chymosin rather than pepsin. Chymosin has low general proteolytic activity but high milk-clotting activity. Presumably, it evolved to coagulate milk in the stomach and thus delay its discharge into the intestine and increase the efficiency of digestion. Shortly after the domestication of dairy animals (~ 8000 B.C.), humans learned to exploit the ability of chymosin and some other proteinases, collectively referred to as rennets, to coagulate milk for the production of cheese, which was probably the first application of enzymes in food processing.

The rennet coagulation of milk is a two-stage process. The first (primary) phase involves the enzymatic production of “para-casein” and TCA-soluble peptides (glycomacropeptides), while the secondary phase involves the Ca-induced gelation of para-casein at a temperature in the range of 30–35°C. Proteolysis is essentially complete before the onset of coagulation.

The enzymatic coagulation of milk exploits certain properties of the caseins. As discussed above, bovine casein consists of four proteins— $\alpha_{s1}$ -,  $\alpha_{s2}$ -,  $\beta$ -, and  $\kappa$ -caseins—in the approximate ratio of 40:10:35:12. These contain 8–9, 10–13, 4–5, and 1–2 mol of P per mol, respectively. Owing to their high phosphate content,  $\alpha_{s1}$ -,  $\alpha_{s2}$ -, and  $\beta$ -caseins bind  $\text{Ca}^{2+}$  strongly and precipitate at  $\text{Ca}^{2+} > 6 \text{ mM}$ . However,  $\kappa$ -casein binds  $\text{Ca}^{2+}$  weakly and is soluble at high  $\text{Ca}^{2+}$ . It also reacts hydrophobically with  $\alpha_{s1}$ -,  $\alpha_{s2}$ -, and  $\beta$ -caseins and can stabilize up to 10 times its weight of these  $\text{Ca}^{2+}$ -sensitive caseins against precipitation by forming colloidal aggregates, called micelles.

In milk, > 95% of the casein exists as micelles, which consist, on a dry weight basis, of ~ 94% protein and 6% of other species, mainly  $\text{Ca}^{2+}$  and  $\text{PO}_4^{3-}$  with some  $\text{Mg}^{2+}$  and citrate, collectively called colloidal calcium phosphate (CCP). The micelles are spherical, 50–600 nm (mean, ~ 120 nm) in diameter, with particle weights of ~  $10^8$  daltons; i.e., a typical micelle contains ~ 5000 monomers ( $M_r = 20\text{--}24 \text{ kDa}$ ). The micelles typically bind ~ 2 g  $\text{H}_2\text{O}/\text{g}$  protein.

Within the micelles, the caseins are held together by CCP bridges, hydrophobic interactions, and hydrogen bonds. There is a widely held view that the casein monomers are organized as submicelles (spherical particles,  $M_r \sim 5 \times 10^6$  daltons). The micelles dissociate when CCP is removed (e.g. by  $\text{Ca}^{2+}$  chelators or acidification/dialysis), or when the pH is increased above ~ 9, or on addition of detergents (e.g., sodium dodecyl

sulfate) or urea. In most models of the casein micelle, it is envisaged that the  $\text{Ca}^{2+}$ -sensitive  $\alpha_{s1}$ -  $\alpha_{s2}$ , and  $\beta$ -caseins interact hydrophobically to form the core of the micelles, with  $\kappa$ -casein located predominantly on the surface. The N-terminal two-thirds of  $\kappa$ -casein is hydrophobic and reacts hydrophobically with the core proteins, leaving the hydrophilic C-terminal region projecting into the surrounding environment. It has been proposed that submicelles contain variable amounts of surface  $\kappa$ -casein and aggregate such that  $\kappa$ -casein-rich submicelles predominate at the surface of the micelles with the  $\kappa$ -casein-deficient submicelles buried within. The micelles are stabilized by a zeta potential of  $\sim -20\text{ mV}$  and by steric factors caused by the protruding C-terminal segments of  $\kappa$ -casein which form a "hairy" layer, 7–10 nm thick, on the surface of the micelles, preventing close approach.

a. *Primary Phase of Rennet Action.* During the primary phase of rennet action,  $\kappa$ -casein is the only protein hydrolyzed to a significant extent. It is cleaved by chymosin, and for most of the other proteinases used as rennets, at the bond Phe<sub>105</sub>-Met<sub>106</sub>, which is many times more susceptible to hydrolysis by acid proteinases (which include all commercial rennets) than any other bond in the milk protein system.  $\kappa$ -Casein f1–105, which is referred to as para- $\kappa$ -casein, remains attached to the rennet-altered micelle but the hydrophilic peptide,  $\kappa$ -CN f106–169, referred to as the caseino(glyco)macropeptide, diffuses into the whey and consequently the micelle-stabilizing properties of  $\kappa$ -casein are lost.

A number of attempts have been made to explain the unique sensitivity of the Phe-Met bond. Di-, tri-, or tetrapeptides containing a Phe-Met bond are not hydrolyzed. However, the Phe-Met bond is hydrolyzed in the pentapeptide, H.Leu-Ser-Phe-Met-Ala-OMe, i.e., a derivative of  $\kappa$ -CN f103–107. The length of the peptide and the sequence around the cleavage site are important determinants of enzyme-substrate interaction. Ser<sub>104</sub> is particularly important and its replacement by Gly or Ala in the above pentapeptide renders the Phe-Met bond very resistant to hydrolysis by chymosin but not by pepsins. Even substituting D-Ser for L-Ser markedly reduces the sensitivity of the adjacent Phe-Met bond. Extension of the above pentapeptide from the N- and/or C-terminal to reproduce the sequence of  $\kappa$ -casein increases the efficiency of hydrolysis of the Phe-Met bond by chymosin; the tetradecapeptide,  $\kappa$ -CN f98–111, is hydrolyzed as efficiently as intact  $\kappa$ -casein and  $\sim 66,000$  faster than the

parent pentapeptide,  $\kappa$ -CN f103–107, with a  $k_{\text{cat}}/K_M$  of  $\sim 2\text{ M}^{-1}\text{ sec}^{-1}$ .

The two residues, Phe-Met, are not intrinsically essential for chymosin action. Replacement of Phe by PheNO<sub>2</sub> or cyclohexylalanine decreases  $k_{\text{cat}}/K_M$  about threefold and  $\sim 50$ -fold, respectively. Oxidation of Met<sub>106</sub> decreases  $k_{\text{cat}}/K_M \sim 10$ -fold but substitution of Ile for Met increases this ratio about threefold. In fact, the chymosin-susceptible bond in porcine or human  $\kappa$ -caseins is Phe-Ile, which is readily hydrolyzed by calf chymosin. Thus, the sequence around the Phe-Met bond, rather than the bond itself, contains the important determinants of hydrolysis. The sequence Leu<sub>103</sub>-Ser-Phe-Met-Ala-Ile<sub>108</sub> of  $\kappa$ -casein, which may exist as a  $\beta$ -structure, fits into the active site cleft of acid proteinases. The hydrophobic residues, Leu<sub>103</sub>, Phe<sub>105</sub>, Met<sub>106</sub>, and Ile<sub>108</sub>, probably interact with hydrophobic residues along the active site cleft while the hydroxyl group of Ser<sub>104</sub> forms a hydrogen bridge with a counterpart on the enzyme. Residues 98–102 and 109–111 probably form  $\beta$ -turns around the edges of the active site cleft in the enzyme · substrate complex; this conformation is stabilized by Pro residues at positions 99, 101, 109, and 110. One or more of the three His residues, 98, 100, 102, and Lys<sub>111</sub>, are probably involved in electrostatic bonding.

Pepsins and most other acid proteinases used as rennets hydrolyze  $\kappa$ -casein at Phe<sub>105</sub>-Met<sub>106</sub> but the acid proteinase of *Cryphonectria parasitica* hydrolyzes Ser<sub>104</sub>-Phe<sub>105</sub>. Although the specificity of cathepsin D on  $\alpha_{s1}$ - and  $\beta$ -caseins is generally similar to that of chymosin, it has very poor milk-clotting activity. The aggregation characteristics of micelles vary with the rennet used, suggesting differences in the extent and/or specificity of the hydrolysis of  $\kappa$ -casein or perhaps of the other caseins. Furthermore, the commonly used rennets have markedly different specific activities on synthetic  $\kappa$ -casein-related peptides.

Reviews on the enzymatic coagulation of milk include Dalgleish (8, 9), Fox (10–12), Fox and Mulvihill (13), and Fox and McSweeney (14).

b. *Rennets.* The rennets used to coagulate milk are crude preparations of selected proteinases. Many proteinases can coagulate milk but most are too proteolytic relative to their milk clotting activity and hydrolyze the coagulum too quickly, causing reduced cheese yield and/or defective, e.g., bitter cheese. Traditionally, rennets were prepared from calves', kids', or lambs' stomachs; the principal proteinase in such rennets is chymosin. The molecular and enzy-

matic properties of chymosins have been studied extensively (15–17).

Owing to increasing world production of cheese (~3% per year over the past 30 years), concomitant with a reduced supply of calf vells, the supply of veal rennet has been inadequate for many years, which has led to a search for rennet substitutes. Although many proteinases can coagulate milk, only six have been found to be more or less acceptable as rennets: bovine, porcine, and chicken pepsins and the acid proteinases from *Rhizomucor miehei*, *R. pusillus*, and *C. parasitica*. Chicken pepsin is the least suitable of these and is used only in special circumstances. Bovine pepsin gives generally satisfactory results with respect to cheese yield and quality; many commercial “calf rennets” contain a substantial proportion of bovine pepsin. Although the proteolytic specificity of the three commonly used fungal rennets on  $\alpha_{s1}$ - and  $\beta$ -caseins is considerably different from that of calf chymosin, they generally yield acceptable cheese and were widely used in the United States before the introduction of microbial recombinant chymosin. Acid proteinases from flowers of the genus *Cynara* are used to coagulate sheep’s milk for some artisanal cheeses in Portugal and Spain, especially Serra d’Estrala cheese; these proteinases are not generally suitable as rennets. The extensive literature on rennet substitutes has been reviewed (18–21).

The gene for calf chymosin has been cloned in selected bacteria, yeasts, and molds. Chymosin from genetically engineered *Kluyveromyces marxianus* var. *lactis* (Gist-brocades), *Escherichia coli* (Pfizer), and *Aspergillus nidulans* (Hansens) is commercially available and used extensively, with excellent results; however, these products are not yet permitted in all countries. Reviews on microbial recombinant chymosin include Teuber (22) and IDF (23).

Microbial recombinant chymosin preparations contain no pepsin whereas 5–50% of the milk-clotting activity of calf rennets may be due to pepsin; hence, some minor differences in the pattern of proteolysis in cheese made with microbial recombinant chymosin or calf rennet are observed, most notably the formation of the peptide  $\alpha_{s1}$ -CN f110–199 in cheese made using calf rennet (owing to the action of pepsin). For those wishing to simulate the action of calf rennet more closely, blends of microbial recombinant chymosin and bovine pepsin are commercially available.

Calf chymosin contains three isoforms—A, B, and C. A and B are gene products that differ from each other by one amino acid; A has Asp at position 243 while B has Gly at this position. Chymosin C appears to be a degradation product of chymosin A

which lacks three residues, Asp<sub>244</sub>-Phe<sub>246</sub>. Commercially available microbial recombinant chymosins contain only chymosin A or B; it is not known if the different forms of chymosin differ in specificity, but it is claimed by rennet manufacturers that the cheesemaking properties of chymosin A and B are not equivalent.

The primary, and probably higher, structures of commercially available microbial recombinant chymosins are identical to that of calf chymosin. However, several modified chymosins have been produced from genetically engineered microorganisms. At present, the objective of these investigations is to study the mechanism of chymosin action at the molecular level, but it is probable that chymosin with improved cheese-making properties will emerge from such studies, e.g., enzymes with increased activity on certain bonds shown to produce cheese with improved quality or reduced activity on other bonds, cleavage of which results in flavor or textural defects. It should be remembered that chymosin evolved to coagulate milk in the neonatal stomach (to improve the efficiency of digestion) and not to produce cheese. It is fortuitous that chymosin is the best proteinase for cheese production, not just for milk coagulation, but it is highly probable that it can be improved. For reference on genetically engineered chymosins, see (14, 17).

Most (70–90%) of the rennet added to cheese milk is lost in the whey. Therefore, the possibility of immobilizing rennet has been investigated as a means of extending its working life. Several rennets have been immobilized but their efficacy as milk coagulants has been questioned. There is widespread support for the view that properly immobilized enzymes can not coagulate milk owing to inaccessibility of the Phe-Met bond of  $\kappa$ -casein and that the apparent coagulating activity of immobilized rennets is due to leaching of enzyme from the support. Even if immobilized rennets could hydrolyze micellar  $\kappa$ -casein, operational difficulties would exist at the cheese factory level. Furthermore, as discussed in Section II.A.2.d, the residual rennet in cheese curd plays an essential role in cheese ripening and it would be necessary to add some chymosin or similar enzyme to the curd after coagulation, which would be difficult or impossible (see 8, 9, 24 for reviews).

c. *Factors Affecting the Hydrolysis of  $\kappa$ -Casein.* The pH optimum for chymosin and bovine pepsin is ~4.7 on small Phe-Met-containing peptides and 5.3–5.5 on  $\kappa$ -CN f98–111 or on whole  $\kappa$ -casein. The pH optimum for the first stage of rennet action

in milk is  $\sim$  6.0. Milk for most cheese varieties is renneted at about pH 6.5.

Increasing ionic strength (0.01–0.11) decreases the rate of hydrolysis of  $\kappa$ -CN f98–112, especially if the pH is also increased. At 1 mM, NaCl, CaCl<sub>2</sub>, and MgCl<sub>2</sub> stimulate the hydrolysis of  $\kappa$ -casein in isolated form or in sodium caseinate.

The optimum temperature for the coagulation of milk by calf rennet at pH 6.6 is  $\sim$  45°C. The temperature coefficient ( $\Delta$  rate/10°C) for the hydrolysis of  $\kappa$ -casein in solutions of Na-caseinate is  $\sim$  1.8, the  $E_a$  is  $\sim$  10,000 cal mol<sup>-1</sup> and the activation entropy is  $\sim$  -39 cal deg<sup>-1</sup> mol<sup>-1</sup>; generally similar values have been reported for the hydrolysis of isolated  $\kappa$ -casein.

The efficacy of  $\kappa$ -casein as a substrate for chymosin decreases as its level of glycosylation increases. At pH 6.6,  $k_{cat}$  decreases from  $\sim$  43 sec<sup>-1</sup> for carbohydrate-free  $\kappa$ -casein to  $\sim$  25 sec<sup>-1</sup> for  $\kappa$ -casein containing 6 moles N-acetyl neuraminic acid (NANA) per mol. However,  $K_m$  is lowest for the  $\kappa$ -casein component containing 3 moles NANA per mol. Polymerization (aggregation) markedly increases  $K_m$  with little effect on  $k_{cat}$ .

*d. Secondary (Nonenzymatic) Phase of Rennet Coagulation.* Hydrolysis of  $\kappa$ -casein removes its highly charged, hydrophilic C-terminal segment from the surface of the casein micelles, thereby reducing their zeta potential from  $\sim$  -20 mV to  $\sim$  -7 mV and removing the steric stabilizing layer. When  $\sim$  85% of the total  $\kappa$ -casein has been hydrolyzed, the casein micelles begin to aggregate and eventually form a gel. Reducing the pH or increasing the temperature from the normal ( $\sim$  6.6 and  $\sim$  31°C, respectively) induces coagulation at a lower degree of  $\kappa$ -casein hydrolysis.

The mechanism involved in the coagulation of rennet-altered micelles is not known precisely. Coagulation is dependent on Ca<sup>2+</sup> and on colloidal calcium phosphate, which are exchangeable to a certain extent. Ca<sup>2+</sup> may function by neutralizing negative charges on the caseins. Coagulation is highly temperature dependent; rennet-altered micelles do not coagulate below  $\sim$  20°C, above which the Q<sub>10°C</sub> for coagulation is  $\sim$  16. The high temperature dependence of coagulation suggests that hydrophobic bonds may be involved or that multiple bonds are formed.

The rennet coagulability of milk is adversely affected by heat treatments at temperatures  $>$  65°C and is prevented by very severe heat treatments ( $>$  90°C for 10 min). Although changes in the equilibria of milk salts, especially calcium phosphate, are contributory factors, complexation of  $\kappa$ -casein with

$\beta$ -lactoglobulin and/or  $\alpha$ -lactalbumin is primarily responsible for the increased rennet coagulation time of heated milk; both the primary phase and especially the secondary phase are adversely affected. The adverse effects of heating can be reversed by acidification before or after heating or by addition of CaCl<sub>2</sub>.

Rennet-coagulated milk gels are relatively stable if left undisturbed but syneresis strongly if cut or broken. The rate and extent of syneresis are promoted by reducing the pH, increasing the temperature, and applying pressure, e.g., agitation. By controlling the extent of syneresis, the cheese maker can control the moisture content of cheese which is a major factor affecting the rate and pattern of ripening and the stability of cheese. Differences in moisture content are, in fact, a major factor responsible for the diversity of cheese flavor and texture.

## 2. Proteolysis During Cheese Ripening

Acid-coagulated cheeses are usually consumed fresh, but the vast majority of rennet-coagulated cheeses are ripened (matured) for a period ranging from  $\sim$  3 weeks to  $>$  2 years; the rate of ripening is directly related to the moisture content of the cheese. During ripening, numerous microbiological, biochemical, and chemical events occur, as a result of which the principal constituents of the cheese—the proteins, lipids, and lactose—are transformed to primary, and later to secondary, products. Among the principal flavor compounds present in most cheese varieties are: peptides, amino acids, amines, acids, thiols, and thioesters (derived from proteins); fatty acids, methyl ketones, lactones, esters, and thioesters (derived from lipids); organic acids (lactic, acetic, and propionic); carbon dioxide; esters; and alcohols (derived from lactose). At appropriate concentrations and combinations, these compounds are responsible for the characteristic flavor of the various cheese varieties.

The biochemistry of cheese ripening has been reviewed by Fox et al. (25, 26) and Fox and Wallace (27); only proteolysis is discussed here.

*a. Significance of Proteolysis.* Proteolysis is essential in all rennet-coagulated cheese varieties, especially internal- and surface-bacterially ripened cheeses in which it is probably the principal biochemical event during ripening. Proteolysis contributes to cheese ripening in at least four ways: (a) makes a direct contribution to flavor, or off-flavor, e.g., bitterness, or indirectly since free amino acids are catabolized to amines, acids, thiols, thioesters, etc.; (b) facilitates the release of sapid compounds during mastication; (c) the

production of NH<sub>3</sub> from amino acids released by proteolysis affects flavor and texture; (d) changes in texture due to breakdown of the protein network, increase in pH, and greater water binding by the newly formed amino and carboxyl groups. There is a good correlation between the intensity of Cheddar cheese flavor and the extent and depth of proteolysis.

Considerable information is available on the level and type of proteolysis in the principal cheese groups (14, 25, 26, 28–33).

b. *Proteolytic Agents in Cheese.* Four, and in some varieties five, agents contribute to proteolysis in cheese during ripening: rennet or rennet substitute; indigenous milk enzymes, especially plasmin; starter bacteria and their enzymes, released on cell lysis; non-starter bacteria, which either survive pasteurization of the cheese milk or gain access to the pasteurized milk or curd during manufacture; and secondary inocula, e.g., propionic acid bacteria, *Brevibacterium linens*, yeasts, and molds (*Penicillium roqueforti* and *Geotrichum candidum*), and their enzymes are of major importance in some varieties. Techniques have been developed which permit quantitation of the contribution of each of these five agents to the primary aspects of cheese ripening (25, 31).

Studies using these techniques have shown that primary proteolysis, as determined by gel electrophoresis or the formation of water- or pH 4.6-soluble N, is due mainly to the coagulant except in those varieties, e.g., Emmental, Parmesan, and mozzarella, cooked to a high temperature (52–55°C) in which the coagulant is extensively or completely denatured. In these latter varieties, primary proteolysis is relatively limited and is due mainly to plasmin, which also contributes to proteolysis, especially of  $\beta$ -casein, in low-cooked cheese. The peptides produced by the coagulant and plasmin are further hydrolyzed by the proteinases and peptidases of starter and nonstarter bacteria, leading to the formation of many small peptides and free amino acids. Proteolysis varies widely among varieties, from very limited in short-ripened cheeses such as mozzarella, to very extensive in extramature Cheddar, Parmesan, or blue cheeses. Proteolysis in cheddar cheese has been well characterized and considerable information is also available on Gouda, Emmental, and Parmesan cheeses (33).

c. *Contribution of Coagulant to Proteolysis in Cheese.* Most of the rennet added to cheese milk is either denatured or lost in the whey. The amount retained is influenced by the type of rennet; e.g., porcine pepsin is extensively denatured during cheese

making, pH (low pH favors retention of chymosin but not microbial rennets and reduces denaturation, e.g., of pepsins), and cooking temperature, e.g., little, if any, coagulant survives the cooking conditions used for Swiss-type cheeses. About 6% of the added chymosin is retained in Cheddar cheese and up to 20–30% in high-moisture, low-cook, low-pH cheeses, such as Camembert.

The proteolytic specificity of calf chymosin on  $\alpha_{s1}$ -,  $\alpha_{s2}$ -, and  $\beta$ -caseins in solution has been established and these findings can, largely, be extended to cheese (14, 33).

The principal chymosin cleavage sites on  $\alpha_{s1}$ -casein in cheese are: Phe<sub>23</sub>-Phe<sub>24</sub>, which is hydrolyzed rapidly and completely in cheese (e.g., within ~3 months in Cheddar), and Leu<sub>101</sub>-Lys<sub>102</sub>, which is cleaved fairly extensively; Phe<sub>33</sub>-Gly<sub>34</sub> and Leu<sub>98</sub>-Leu<sub>99</sub> are also cleaved to some extent in cheese. Surprisingly, the Trp<sub>164</sub>-Tyr<sub>165</sub> bond, which is the second most susceptible bond in  $\alpha_{s1}$  casein in solution, does not appear to be hydrolyzed in cheese. The small peptide,  $\alpha_{s1}$ -CN f1–23, does not accumulate in cheese but is hydrolyzed rapidly by the cell envelope-associated lactococcal proteinase, with a specificity dependent on the strain (34).

Some peptide bonds in  $\beta$ -casein in solution are hydrolyzed quite rapidly by chymosin in the order: Leu<sub>192</sub>-Tyr<sub>193</sub>, Ala<sub>189</sub>-Phe<sub>190</sub>, Leu<sub>163</sub>-Ser<sub>164</sub>, and Leu<sub>139</sub>-Leu<sub>140</sub>. In cheese, these bonds are hydrolyzed to a very limited extent or not at all, probably because the C-terminal region of  $\beta$ -casein is very hydrophobic and undergoes hydrophobically driven interactions in cheese. These interactions appear to be accentuated by NaCl; even in solution, the hydrolysis of  $\beta$ -casein is strongly inhibited by 5% NaCl, which is the typical NaCl concentration in the aqueous phase of many cheese varieties. Inhibition of the hydrolysis of  $\beta$ -casein in cheese is desirable since the peptide  $\beta$ -CN f193–209 and fragments thereof are very bitter.

Although  $\alpha_{s2}$ -casein in solution is fairly readily hydrolyzed by chymosin, its fate in cheese is not clear, and para- $\kappa$ -casein ( $\kappa$ -CN f1–105) is very resistant to chymosin (and to other proteinases in cheese).

The specificity of pepsins is generally similar to that of chymosin but has not been established precisely. Bovine pepsin cleaves the Leu<sub>109</sub>-Glu<sub>110</sub> bond of  $\alpha_{s1}$ -casein quite rapidly, a bond which is cleaved very slowly by chymosin. The specificity of the fungal rennet substitutes is quite different from that of chymosin (35). The principal cleavage sites of *R. miehei* proteinase in  $\alpha_{s1}$ -casein in solution are Phe<sub>23</sub>-Phe<sub>24</sub>, Met<sub>123</sub>-Lys<sub>124</sub>, and Tyr<sub>165</sub>-Tyr<sub>166</sub> while those in  $\beta$ -casein are Glu<sub>31</sub>-Lys<sub>32</sub>, Val<sub>58</sub>-Val<sub>59</sub>, Met<sub>93</sub>-Gly<sub>94</sub>, and

Phe<sub>190</sub>-Leu<sub>191</sub> (35). *C. parasitica* proteinase is much more active on  $\beta$ -casein in cheese than chymosin, pepsin, or *Rhizomucor* proteinases, but its specificity on the caseins has not been determined; since it does not cause significant bitterness in cheese, its primary cleavage sites in  $\beta$ -casein may be in the N-terminal rather than in the C-terminal region (the N-terminal region of  $\beta$ -casein is quite hydrophilic, and small peptides produced from it would be expected to be nonbitter).

*d. Significance of Secondary Coagulant Proteolysis.* The proteolytic activity of the coagulant in cheese influences quality in four ways:

1. Some rennet-produced peptides may have a positive influence on flavor but excessive or unbalanced proteolysis, e.g., too much or excessively proteolytic rennet or unsuitable environmental conditions, e.g., too much moisture or too little NaCl, leads to bitterness. The peptide  $\beta$ -CN f193–209 derived from the C-terminal of  $\beta$ -casein and fragments thereof are particularly bitter.

2. Rennet-produced peptides serve as substrates for microbial proteinases and peptidases which produce small peptides and amino acids. These contribute at least to background flavor and perhaps to bitterness if the activity of such enzymes is excessive. Catabolism of amino acids by microbial enzymes and perhaps alterations via chemical mechanisms leads to a range of sapid compounds—amines, acids, NH<sub>3</sub>, thiols—which are major contributors to characteristic cheese flavors.

3. Alterations in cheese texture appear to influence the release of flavorful and aromatic compounds, arising from proteolysis, lipolysis, glycolysis, and secondary metabolic changes, from cheese during mastication, and this may be the most significant contribution of proteolysis to cheese flavor.

4. Texture is an important attribute of all cheeses and is critical in some varieties. Protein forms a continuous solid matrix in cheese, and its hydrolysis leads to a softening of the texture. Chymosin is primarily responsible for textural changes during the early stages of ripening. The functionality (stretchability and meltability) of mozzarella is strongly influenced by proteolysis; a low level of proteolysis improves functionality, but quality deteriorates on further proteolysis.

### 3. Acceleration of Cheese Ripening

The original objective of cheese manufacture was conservation of the principal nutrients in milk (i.e., lipids and proteins) by a combination of acidification,

dehydration, low E<sub>h</sub>, and salting. Chemical and biochemical changes do occur during storage but stability was the prime objective. While still important, stability is no longer the primary objective of cheese manufacture, and since ripening is expensive, its acceleration, especially in low-moisture, slow-ripening varieties, is desirable, at least under certain circumstances, provided the whole process can be maintained in balance.

Some high-moisture cheeses develop an intense flavor through a very active secondary flora, e.g., internal blue mold, external white mold, or a bacterial surface smear; these cheeses ripen quickly, e.g., 4–16 weeks. High-moisture internal bacterially ripened cheeses also mature rapidly but develop a low flavor intensity; if the ripening of such cheeses is extended, they will probably develop off-flavors. It is possible to develop an intense flavor in internal bacterially ripened cheeses only if the moisture content is low and they are ripened for a long period, e.g., Parmesan, extramature Cheddar, or extramature Gouda, which are ripened for 2–3 years. Owing to the high cost of ripening facilities and stocks, the ripening of extramature cheeses is expensive. Consequently, there is commercial interest in accelerating the ripening of these cheeses, provided quality can be maintained. It might also be possible to apply similar techniques to medium-moisture, medium-flavor cheeses, e.g., regular Cheddar and Gouda, with the objective of accentuating their flavor. Most of the work on accelerating cheese ripening has in fact been on Cheddar. Techniques for accelerating ripening may also be applicable to reduced-fat cheeses, which tend to ripen slowly. A substantial literature on attempts to accelerate cheese ripening has accumulated and has been reviewed regularly (36).

Glycolysis is rapid in all cheeses and does not require acceleration. Lipolysis is limited in most cheeses and excessive lipolysis is undesirable. Consequently, most studies on accelerated ripening of cheese have focused on proteolysis, which contributes to flavor and is mainly responsible for changes in texture.

Methods for accelerating cheese ripening fall into six categories: elevated ripening temperature, exogenous enzymes, chemically or physically modified cells, genetically modified starters, adjunct starters, and enzyme-modified cheeses. These methods either seek to make the conditions under which indigenous enzymes function more favorable (i.e., elevated temperature) or to increase the level of certain key enzymes which are considered to be particularly important in cheese ripening.

A complex cascade of enzymes is involved in cheese ripening, and most key enzymes have not been identified. Not surprisingly, the use of single enzymes, e.g., additional coagulant (which is mainly responsible for primary proteolysis), plasmin (for which some benefits are claimed), or Neutrerase (from *B. subtilis*), while accelerating proteolysis, does not accelerate flavor development and may cause off-flavors. It has been claimed that a combination of exogenous proteinases and lactococcal cell-free extracts (rich in peptidases) accelerate ripening, but the results are equivocal. Uniform incorporation of the enzyme preparation into cheese curd poses problems. For Cheddar, the enzyme preparation, diluted with salt, may be added to milled curd, but this method is not applicable to most varieties. Addition of microencapsulated enzyme(s) to cheese milk is technically feasible, but microencapsulation techniques currently available are not very efficient. At present, exogenous enzymes are not being used commercially to accelerate the ripening of natural cheese.

Exogenous lipase, traditionally pregastric esterase, is added to certain hard Italian cheeses, e.g., Romano and provolone. It has been claimed that inclusion of selected lipases in the blend of exogenous enzymes accelerates the ripening of other cheeses, e.g., Cheddar and Ras.

Most of the enzymes involved in cheese ripening are produced by microorganisms that grow in or on the cheese. By increasing the number of these organisms it should be possible to accelerate ripening. The use of whole cells should have two advantages over isolated enzymes: they contain the "natural" cocktail of enzymes found in cheese and they are cheaper to produce. Three approaches have been considered in the use of bacterial cells to accelerate cheese ripening: attenuated starter cells, genetically modified cultures, adjunct cultures.

The starter, in addition to its essential role in curd acidification, is also essential for secondary proteolysis and flavor development. Therefore, it might be expected that increasing the number of starter cells in cheese would accelerate ripening. However, increasing the level of active starter added to the cheese milk causes an excessively rapid rate of acid production which has undesirable effects, e.g., a crumbly texture and overacid flavor. The acid-producing ability of starter cells may be attenuated or destroyed by heat-shocking, freeze-shocking, or solvent treatment with very little effect on their enzyme activities. These attenuated cells are in effect packages of enzymes and their use has been reported to accelerate the ripening of a number of cheese varieties.

A simpler and probably more effective approach is the use of lactose-negative strains of *Lactococcus*, which cannot grow in milk or cheese curd but serve as a balanced "natural" source of enzymes important in cheese ripening. Such cultures are available commercially and are claimed to give satisfactory results.

Cells of selected non-lactic-acid bacteria, which do not grow in a particular cheese, either because they are aerobic, e.g., *Pseudomonas* spp. or *Brevibacterium* spp., or because they have a high growth temperature, e.g., *Propionibacterium*, might also serve as suitable "packages of enzymes" for addition to cheese curd; however, such cultures do not appear to be used commercially at present.

It is probable that certain enzymes are rate limiting in cheese ripening. At present, the key limiting enzymes are unknown, but studies are in hand with the objective of identifying these enzymes using deficient or overproducing mutants. It is possible to genetically modify *Lactococcus* to overproduce certain desirable enzymes, to delete undesirable genes, or to introduce foreign genes for putatively important enzymes. It is highly probable that genetically modified bacteria with the ability to accelerate ripening and improve cheese quality will become available in due course for use as primary or secondary cultures.

All cheese acquires an adventitious nonstarter microflora, predominantly mesophilic lactobacilli, which grow from low numbers initially (e.g.,  $< 10^3$  cfu/g) to  $10^7$ – $10^8$  cfu/g and which dominate the microflora of cheese after  $\sim 3$  months owing to the death of the primary starter. These nonstarter lactic acid bacteria (NSLAB) probably affect cheese ripening, and there is considerable interest in inoculating cheese milk with selected strains of NSLAB to accelerate or modify cheese flavor development (37).

An extreme form of accelerated ripening is practiced in the production of enzyme-modified cheese (EMC); the subject has been reviewed by Kilcawley et al. (38). EMCs are produced by adding a cocktail of enzymes (proteinases, peptidases, lipases) and perhaps bacterial cultures to homogenized, pasteurized fresh curd or young cheese. The mixture is incubated for a requisite period and repasteurized to terminate the microbiological and enzymatic reactions. The preparation may be spray-dried or commercialized as a paste.

Although the flavor of EMCs does not approximate that of natural cheese, they have the ability to potentiate cheeselike flavor in various food products, e.g., processed cheese, cheese analogs, cheese sauces, and dips, and products containing cheese, e.g., crackers, crisps, etc. For such applications, EMCs may replace

20–50 times their weight of natural cheese and are cheaper. Cheddar EMCs are the most important commercially, but EMCs that stimulate several varieties have been developed, e.g., blue, Swiss, and Romano.

## B. Other Applications of Proteinases

In comparison with their use in cheese making, the other applications of proteinases in dairy technology are quite small but some have considerable growth potential. The more important of these are discussed below.

### 1. Dietary Products

Protein hydrolysates for use in soups, gravies, flavorings, and dietetic foods are generally prepared from soy proteins, gluten, milk proteins, meat, or fish protein by acid hydrolysis. Neutralization results in a high salt content which is acceptable for certain applications but may be unsuitable for dietetic foods and food supplements. Furthermore, acid hydrolysis causes total or partial destruction of some amino acids. Enzymatic hydrolysis is a viable alternative (39), but bitterness due to hydrophobic peptides is frequently encountered. Caseins are strongly hydrophobic and yield very bitter hydrolysates, but bitterness may be eliminated, or at least reduced, by one of several treatments (39, 40).

There is increasing interest in the production of casein-derived peptides with special nutritional or physiological properties; some of the possibilities have been reviewed (41, 42). Apart from the interest in casein hydrolysates for the nutrition of patients with digestive problems, interest has been focused recently on phosphopeptides derived from casein which it is claimed stimulate the absorption of calcium and iron, but views on this are not unanimous (43). Methods for the production of caseinophosphopeptides for nutritional and/or medical applications have been developed (44–46).

The casein(glyco)macropeptide (CMP),  $\kappa$ -CN f106–169, produced from  $\kappa$ -casein during the enzymatic coagulation of milk for cheese or rennet casein, is lost into the whey. CMP is devoid of aromatic amino acids and hence is a suitable nutrient for patients suffering from phenylketonuria. Several biological activities have been attributed to the CMP, including inhibition of adhesion of oral actinomyces and streptococci to erythrocytes, effects on gastrointestinal motility, growth factors for *Bifidobacterium* spp., inhibition of the binding of cholera toxin, inhibition of influenza virus hemagglutinin, stimulation of cholecystokinin release from intestinal

cells, and inhibition of acid secretion in the stomach (47, 48). Methods have been developed for the industrial production of CMP from whey (48, 49).

There is considerable interest in the fortification of performance-enhancing drinks with protein hydrolysates; bitterness is a problem here, and whey protein hydrolysates are preferred to casein hydrolysates.

### 2. Physiologically Active Peptides from Milk Proteins

Peptides with various physiological activities have been isolated from milk protein hydrolysates; at least some of these peptides are produced *in vivo* and may play a physiological role (50). The best-studied of these are the  $\beta$ -caseinomorphins, a family of peptides containing 4–7 amino acids (representing  $\beta$ -CN f60–63/7) with opioid activity. These peptides are produced in the intestine *in vivo* but it is still unclear whether or not they reach the brain. Peptides with opiate properties have also been isolated from hydrolysates of  $\alpha_{s1}$ - and  $\kappa$ -caseins, lactotransferrin,  $\alpha$ -lactalbumin, and  $\beta$ -lactoglobulin.

Other biologically active peptides that have been isolated from hydrolysates of milk proteins include: immunomodulating peptides, an inhibitor of angiotensin-converting enzyme, blood platelet modifiers, and stimulators of DNA synthesis (50). Whether any of these peptides are active *in vivo* remain to be established, but their formation has led to casein being referred to as a pro-hormone (51).

The release of biologically active peptides requires precise hydrolysis of the parent molecules at specific bonds. If the application of these peptides develops as predicted, very interesting applications for proteinases in the dairy industry will emerge.

### 3. Modification of Protein Functionality

Milk proteins are among the principal functional proteins used in food products (52). In general, milk proteins possess very good functional properties but suffer some limitations, notably the insolubility of casein in the pH range 3.0–5.5. The functional properties of milk proteins may be improved by limited proteolysis (1, 40, 53, 54). An acid-soluble casein, free from off-flavor and suitable for incorporation into beverages and other acid foods, has been prepared by limited proteolysis. The antigenicity of casein is destroyed by proteolysis, and the hydrolysate is suitable for use in milk protein-based foods for infants allergic to cow's milk. Controlled proteolysis improves the meltability of directly acidified cheese but excessive proteolysis

causes bitterness. Casein solutions are very viscous at concentrations > 20%, w/v, which increases the cost of drying caseinates. Viscosity may be reduced by limited proteolysis, but only a small increase in solids is possible owing to bitterness after even moderate levels of proteolysis.

The surface activity of sodium caseinate can be increased considerably by the treatment with plasmin, apparently owing to the formation of  $\gamma^2$ - and  $\gamma^3$ -caseins ( $\beta$ -CN f106–209,  $\beta$ -CN f108–209) which are very surface active. Generally, the emulsifying and foaming properties of small peptides are poor, since they form very thin interfacial layers.

Limited proteolysis of lactalbumin (heat-denatured whey protein), which is insoluble and has very poor functional properties, yields a product with greatly improved solubility and functionality. Limited proteolysis of whey protein concentrate (WPC) reduces its emulsifying capacity and increases its specific foam volume but reduces foam stability. The heat stability of WPC may be improved considerably by limited hydrolysis without concomitant impairment of other functional properties or off-flavor development.

The plastein reaction has been proposed as a mechanism by which the functional and nutritional properties of proteins may be improved. The reaction is of little relevance to milk proteins because they already have good functional and nutritional properties and yields of plastein are low.

One of the principal food applications of whey protein (WP) and whey protein isolates (WPI) is in the production of thermo-set gels. The gelation of WPCs at low temperatures has been achieved by limited proteolysis by certain enzymes (55); perhaps gelation occurs through the plastein reaction.

### III. LIPASES

Lipases have a number of relatively low-volume applications in the dairy industry. Some of these applications are traditional and essential for the manufacture of particular products: others are emerging but hold considerable potential.

#### A. Lipases in Cheese Production

The principal application of lipases in dairy technology is in cheese manufacture, particularly, some Italian varieties, e.g., Romano and provolone. The characteristic “piquant” flavor of these cheeses is due primarily to short-chain fatty acids resulting from the action of

lipase(s) in the rennet paste traditionally used in their manufacture.

Rennet pastes are prepared from the stomachs of calves, lambs, or kids slaughtered after suckling; the stomachs and contents are held for a considerable period prior to maceration. Because of possible risks to public health, the use of rennet pastes, which have proteolytic and lipolytic activities, is prohibited in some countries. The lipase in rennet paste is of oral origin and its secretion is stimulated by suckling: the secreted lipase is washed into the stomach with the ingested milk. Oral (lingual) lipase, commonly referred to as a pregastric esterase (PGE), is secreted by several species and probably makes a significant contribution to the digestion of lipids by the neonate in which the activity of pancreatic lipase is limited. The considerable literature on PGE has been comprehensively reviewed (3, 56). PGE shows a high specificity for short chain fatty acids, especially butyric, esterified on the Sn-3 position of glycerol, although some interspecies differences in specificity have been reported. They are maximally active at 32–42°C, pH 4.8–5.5, and in the presence of 0.5 M NaCl. Calf, kid, and lamb PGEs have been partially purified from commercial preparations (57). Calf PGE has been isolated from oral tissue and characterized with respect to pI (7.0), molecular weight (~ 49 kDa), and amino acid composition (58, 59). The secondary structures of rat lingual lipase and pancreatic lipase were studied and compared (60). The gene for rat lingual lipase has been cloned and sequenced, and the amino acid sequence of the enzyme has been deduced (61).

PGE-containing extracts from calf, kid, or lamb tissue are commercially available as alternatives for rennet pastes. Slight interspecies differences in specificity render one or another more suitable for particular applications. Particularly large differences in the ability of lipases to release 4-methyloctanoic acid, which exhibits a goat-muttony aroma, have been found (62). Such differences in specificity permit the generation of a range of flavors in cheese products. The propensity of PGE to synthesize triglycerides is increased in the  $a_w$  range 0.75–0.90 or by the addition of ethanol to the reaction mixture (63); this property may be exploited to modify cheese flavors.

Although PGE extract is now widely used in the manufacture of hard Italian cheese varieties, connoisseurs of Italian cheese claim that rennet paste gives superior results. Perhaps rennet paste contains enzymes in addition to chymosin and PGE. A second lipase, termed gastric lipase, was identified in an extract of cleaned gastric tissue and partially charac-

terized. A combination of calf gastric lipase and goat PGE gave Cheddar and provolone of superior quality to cheese made with PGE alone (64). However, Nelson et al. (56) expressed reservations on the occurrence of a gastric lipase distinct from PGE. Traditional rennet paste would be expected to contain both PGE and gastric lipase.

*R. miehei* secretes a lipase that is reported to give satisfactory results in Italian cheese manufacture (65). The enzyme has been characterized (66) and is commercially available as Piccantase. The lipases secreted by selected strains of *Penicillium roqueforti*, *P. candidum*, or *A. niger* are considered to be potentially useful for the manufacture of Romano, provolone, and other cheese varieties (67, 68). Unlike PGE, the fungal lipases do not preferentially release short-chain fatty acids. The use of different lipase preparations or blends of lipases opens possibilities for producing Italian cheeses with different degrees of sharpness.

*A. oryzae* secretes a lipase which has as exceptionally high specificity for C<sub>6</sub>–C<sub>8</sub> acids (69). Another interesting characteristic of this enzyme is that it forms micelles, ~0.2 μm in diameter, in aqueous media, as a result of which ~94% of the enzyme added to milk is recovered in cheese curds. The formation of short-chain fatty acids was reported to parallel flavor intensity in Cheddar cheese containing this enzyme. In contrast to the FFA profile caused by calf PGE, which liberated high concentrations of C<sub>4:0</sub>, the FFA profile in the cheese containing *A. oryzae* lipase was similar to that in the control cheese, but the level of FFA was much higher.

Extensive lipolysis also occurs in blue cheese varieties, and in addition to making a direct contribution to flavor, the free fatty acids serve as substrates for fungal enzyme systems in the biosynthesis of methyl ketones, which are the principal contributors to the typical flavor of blue cheese (70). *P. roqueforti* lipase predominates the ripening of blue cheeses. However, blue cheese ripening may be accelerated and quality improved by the addition of exogenous lipases (71, 72).

Blue cheese is a popular ingredient for salad dressings and cheese dip. High-quality natural cheese is not normally required for these applications and there is considerable interest in the production of cheaper substitutes. Various methods have been developed for the production of blue cheese flavor concentrates; most of these methods involved the use of fungal lipases and usually *P. roqueforti* spores (1, 2, 73).

The low level of lipolysis that occurs in most other varieties is catalyzed by lipases/esterases derived from the starter or nonstarter lactic acid bacteria. Consider-

ably more lipolysis occurs in cheeses made from raw milk than in pasteurized milk cheeses, possibly owing to the indigenous milk lipoprotein lipase and/or a more diverse nonstarter microflora in the former. It has been claimed that the flavor of many cheeses can be intensified or their ripening accelerated by incorporating PGE or fungal lipases, although their use appears to be very limited (1–3). Relatively extensive lipolysis occurs in Parmigiano-Reggiano, which can probably be attributed to the use of raw milk (which contains an indigenous lipase) and the long ripening time (2 years).

Lipases, probably mainly of fungal origin, are used in the production of some enzyme-modified cheeses (38).

## B. Other Applications of Lipases

Lipases are used to hydrolyze milk fat for a variety of uses in the confectionery, candy, chocolate, sauce, and snack food industries. The partially hydrolyzed fat imparts a greater intensity of butterlike flavor to the products and delays stalling, presumably as a result of the emulsifying effect of di- and monoglycerides (56, 71, 74).

An important new application of lipases is in the trans/interesterification of fatty acids on triglycerides (75). This approach can be used to modify the melting point of triglycerides, and hence their rheological properties. An important application of this technology is in the production of cocoa butter substitutes for chocolate manufacture. Mono- or polyunsaturated fatty acids may also be introduced to relatively saturated milk lipids to improve their nutritional qualities. Immobilized lipase systems have been developed for these applications (74).

## IV. $\beta$ -GALACTOSIDASE

Lactose is a reducing disaccharide containing galactose and glucose linked by a  $\beta$ -1-4 O-glycosidic bond (O- $\beta$ -D-galactopyranosyl-(1-4)- $\alpha$ - or  $\beta$ -D-glucopyranose,  $\alpha$ - and  $\beta$ -lactose, respectively). Lactose is by far the dominant carbohydrate in milks which are, in turn, the only significant natural sources of lactose. The concentration of lactose in milk ranges from 0% in the milk of marine mammals to ~10% in milk from some species of monkey; bovine and human milk contain ~4.8% and 7% lactose, respectively. Lactose is an important source of energy for the newborn mammal, but when a very energy-dense milk is required (mammals in aquatic or polar environments), the lipid rather than the lactose content is increased. In fact, there is a fairly

good inverse relationship between the level of fat and that of lactose.

Among sugars, lactose possesses many fairly unique properties: low solubility ( $\sim 18\text{ g}/100\text{ mL H}_2\text{O}$  at  $20^\circ\text{C}$ ); a marked tendency to form supersaturated solutions which are difficult to crystallize; when crystallization does occur, the crystals are hard and sharp and, unless kept to dimensions  $< 20\text{ }\mu\text{m}$ , cause a sandy texture in foods; crystallization is complicated by its mutarotation characteristics since  $\alpha$ - and  $\beta$ -lactose differ considerably in solubility and degree of hydration; it has low sweetness (16% as sweet as sucrose at 1%, w/v); owing to its crystallization and mutarotation characteristics, it is hygroscopic and may cause "caking" of dairy powders; it has a strong tendency to absorb flavors and odors.

At  $20^\circ\text{C}$ ,  $\alpha$ -lactose is considerably less soluble ( $\sim 7\text{ g}/100\text{ g H}_2\text{O}$ ) than  $\beta$ -lactose ( $\sim 50\text{ g}/100\text{ g H}_2\text{O}$ ). However, the solubility of the  $\alpha$ -anomer increases more sharply with increasing temperature than that of the  $\beta$ -anomer and the solubility curves intersect at  $\sim 93.5^\circ\text{C}$ ; therefore, when lactose is crystallized at a temperature  $< 93.5^\circ\text{C}$ ,  $\alpha$ -lactose is obtained.  $\alpha$ -Lactose crystallizes as a monohydrate while  $\beta$ -lactose crystals are anhydrous.

When milk is spray-dried, there is insufficient time for lactose to crystallize and an amorphous lactose glass is formed. If the moisture content of the powder is low, the glass is stable, but if the moisture content increases, the glass becomes hygroscopic, and lactose crystallizes as  $\alpha$ -lactose monohydrate, leading to caking. In practice, the problem is solved by precrystallizing the lactose, usually induced by seeding with powdered lactose crystals.

When milk is frozen, the lactose usually does not have time to crystallize and the concentration of inorganic solutes in the liquid aqueous phase increases. On holding in the frozen state, calcium phosphate crystallizes as  $\text{Ca}_3(\text{PO}_4)_2$ , releasing  $\text{H}^+$  and reducing the pH to  $\sim 5.8$ , and lactose crystallizes as  $\alpha$ -lactose monohydrate, reducing the amount of solvent water, further increasing the concentration of inorganic solutes. The combination of low pH and high  $\text{Ca}^{2+}$  destabilizes the casein micelles which aggregate when the milk is thawed. Unless properly controlled, these characteristics of lactose may cause defects in concentrated, dehydrated, and frozen dairy products. However, some of the same characteristics may be exploited to make lactose an interesting and useful food additive—e.g., as a free-flowing agent, an agglomerating (instantizing) agent, an additive to stabilize color, flavor, and texture, especially when concomitant sweetness is undesirable,

and as a reducing sugar in products in which Maillard browning is desirable as a source of color and flavor. The chemistry, properties, problems, modifications, and applications of lactose and lactose derivatives have been reviewed (76–85).

It is claimed that lactose promotes the intestinal absorption of calcium and phosphorus and hence should be nutritionally beneficial, especially in infant nutrition. However, lactose is involved in two enzyme deficiency diseases: lactose intolerance and galactosemia. There are in fact two forms of galactosemia, both arising from the congenital deficiency of an enzyme in their Leloir pathway for galactose metabolism (86). Classical galactosemia is due to a deficiency of galactose-1-phosphate:uridyl transferase. Ingested galactose (from lactose or other source) is phosphorylated to galactose-1-phosphate which is not metabolized further, leading to the accumulation of galactose and galactose-1-phosphate. Galactosemic infants appear normal at birth but develop various symptoms, including mental retardation, unless put on a galactose-free diet within 2–3 months. The second form, galactokinase-deficient galactosemia, results in the failure to phosphorylate galactose, some of which is metabolized to galactitol which accumulates in the eye, causing cataracts.

Disaccharides must be hydrolyzed to monosaccharides in the intestine prior to absorption, in the case of lactose by  $\beta$ -galactosidase. The vast majority of infants secrete adequate levels of  $\beta$ -galactosidase in the brush border of the small intestine to hydrolyze ingested lactose; however, a small minority of infants secrete an inadequate level of  $\beta$ -galactosidase. The level of intestinal  $\beta$ -galactosidase reaches a maximum shortly after birth and declines thereafter to a low level. With the exception of northwestern Europeans and a few African tribes, the level of intestinal  $\beta$ -galactosidase becomes so low within 6–8 years as to render the subject incapable of hydrolyzing ingested lactose at an adequate rate, leading to lactose intolerance. The unhydrolyzed lactose passes to the large intestine where it leads to flatulence, cramps, diarrhea, and possibly death. Thus, only a minority of the world's population can consume large quantities of lactose-containing foods with impunity. The subject of lactose intolerance has been reviewed extensively (87, 88).

The third feature of the lactose problem is the development of economic outlets for the large quantities ( $\sim 5 \times 10^9\text{ kg/year}$ ) available from cheese and casein wheys. The technology for lactose production is well developed but  $< 10\%$  of the potentially available lactose is recovered as such; although lactose has a num-

ber of special food applications, the market appears to be limited. Increasing concern about environmental pollution has focused attention on more complete utilization of whey for which there are many options (76–85).

The dairy industry has developed methods for controlling the physicochemical problems posed by lactose, and lactose intolerance may not be too serious if lactose-containing products are introduced gradually to the diet. However, all the various problems posed by lactose (technological, nutritional, utilization) may be solved via hydrolysis by  $\beta$ -galactosidase (lactase) to the less problematic sugars, glucose and galactose.

$\beta$ -Galactosidase ( $\beta$ -D-galactoside galactohydrolase; EC 3.2.1.23) catalyzes the hydrolysis of lactose to its component monosaccharides, glucose and galactose. The use of  $\beta$ -galactosidase in dairy technology has been considered as one of the most promising applications of exogenous enzymes in food processing. However, although many interesting applications have been demonstrated, the use of  $\beta$ -galactosidase has not yet become commercially successful for economic reasons. The voluminous literature on the preparation, properties, and uses of  $\beta$ -galactosidases has been the subject of several reviews (76, 81, 83, 89, 90).

Although  $\beta$ -galactosidase is widely distributed in plant, animal, and microbial sources, only the enzymes from *Aspergillus niger*, *A. oryzae*, *Kluveromyces marxianus* var. *lactis*, *K. fragilis*, *Bacillus stearothermophilus*, and *Escherichia coli* are commercially available.  $\beta$ -Galactosidases from several sources have been isolated and characterized; the important properties have been summarized by Mahoney (89, 90). In general,  $\beta$ -galactosidases produced by molds have an acid pH optimum (2.5–4.5) and are therefore best suited for use in acid wheys, while yeast and bacterial  $\beta$ -galactosidases, with a pH optimum in the range 6–7.5, are more suitable for use in milk or rennet wheys.  $\beta$ -Galactosidases with high thermal stability have been isolated and are attractive because they can be used at high temperatures at which microbial growth is slow or absent. The heat stability of  $\beta$ -galactosidase from *K. lactis* and *Streptococcus thermophilus* is considerably greater in milk than in buffer systems owing to the combined effects of casein and lactose.

$\beta$ -Galactosidases from several sources have been immobilized by encapsulation; entrapment in fibers, gels, or semipermeable membranes; adsorption or covalent attachment by a variety of techniques to various supports, e.g., porous glass, collagen, cellulose derivatives, and various resins (76, 83, 89, 90).

The principal applications of  $\beta$ -galactosidase in dairy technology are: (a) production of low-lactose milk and dairy products for  $\beta$ -galactosidase-deficient patients; (b) modification of dairy products for use in ice cream, baked goods, yogurt, etc.; (c) production of syrups and sweeteners for food applications; and (d) pretreatment of milk for freezing.

In spite of the widespread incidence of  $\beta$ -galactosidase deficiency among non-Caucasians, such subjects adjust to lactose-containing diets if lactose is introduced gradually and the response to lactose is moderated by other components in the diet. Researchers are divided as to the desirability of including milk in the diets of lactose-intolerant subjects (87, 88). However, it appears to be generally agreed that treatment with  $\beta$ -galactosidase would enhance the nutritional value of dairy products in such cases and render protein-rich dairy products suitable for supplementation of nutritionally deficient diets. Lactose-hydrolyzed milk is commercially available but is more expensive than normal milk.  $\beta$ -Galactosidase is also available in powder or liquid form for home use (89, 90). Direct addition of  $\beta$ -galactosidase to milk at mealtime ("enzyme replacement therapy") has also given satisfactory results. A promising method for reducing treatment cost is the addition of a very low level of soluble  $\beta$ -galactosidase to UHT milk which, during prolonged storage, induces extensive hydrolysis. This approach has been commercialized by the Tetra-Pak Company (Lund, Sweden). The increased sweetness of lactose-hydrolyzed milk does not appear to be a problem and may actually be preferred by some individuals.

$\beta$ -Galactosidase can act as a transferase resulting in the synthesis of several oligosaccharides (galacto-oligosaccharides), the range and concentration of which appear to vary with the source of the  $\beta$ -galactosidase and the duration of treatment. Many of the oligosaccharides are  $\beta$ -(1  $\rightarrow$  6) galactosides which are not hydrolyzed in the small intestine and pass into the large intestine where they are acted on by bacteria leading to intestinal disturbances, mainly flatulence. However, galacto-oligosaccharides stimulate the growth of *Bifidobacterium* spp. in the lower intestine, which is believed to be beneficial. A product (oligonate, 6'-galactosyl lactose) is produced commercially by the Yokult Company in Japan for addition to infant formulae. Some galacto-oligosaccharides have interesting functional properties and may find commercial applications (91, 92).

Hydrolysis of lactose in milk for yogurt has been suggested as a means of increasing the sweetness of yogurt without a concomitant increase in calories; it

is reported to reduce fermentation time (89, 90). Some authors have reported that lactose-hydrolyzed yogurt has superior texture and consistency, with less whey off, than controls. Off-flavors have been reported in some lactose-hydrolyzed yogurts, perhaps owing to the action of contaminating proteinases. Yogurt and other cultured milks are well tolerated by lactose-intolerant subjects, apparently owing to the secretion of  $\beta$ -galactosidase by the thermophilic culture used or to slower gastric emptying (88).

It is also claimed that the manufacturing time for Cheddar and other cheeses is reduced by pretreatment of cheese milk with  $\beta$ -galactosidase, and, possibly more significantly, the quality of the cheese is improved and ripening accelerated. However, a proteinase present in the commercial  $\beta$ -galactosidase preparations used, rather than to the action of  $\beta$ -galactosidase, was probably responsible for the accelerated ripening.

Hydrolysis of lactose improves the functionality of milk powder in bakery products. The glucose moiety is fermentable by baker's yeast (*Saccharomyces cerevisiae*), leading to increased loaf volume, while the non-fermentable galactose contributes to flavor and crust color through Maillard browning. Prehydrolysis of lactose using  $\beta$ -galactosidase renders milk stable to freezing (89, 90, 93).

Dulce de Leche, a sweetened concentrated dairy product, is popular in Latin America as a dessert or spread. Lactose crystallization is a major problem in this highly concentrated product. Growth of *K. marxianus* var. *lactis* in milk for the preparation of Dulce de Leche has been recommended for the control of lactose crystallization (94). About 50% of the lactose was hydrolyzed in 12 h (at  $5.2 \times 10^7$  cells/mL) or 100% in 24 h. When the delactosed milk was mixed in proportions of 1:2 with normal milk and concentrated, no lactose crystallization and no significant changes in flavor were noted. The use of permeabilized *K. marxianus* var. *lactis* cells for the same application was found to be very satisfactory (95). Presumably, isolated  $\beta$ -galactosidase could be used successfully in the preparation of Dulce de Leche.

Lactose crystallization may also be a problem in conventional sweetened condensed milk, although the problem can be controlled by appropriate manufacturing steps. Prehydrolysis with  $\beta$ -galactosidase offers an alternative solution.

Treatment with  $\beta$ -galactosidase prevented lactose crystallization in a whey retentate–buttermilk powder spread (96). Acid (mold)  $\beta$ -galactosidase was preferable to neutral (yeast) enzyme, and hydrolysis of 30% of the lactose was sufficient. Lactose-hydrolyzed

whey appears to be suitable for incorporation into ice cream in which up to 25% of the skim milk solids may be replaced by hydrolyzed whey syrup without adverse effects on quality; 50% of the sucrose may also be replaced by whey syrup (89, 90, 97). Lactose-hydrolyzed whey may be fed in larger amounts than normal whey to animals, especially pigs.

Probably the principal commercial interest in  $\beta$ -galactosidase is for the production of syrups as a profitable outlet for lactose. Glucose-galactose syrups are ~70% as sweet as sucrose and about four times sweeter than lactose. It has been known for a long time that lactose can be hydrolyzed to glucose and galactose by strong mineral acids, and there has been renewed commercial interest in the process, using free acid or ion exchange resins, as a means of producing glucose-galactose syrups. Production costs are reported to be lower than for enzymatic hydrolysis, but acid hydrolysis is applicable only to purified lactose solutions or perhaps ultrafiltration permeates.

Numerous applications have been reported for glucose-galactose syrups (in addition to the use of lactose-hydrolyzed whey) (83, 89, 90). Although effective systems for the production of glucose-galactose syrups and other lactose-hydrolyzed products are available and continued research will undoubtedly lead to improved systems, the cost of such syrups vis-à-vis alternatives, mainly glucose syrups from starch, remains a problem.

The sweetness of glucose-galactose syrups may be increased by isomerizing the glucose to fructose (which is about twice as sweet as glucose) using glucose isomerase, which is now widely used in the commercial production of high-fructose syrups from starch. Such a system has been patented and a glucose-fructose-galactose-lactose syrup with a sweetness equal to sucrose (both at 10% solution) has been prepared by treating a glucose-fortified lactose hydrolyzate with glucose isomerase. Conversion of lactose to lactulose offers another avenue for the production of novel sugar mixtures. Lactulose is a disaccharide consisting of galactose and fructose, which can be produced from lactose by mild alkaline treatment. At least some  $\beta$ -galactosidases can hydrolyze lactulose, although more slowly than lactose.

It will be apparent that  $\beta$ -galactosidase has numerous applications in the dairy industry. However, in spite of very considerable research and demonstrated technological feasibility in pilot-scale experiments,  $\beta$ -galactosidase is not yet exploited commercially on a significant scale, except for lactose-hydrolyzed pasteurized and UHT milks. Zadow (98) concluded that the

markets for lactose-hydrolyzed syrups are likely to remain limited for economic reasons.

## V. LYSOZYME

Lysozyme (muramidase, EC 3.2.1.17), an enzyme which causes lysis of certain bacteria by hydrolyzing cell wall polysaccharides, is widely distributed in animal tissues and secretions. Some bacteria and bacteriophage secrete similar enzymes, lysins. Egg white is a particularly rich source of lysozyme, which is the best characterized of these enzymes. The molecular and biological properties of lysozyme and its use in food preservation and as a pharmaceutical have been comprehensively reviewed by Proctor and Cunningham (99) and Cunningham et al. (100).

The milks of most species contain an indigenous lysozyme; human and equine milks are particularly rich in this enzyme. Various aspects of indigenous milk lysozyme were reviewed by Farkye (101, 102).

In view of its antibacterial activity, the large difference in lysozyme content between human and bovine milks may have significance in infant nutrition. It is claimed that supplementation of baby food formulae based on cows' milk with egg-white lysozyme gives beneficial results, especially with premature babies; however, results are equivocal (1).

Lysozyme has some other minor applications in dairy technology, but most current interest is focused on its use in Dutch, Swiss, Italian, and other cheese varieties to prevent late gas blowing and/or off-flavors caused by the growth of *Clostridium tyrobutyricum*. Contamination of cheese milk with *Clostridium* spp. can be reduced by good hygienic practices, and populations may be further reduced by bactofugation or microfiltration. However, in most countries it is normal practice to add sodium nitrate as a further precaution. The use of nitrate in foods is suspect because it leads to nitrosamine formation, and many countries have reduced permitted levels or prohibited its use.

Lysozyme is effective in killing *Clostridium* cells and preventing the outgrowth of their spores. It has been shown to be an effective alternative to nitrate in preventing the butyric acid fermentation and late gas blowing in several cheese varieties (1, 2, 99, 100, 103, 104). It was concluded (103, 104) that

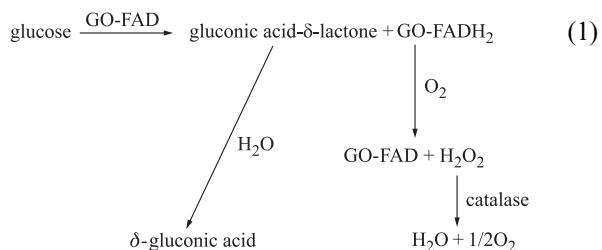

the published information indicates that for some cheese types, lysozyme is a suitable substance for the control of late blowing, provided the number of clostridial spores is low. For these cheese types, which may be considered less sensitive to

late blowing, the level of lysozyme already permitted by regulatory authorities in a number of countries appears to be satisfactory until further evidence is obtained. Lysozyme appears to be of value in the control of late blowing in countries which prohibit nitrate. Published information indicates that in some cheese types which are very sensitive to late blowing, such as Gouda, lysozyme used at the current normal addition under normal manufacturing and storage conditions is less effective than the usual amount of nitrate. In this case, lysozyme can not be considered a suitable alternative to nitrate at present. More information will become available for the various cheese types about the critical number of spores in the raw milk to cause defects when lysozyme is used. Combinations of lysozyme addition and other control measures can then be evaluated further.

Lysozyme appears to be quite effective against *Listeria monocytogenes* and other bacteria involved in foodborne diseases and food spoilage (105). Considering the widespread attention now focused on *Listeria* in dairy products, especially cheeses, it is likely that this application of lysozyme will be the subject of further research. The preservative effects of lysozyme in other foods were reviewed by Proctor and Cunningham (99) and Cunningham et al. (100). It is possible that some of these may be applicable to dairy products.

## VI. GLUCOSE OXIDASE

Glucose oxidase (GO) catalyzes the oxidation of glucose to gluconic acid (via gluconic acid- $\delta$ -lactone) according to the following reactions (106):

The hydrogen peroxide formed is normally reduced by catalase present as a contaminant in commercial preparations of GO (from *P. notatum*, *P. glaucum*, or *A. niger*) or added separately. GO, which has a pH optimum  $\sim 5.5$ , is highly specific for D-glucose and is used to assay specifically for D-glucose in the presence of other sugars, blood, urine, etc.

In the food industry, GO has four principal applications, which are not commercially very significant, especially in the dairy industry (1, 106, 107):

1. *Removal of residual, trace levels of glucose.* This application, which is particularly useful for the treatment of egg white prior to dehydration (although an alternative procedure using yeast fermentation is more commonly used), is of little if any significance in dairy technology.

2. *Removal of trace levels of oxygen.* Traces of oxygen in wines and fruit juices cause discoloration and/or oxidation of ascorbic acid. Chemical reducing agents may be used to scavenge oxygen, but enzymatic treatment with GO may be preferred. The GO system has been proposed as an antioxidant for high-fat products, such as mayonnaise, butter, and whole milk powder, but it does not appear to be used commercially for this purpose, probably because of cost vis-à-vis chemical antioxidants (if permitted) and the relative effectiveness of inert gas flushing of canned milk powder.

3. *Generation of hydrogen peroxide in situ.* The hydrogen peroxide generated by glucose oxidase has a direct bacteriocidal effect (which is a useful side effect of GO applied to egg products), but its bacteriocidal properties can be much more effectively exploited as a component of the lactoperoxidase/hydrogen peroxide/thiocyanate system (see Sec. X). Two components of this system occur naturally in milk: lactoperoxidase is present at  $\sim 30 \text{ mg/L}$ , and thiocyanate, produced in the rumen by hydrolysis of thioglucosides from members of the Brassicaceae family, varies from 0.017 to 0.26 mM. Hydrogen peroxide does not occur naturally in bacteria-free milk, but it can be generated metabolically by catalase-negative bacteria, added directly (which is usually preferred) or produced in situ from sodium percarbonate or by the action of xanthine oxidase on added hypoxanthine or by the action of glucose oxidase on glucose, either added or produced in situ from lactose by  $\beta$ -galactosidase. Activation of the lactoperoxidase-hydrogen peroxide-thiocyanate system suppresses the growth of psychrotrophs in milk stored at  $5^\circ\text{C}$  and has given promising results as a milk preservative in tropical regions where refrigeration is lacking. It would appear that in such applications the use of exogenous hydrogen peroxide is the simplest and most appropriate.

4. *Production of acid in situ.* Direct acidification of dairy products, particularly cottage, feta-type, and mozzarella cheeses, is now fairly common. Acidification is normally performed by addition of acid or acidogen (usually gluconic acid- $\delta$ -lactone) or by a combination of acid and acidogen. In situ produc-

tion of gluconic acid from added glucose or from glucose produced in situ from lactose by  $\beta$ -galactosidase or from added sucrose by invertase has been proposed (108). It is possible to produce gluconic acid from glucose using immobilized glucose oxidase. However, it is doubtful whether immobilized glucose oxidase could be applied to the acidification of milk because of the high probability of fouling by precipitated protein even if low temperatures at which less extensive casein precipitation occurs were used.

## VII. SUPEROXIDE DIMUTASE

Superoxide dismutase (SOD) catalyzes the reduction of superoxide anions,  $\text{O}_2^-$ , according to the following:

The hydrogen peroxide formed may be reduced by catalase, peroxidase, or a suitable reducing agent. SOD occurs widely in tissues where it plays a major antioxidant role in scavenging superoxide radicals which are produced through the action of several enzymes, e.g., XO and peroxidases.

Milk contains a low level of indigenous SOD which has been isolated and characterized (101, 102); the milk enzyme appears to be identical to SOD from bovine erythrocytes. The level of indigenous SOD in milk, which is entirely in the skim phase, varies considerably among individual cows, with stage of lactation and mastitic infection. It may play a role in the oxidative stability of milk, but attempts to correlate stability with SOD activity have been inconclusive, presumably owing to the interaction of various pro- and antioxidants. The tendency of fat in milk to oxidize is directly correlated with increases in XO and negatively with increases in SOD activity. A low level of exogenous SOD, together with catalase, is a very effective antioxidant in dairy products, and it has been suggested that treatment of milk with SOD may be effective in preserving the flavor of UHT milk which is prone to lipid oxidation (1). It has been reported that a combination of SOD and catalase is a more effective antioxidant than butylated hydroxyanisole. However, it appears to be ineffective as an antioxidant in the presence of  $0.1 \text{ ppm Cu}^{2+}$ , apparently because  $\text{Cu}^{2+}$  effectively competes with SOD for  $\text{O}_2^-$  and converts it to lipid-reactive species such as  $\cdot\text{OH}$ . The commercial feasibility of using SOD as an antioxidant depends on cost, particularly vis-à-vis chemical antioxidants, if permitted. As far as is known, SOD is not used commercially as an antioxidant in the dairy industry.

## VIII. SULFHYDRYL OXIDASE

Milk contains an enzyme capable of oxidizing sulfhydryl groups to disulfides:

The enzyme, which has molecular and catalytic properties distinctly different from thioloxidase (EC 1.8.3.2), glutathione:protein disulfide oxidoreductase (EC 1.8.4.2), and protein disulfide isomerase (EC 5.3.4.1), has been isolated and well characterized (101, 102). Sulfhydryl oxidase (EC 1.8.3.-) also has been demonstrated in human milk.

It has been proposed that sulfhydryl oxidase has a physiological role in the formation of disulfide bonds in vivo to give proteins the correct three dimensional structure. Industrially, the potential of the enzyme lies in its ability to ameliorate the cooked flavor of UHT-treated milk (1, 109). The milk enzyme occurs exclusively in the serum (whey) from which it may be easily isolated by exploiting its marked tendency to aggregate, thus facilitating its isolation by chromatography on porous glass. The enzyme has been immobilized on porous glass and titanium oxide, and its effectiveness in ameliorating the cooked flavor of UHT-treated milk has been demonstrated on a pilot scale using immobilized enzyme columns. For industrial-scale use, an adequate supply of the enzyme from whey may be a limitation but production of the enzyme by genetically engineered microorganisms might be feasible.

## IX. CATALASE

Hydrogen peroxide is used for the cold-sterilization of milk in regions lacking refrigeration and perhaps in some developed countries also; e.g., it may be used to treat cheese milk in the United States (1, 107). In underdeveloped regions, treatment of milk with  $\text{H}_2\text{O}_2$  is performed at ambient temperature and excess  $\text{H}_2\text{O}_2$  is reduced by indigenous milk catalase or by chemical interaction with milk proteins in which it causes some physicochemical changes, principally oxidation of methionine, with adverse effects on cheese quality. Side effects can be decreased by short exposure to  $\text{H}_2\text{O}_2$  at  $\sim 65^\circ\text{C}$ , after which the residual  $\text{H}_2\text{O}_2$  is reduced by added catalase, usually from beef liver or *Aspergillus niger*. Most of the recent interest in the use of  $\text{H}_2\text{O}_2$  as a preservative for milk has focused on the lactoperoxidase- $\text{H}_2\text{O}_2$ -thiocyanate system in which

low concentrations of  $\text{H}_2\text{O}_2$  are required (see Sec. X). However, at 400 mg/kg,  $\text{H}_2\text{O}_2$  alone is a more effective long-term bactericidal agent than 8.5 mg/kg  $\text{H}_2\text{O}_2$  in the lactoperoxidase system. There was no significant difference in the quality of cultured milk made from either lactoperoxidase-activated or  $\text{H}_2\text{O}_2$ -treated milk. The activity of lactic starter was significantly lower in the former, but the rennet coagulability of the latter was extended.

There is interest in using immobilized catalase reactors for milk pasteurization or for glucose oxidase-catalase reactors. Although catalase may be readily immobilized, it is inactivated rapidly on exposure to hydrogen peroxide. Hydrogen peroxide appears to be an effective agent for inactivation of aflatoxin M<sub>1</sub>. As discussed above, catalase, usually as a contaminant, is necessary for many of the applications of glucose oxidase and also to optimize the antioxidative properties of SOD.

## X. LACTOPEROXIDASE

Bovine milk is rich in lactoperoxidase ( $\sim 30 \mu\text{g}/\text{mL}$ ), which is distinct from the myloperoxidase of leucocytes and salivary peroxidase. Lactoperoxidase has been purified by several investigators and well characterized (109–112).

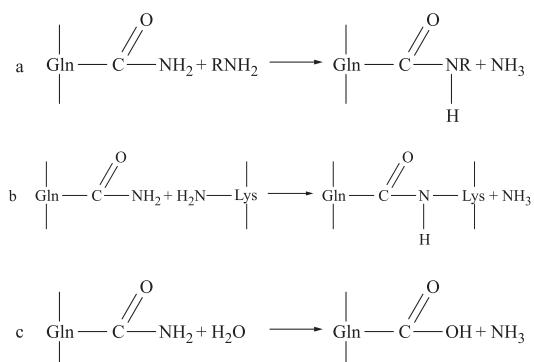

The most important physiological and technological feature of lactoperoxidase is its ability, in the presence of  $\text{H}_2\text{O}_2$  and thiocyanate, to inhibit the growth of several bacteria. Since lactoperoxidase is relatively heat resistant, there is adequate lactoperoxidase activity even in milk that has been moderately to severely heat-treated. Thiocyanate occurs in many animal tissues and fluids. It is produced endogenously during the detoxification of thiosulfates and metabolic products of sulfur amino acids and cyanide and from foods containing thioglucosides. Cows on pastures containing clover (rich in RCN) and nongrasses (e.g., Cruciferae containing thioglucosides) yield milk containing higher concentrations of thiocyanide than cows on winter feed or lay pastures. Saliva contains high levels of thiocyanate which is also secreted by gastric mucosal cells. Milk does not contain indigenous  $\text{H}_2\text{O}_2$  but it may be added or produced in situ (see Sec. VI). Thus, bovine milk possesses an effective antibacterial system which probably affects the intestinal microflora of calves (and presumably other species). Lactoperoxidase also appears to protect the mammary

gland against mastitic infection, especially during the dry period. The antibacterial significance of lactoperoxidase in vivo has been reviewed (113, 114). Human milk appears to contain a low level of lactoperoxidase (< 0.1 µg/mL) as well as myloperoxidase and eosinophil peroxidase. The lactoperoxidase system may be exploited in vitro to extend the shelf life of milk under conditions where refrigeration and pasteurization facilities are lacking (111–114).

While most interest in lactoperoxidase has focused on the indigenous enzyme, it may also acquire significance as an exogenous enzyme. Techniques have been developed for the commercial-scale purification of lactoperoxidase from milk (42). Large-scale trials have shown that addition of purified lactoperoxidase to calf milk replacers markedly reduces the incidence of diarrhea and increases weight gain. Although the antibacterial properties of human milk do not depend on lactoperoxidase, its addition to bovine milk-based infant formulae may have beneficial effects (111–114).

## XI. TRANSGLUTAMINASE

Transglutaminase (TGase; protein-glutamine  $\gamma$ -glutamyltransferase; EC 2.3.2.13) catalyzes an acyl transferase reaction between the  $\gamma$ -carboxamide group of peptide-bound glutamine residues (acyl donors) and a variety of primary amines (acyl acceptors), including amino acids, and the  $\epsilon$ -amino group of lysine residues in certain proteins. In the absence of an amine, TGase catalyzes the deamination of glutamine residues, with water molecules acting as acyl acceptors. Thus, TGase can modify proteins by incorporation of (a) an amine, (b) crosslinking, or (c) deamination:

The amino group might be from a simple aliphatic or aromatic amine, an amino acid, an amino sugar, or a phospholipid ( $\beta$ -aminoethanol moiety).

TGase is present in several animal tissues and body fluids and is involved in several biological phenomena,

including blood clotting, wound healing, keratinization of epidermal tissue, and stiffening of cell membranes. An enzyme with a similar activity has been found in the bacterium *Streptoverticillium moharaense*; this is referred to as MTGase (M = microbial). However, TGase and MTGase differ in a number of respects, most notably in molecular weight (~ 77 and ~ 38 kDa, respectively) and dependence on Ca<sup>2+</sup>; TGase requires Ca<sup>2+</sup>, MTGase does not.

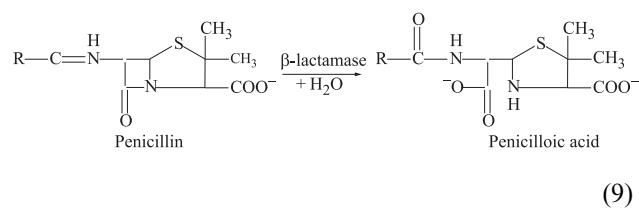

The activity of (M)TGase suggests several possible applications in the food industry:

1. Gelation of proteins by crosslinking
2. Formation of restructured meat and fish products from smaller pieces or comminuted meats
3. Stabilization of protein-stabilized foams or emulsions (by crosslinking proteins in the stabilizing layer)
4. Modification of the functionality, e.g., solubility or water binding, of proteins by converting glutamine to glutamic acid residues or binding of amino sugars or phospholipids
5. Modification of the nutritional value of foods by enzymatically attaching essential amino acids to proteins
6. Conjugation of the same or different proteins
7. Conjugation of amino sugars with proteins
8. Conjugation of phospholipids with proteins
9. Immobilization of enzymes

The feasibility of these applications has been demonstrated in laboratory studies, but the limited availability and cost of the enzyme to date have restricted larger-scale trials (guinea pig liver is the usual source of TGase). However, the gene for TGase has been inserted into microorganisms (115) which would be expected to increase the availability and reduce the cost of the enzyme.

Various aspects of the chemistry of TGase and its applications in foods have been reviewed by Motoki and Seguro (116) and Dickinson (117).

## XII. $\beta$ -LACTAMASE

Residues of penicillin in milk, resulting from treatment of mastitis-infected cows with antibiotics, inhibit or

prevent the growth of lactic acid bacteria used in the production of cheese and fermented milks. They may also evoke an allergic response in susceptible consumers and create conditions for the selection of penicillin-resistant pathogens. The usual approach taken to prevent contamination of the milk supply with antibiotics is to withhold milk from treated cows for an adequate period after treatment; obviously, this results in economic losses to farmers.

Procedures developed for the removal of  $\beta$ -lactam-type antibiotics from milk include columns of activated charcoal, ultrafiltration or diafiltration (1). While these methods may be suitable under certain circumstances, they have obvious limitations. An alternative approach is the inactivation of penicillin by  $\beta$ -lactamase [Eq. (9)].

Korycka-Dahl et al. (118) demonstrated the ability of  $\beta$ -lactamase from *Bacillus cereus* to inactivate penicillin G such that Cheddar or Swiss cheeses of normal quality could be produced from the decontaminated milk. The enzyme was active at 4°C so that penicillin in milk could be inactivated during cold storage on the farm or at the factory. The enzyme lost only 50% of its activity following heating at 63°C for 30 min and hence would retain considerable activity in pasteurized milk, which may be illegal. These problems may be solved by using immobilized  $\beta$ -lactamase (119). This procedure appears promising and awaits further development.

An alternative approach to solving the problems caused by penicillin in fermented products is the selection of  $\beta$ -lactamase-producing mutants of lactic acid bacteria (120).

### XIII. PERSPECTIVES

Owing to the physicochemical properties of its constituents, milk is very amenable to enzymatic modification and it will be apparent from the foregoing that many potential applications of enzymes in dairy technology exist. However, in spite of numerous studies, only a few of these applications are commercially significant. Many of the potential applications are unsuccessful commercially because the proposed application is not sufficiently significant economically or alternative solutions are available.

By far the most important application is the use of rennets in cheese making, for which no alternative exists. It is likely that rennets will remain the principal enzyme in dairy technology for the foreseeable future. An unlimited supply of chymosin from genetically engineered microorganisms is now available; it is possible that the cheese-making properties of these micro-

bial recombinant chymosins will be improved through genetic engineering. The production of cheese is expanding worldwide, and the market for rennets will therefore continue to increase. Development of cheese-like products as food ingredients is a growth area, and it is likely that the application of proteinases and lipases in the production of such products will increase. The use of proteinases and peptidases to produce protein hydrolysates with specific functional, nutritional, or physiological properties appears to be very promising and has been attracting increasing attention.

Lipases have some traditional and novel applications in cheese technology, but the growth potential of these applications is probably limited. However, new and more effective lipases may be identified. Perhaps the greatest potential application of lipases is in the production of tailor-made lipids with superior nutritional or functional properties.

Although  $\beta$ -galactosidase has applications in dairy technology, most of these are not commercially viable at present, mainly for economic reasons. Niche markets exist for lactose-hydrolyzed milks and these may expand. Exploitation of the transferase activity of  $\beta$ -galactosidase in the production of new oligosaccharides with novel functional and/or nutritional properties appears to hold potential.

Transglutaminase should have several interesting applications in dairy technology. The availability of a cheaper enzyme should encourage work on the application of this enzyme.

With the possible exception of lactoperoxidase and lysozyme, the other enzymes discussed in this chapter appear to have very limited application in dairy technology, at least under present circumstances.

## **Flavor Enhancement in Fruit Juices and Derived Beverages by Exogenous Glycosidases and Consequences of the Use of Enzyme Preparations**

**Ziya Günata**

*University of Montpellier II, Montpellier, France*

### **I. INTRODUCTION**

Research over the past two decades has revealed that in a great number of fruit and plant tissues important flavor compounds are glycosylated and accumulate as nonvolatile and flavorless glycoconjugates (1–6). Although results in the literature had long suggested the occurrence of glycosidically bound flavor compounds in plants, the first clear evidence was found in 1969 by Francis and Allcock in rose flowers (7). The work of Cordonnier and Bayonove in 1974, suggesting the occurrence in grapes of important flavor compounds (monoterpene) as glycoconjugates on the basis of enzymatic work (8), was later confirmed by Williams et al. in 1982 by the identification of glycosides (1). These findings opened a new field of intensive research on the chemistry of glycoconjugated flavor compounds to exploit this important flavor source present in both fruit and plant tissues. The expanding literature on the chemistry and occurrence of glycosidically bound volatiles in the plant kingdom has been recently reviewed by Vasserot et al. (9), Stahl-Biskup (4), and Winterhalter and Skouroumounis (6).

This chapter briefly presents the diversity and structure of glycosides found in fruits and plants. Attention will focus on those glycosidases involved in flavor release from glycoconjugated precursors, examining

the properties and current use of these enzymes for flavor enhancement in fruit juices and derived beverages (mainly wines) and future developments. Flavor enhancement by glycosidases has been the subject of a review by the author and colleagues in 1993 (10), and brief summaries are also found in the reviews of Williams (11), Vasserot et al. (9), and Winterhalter and Skouroumounis (6).

### **II. STRUCTURE AND OCCURRENCE OF GLYCOCONJUGATED FLAVOR COMPOUNDS**

The publication of two techniques in 1982 (12) and 1985 (2), which allow the selective retention of glycosides on hydrophobic adsorbents ( $C_{18}$  reversed-phase and Amberlite XAD-2) from the complex matrix of fruit and plant materials, replaced tedious classical techniques and greatly contributed to progress in the field of glycosidic flavor precursors. Once the glycosidic extract is obtained, different liquid chromatography techniques are applied to isolate and purify glycosides. Countercurrent chromatography, which is a liquid–liquid partition chromatography, improved separations especially by eliminating or decreasing the formation of artifacts observed on solid adsorbents (13). Various combined chromatographic and spectral

techniques (GC-MS\*, GC-FTIR, HPLC-MS/MS, FAB-MS/MS) are used for identification. A recent review (6) gives general approaches to the analysis of glycosides with abundant references related to the subject.

Glycosidically bound volatiles identified in fruits and plants are highly complex and diverse, especially with regard to the aglycone moiety. The sugar parts consist of  $\beta$ -D-glucopyranosides and different diglycosides: 6-O- $\alpha$ -L-arabinofuranosyl- $\beta$ -D-glucopyranosides; 6-O- $\alpha$ -L-arabinopyranosyl- $\beta$ -D-glucopyranosides (vicianosides); 6-O- $\alpha$ -L-rhamnopyranosyl- $\beta$ -D-glucopyranosides (rutinosides); 6-O- $\beta$ -D-glucopyranosyl- $\beta$ -D-glucopyranosides (gentiobiosides); 6-O- $\beta$ -D-apiofuranosyl- $\beta$ -D-glucopyranosides; and 6-O- $\beta$ -D-xylylpyranosyl- $\beta$ -D-glucopyranosides (primeverosides) (Fig. 1) (1, 2, 4–7, 14–19). In rare cases trisaccharide glycoconjugates were isolated (6). As far as we are aware, only (1 → 6) intersugar linkages have been detected in plant flavor glycoconjugates, while (1 → 2), (1 → 3), and (1 → 4) linkages together with (1 → 6) linkages were observed for diglycosides of flavonoids (20). Therefore, different glycosyl transferases seem to exist in plants. Recently,  $\beta$ -D-glucopyranosides of some volatiles of fruit and plant tissues have been shown to be acylated at the C-6 hydroxyl group of the sugar moiety with malonic acid (21, 22). Malonylated glycoconjugates of flavonoids are often detected in plants (20).

A common feature of glycosidic flavor precursors is that the aglycone moiety is always linked to  $\beta$ -D-glucopyranose. To date ~200 aglycones have been identified in 150 plant species (4, 6). The aglycone moiety is predominantly mevalonic acid (monoterpene, C<sub>13</sub>-norisoprenoids, sesquiterpenes), and shikimic acid-derived secondary metabolites. Medium-chain alkanols and alkenols have also been detected. Some abundant and important aglycones for flavor are given in Figure 1. Further information can be obtained from the reviews (4, 6).

Glycoconjugates of flavor compounds are present in several fruits, such as grape (1, 2, 19), apricot (3, 23), peach (3), yellow plum (3), quince (24), sour cherry (25), passion fruit (15, 26), kiwi (27), papaya (28, 29), pineapple (30), mango (31), lulo (32), raspberry

(33), and strawberry (34). The amount of glycosidically bound volatiles is typically two to eight times greater than that of their free counterparts (2, 3, 19). Moreover, most norisoprenoids in fruit, some of which are precursors of very potent flavor compounds, have been detected mainly in glycosidic forms. This, together with the low aroma threshold and sensory properties of aglycones, makes the glycosidic compounds an important potential source of flavor volatiles during fruit juice processing.

The glycosidically bound volatiles can be released by either acid or enzyme hydrolysis (1, 2, 36). Slow acid hydrolysis takes place at fruit juice pH (35) and can be accelerated by thermal treatment (36–38). This treatment, however, can reduce the sensory quality of the products (38).

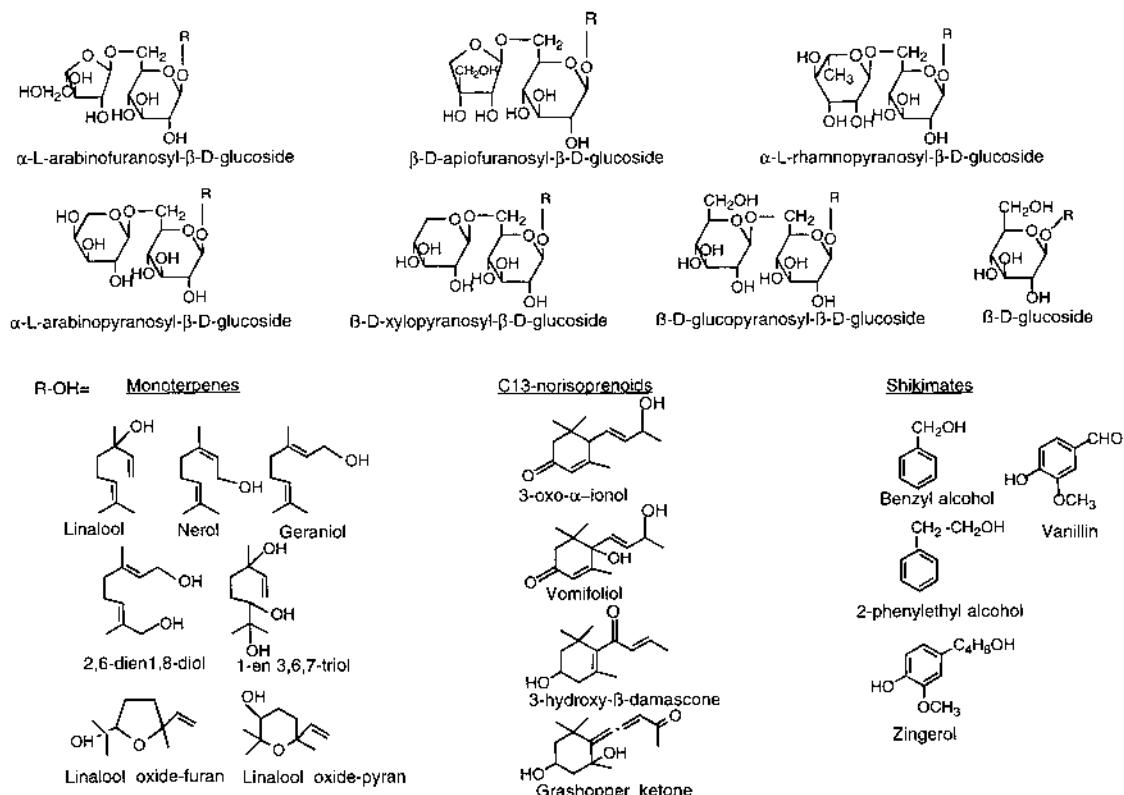

Some aglycones are already odorous when released from glycosides. They can therefore contribute to the floral aroma of some wines (36, 39), grapes (10, 36, 39), apricots (40), peaches (41), and tea (5, 7, 16, 17). This is the case, for example, of monoterpene such as geraniol, nerol and linalool which possess mainly floral attributes and low odor thresholds (100–400 ppb in water) (39).

In contrast, polyhydroxylated monoterpenes (polypols) and the majority of norisoprenoids are odorless, but can generate potent aroma compounds due to their reactivity in the acidic medium (pH 2.8–3.8) of fruit juices (36, 37, 42). For example, some hydroxylinalool derivatives can give rise at ambient temperature and grape juice pH (3.0–3.6), to the formation of odorous monoterpenes, such as hotrienol, nerol oxide, and linalool oxides (37). The review by Strauss et al. discusses the acid catalyzed conversions of monoterpenes and role of these compounds in grape and wine flavor (36).

Potent C<sub>13</sub>-norisoprenoid flavorants in fruit- and plant-derived products, such as theaspiranes, viti-spiranes, edulans, and  $\beta$ -damascenone, are similarly generated from relevant progenitors by acid-catalyzed reactions. The major pathways leading to these flavor compounds are discussed in the review by Winterhalter (42). For example,  $\beta$ -damascenone, which is among the most potent flavoring substances known to date (odor threshold 2 ppt in water; floral, fruity, and iononelike odor) (43), can be generated from multiple glycosylated precursors detected in fruits and plants (42).

Glycosylated volatile compounds in plants are often considered as physiologically inactive plant storage and transport forms of secondary metabolites. However, their exact role is far from understood (4).

### III. ENZYMES INVOLVED IN THE RELEASE OF FLAVOR COMPOUNDS FROM GLYCOSIDES

The elucidation of the enzymes responsible for the release of flavor compounds from glycosides is the first step in the development of technological applications. Glycosidases catalyze hydrolysis of the glycosidic bond of their carbohydrate substrates by two general mechanisms, leading to either the retention or inversion of the anomeric configuration at the cleavage point (44). The mechanism of hydrolysis is presumed to proceed in the same way as the acid-catalyzed cleavage of glycosidic bond, via a carbocation intermediate. Glycosidases discussed here refer to those enzymes which catalyze the hydrolysis of *O*-glycosyl compounds.

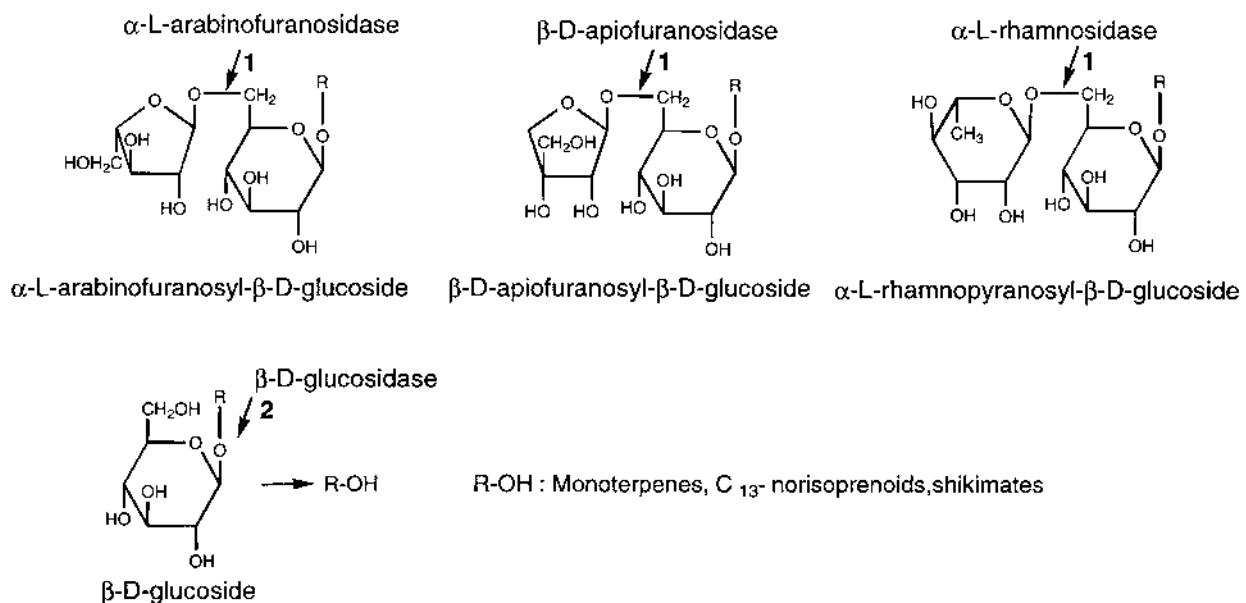

As had been suggested as early as 1913 (45) and 1924 (46), volatile compounds (monoterpene, vanillin) can be liberated from  $\beta$ -D-glucosides through the action of  $\beta$ -glucosidase (EC 3.2.1.21). The involvement of enzymes in the release of volatiles from disaccharides, however, was shown only recently because the relevant substrates were first reported in 1982 (1). As

will be later discussed, the release of the aglycone moiety may occur through two-step (sequential hydrolysis) or one-step (endoglycosidase) enzyme-catalyzed reactions. The term "endoglycosidase" is used in this chapter for glycosidases involved in flavor release as a function of their catalytic activities.

#### A. Sequential Hydrolysis

Preliminary work carried out on the hydrolysis of grape glycosides, by using fungal enzyme preparations (pectinases, hemicellulases, and glucanases), has shown that the release of flavor compounds depends on the presence of glycosidases as side activities in the enzyme preparations (47). With the aid of suitable analytical techniques (TLC, HPLC, GC/MS), a study using purified glycosidases and synthesized substrates was able to elucidate the sequential reaction involved in the hydrolysis of disaccharidic flavor precursors (Fig. 2) (48).

First, the inter-sugar linkage is cleaved by exoglycosidases; either an  $\alpha$ -arabinofuranosidase (EC 3.2.1.55), an  $\alpha$ -rhamnopyranosidase (EC 3.2.1.40), or a  $\beta$ -apiofuranosidase depending on the disaccharidic moiety.

**Figure 2** Sequential enzymatic hydrolysis of disaccharidic flavor precursors.

This releases terminal sugars and  $\beta$ -D-glucosides. Subsequently,  $\beta$ -glucosidase cleaves the aglyconic linkage of  $\beta$ -D-glucosides to liberate volatiles. This hydrolysis mechanism has been patented (49). Such two-step reactions, involving exoglycosidases (5, 6, 50, 51), are also possible in the hydrolysis of diglycosides of fruit or plant volatiles, which possess  $\alpha$ -L-arabinopyranosyl,  $\beta$ -D-xylopyranosyl or  $\beta$ -D-glucopyranosyl as terminal sugars.

### B. One-Step Hydrolysis of Disaccharide Glycosides (Endoglycosidase)

This one-step reaction occurs through the cleavage of the aglyconic linkage which yields a disaccharide and aglycone, the identity of which were confirmed by HPLC and GC/MS analysis (Fig. 3) (5, 51). The enzymes catalyzing this reaction were isolated from tea leaves (5) and grapes (51). The enzyme from tea is called primeverosidase, after primeverosides, which are the most abundant glycoconjugated flavors in this plant.

### IV. OCCURRENCE OF GLYCOSIDASES

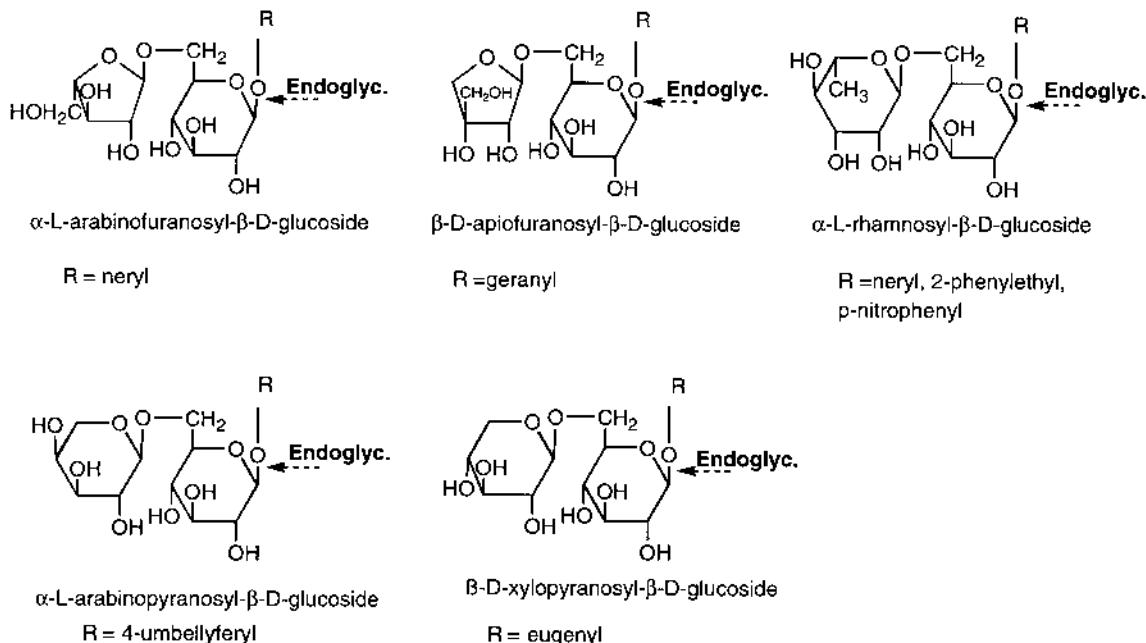

Exoglycosidases involved in flavor release are widely distributed among plants (10, 52–60) and microorganisms (61–66). The enzymes presented here mainly concern those found in fruits or plants where the occurrence of glycoconjugated flavors has been

demonstrated. With regard to microbial enzymes, mainly those originating from GRAS (generally recommended as safe) will be discussed.

#### A. Plant-Originated Glycosidases

Most work has been devoted to grape glycosidases because the first evidence of multiple forms of glycosidic flavor precursors was found in this fruit.  $\beta$ -Glucosidase (55, 56, 69, 67, 68),  $\alpha$ -arabinofuranosidase (56, 59),  $\alpha$ -arabinopyranosidase (19),  $\alpha$ -rhamnopyranosidase (56, 69), and  $\beta$ -xylosidase (51) activities were detected in grapes of various cultivars. The presence of  $\beta$ -apiosidase in grapes has not yet been confirmed. On the basis of glycosidase activity determinations with pNP-glycosylated substrates,  $\beta$ -glucosidase activity is considered the most important. Multiple forms of  $\beta$ -glucosidase exist in grape berries (51, 55, 59) and are also found in almond emulsin (69) but not in papaya fruit (54). The enzyme from papaya fruit, unlike that from grapes, is readily soluble and does not require the use of detergent for extraction.

Glycosidases are found predominantly in grape skins (67, 68), although contradictory results may arise owing to the enzyme extraction method employed (59).  $\beta$ -Glucosidase,  $\alpha$ -arabinofuranosidase, and  $\alpha$ -rhamnosidase activities have been shown to increase during the ripening of grape berries (56, 59, 67), unlike  $\beta$ -glucosidase activity from papaya fruit which is unaffected by the ripening stage of the fruit (54).

**Figure 3** One-step hydrolysis of disaccharidic flavor conjugates by grape endoglycosidase.

The presence of  $\beta$ -glucosidase activity has also been reported in vine leaves (59, 67) where flavor glycoconjugates are abundant (70). It should be noted that glycosidases substrates other than glycosidic flavor conjugates are found in plants. Indeed, many of the secondary metabolites synthesized are glycosylated, and > 1500 flavonoid glycosides have been characterized (71).

Endoglycosidase, active on disaccharidic flavor precursors in fruits, has been recently isolated and partially characterized from grape skins (51). The extraction was only possible with the use of a detergent, the type of which greatly influenced the yield. In contrast, the extraction of tea enzyme (primeverosidase) was possible without the use of detergent (5, 72). This suggests that the structure of grape endoglycosidase differs from that obtained from tea and/or could be a membrane-bound protein. Moreover, although needing confirmation, grape endoglycosidase also seems to possess  $\beta$ -glucosidase activity (51).

## B. Fungal-Derived Glycosidases

These can be present in fruit due to the development of fungi such as *Botrytis cinerea*. Other filamentous fungi, for example *Aspergillus* sp., and yeast are also able to produce glycosidases.

### 1. *Botrytis cinerea*

The ability of *B. cinerea* to produce  $\beta$ -glucosidase (64, 65) and  $\alpha$ -arabinofuranosidase (62) when cultured in a suitable medium was shown. Grape berries contaminated by fungi such as *B. cinerea* were found to contain higher levels of  $\alpha$ -arabinofuranosidase and  $\alpha$ -rhamnosidase activities compared to uncontaminated grapes (56). This fungus has been shown to exhibit these same activities when developed on grape juice (56). In these conditions,  $\beta$ -glucosidase is also produced but its activity is strongly inhibited by glucono- $\delta$ -lactone which is produced from glucose through glucose oxidase activity of the fungus (10, 56). The presence of gluconolactone in grapes is one of the major limitations on flavor release by glycosidases and will be discussed later.

The development of *B. cinerea* on grapes has a very detrimental effect not only on the flavor of juice and wine, through the degradation of monoterpenes (73–75) and fatty acid esters (76), but also on the overall quality due to the action of several enzymes produced by the fungus (77–79).

### 2. Yeast

In wine making the alcoholic fermentation is essentially performed by yeast *Saccharomyces cerevisiae*.  $\alpha$ -Arabinofuranosidase (80),  $\alpha$ -rhamnosidase (80), and

$\beta$ -glucosidase (80, 81) activities were only detected at low levels in juices and in cells during fermentation.  $\beta$ -Glucosidase activity was the most abundant, followed by  $\alpha$ -arabinofuranosidase activity. The activities reached their maximum levels during exponential growth of the yeast population, then dropped dramatically. No differences have been observed among enological yeast (*S. cerevisiae*) strains in the production of glycosidases during fermentation (80).

Owing to the low level of glycosidases production by *S. cerevisiae*, a recombinant yeast strain, expressing  $\beta$ -glucosidase from *C. molischiana* (82) and  $\alpha$ -arabinofuranosidase from *A. niger* (83), has been recently constructed. The relevant proteins were detected during grape juice fermentation, although poor secretion of the *C. molischiana* protein was observed. There is a lack of data on the contribution of these recombinant yeast strains to flavor release during fermentation.  $\beta$ -Glucosidases from *Kluyveromyces fragilis* (84), *A. niger* (6), and *Bacillus polymyxa* (85) have been expressed in *S. cerevisiae* in order to obtain strains able to ferment disaccharides (cellobiose and lactose).

The yeast species from the genera *Saccharomyces* (63, 86), *Dekkera* (87), *Debaryomyces* (88, 89), *Kloeckera* (90), *Hansenula* (91), and *Candida* (92–95) are able to synthesize  $\beta$ -glucosidase when cultured on carbon sources such as glucose, cellobiose, xylose, and alkyl thioglucosides. The lowest enzyme synthesis is generally found in the *Saccharomyces* spp. Except for *Candida* and *Debaryomyces* spp., yeast seldom secretes  $\beta$ -glucosidase into a growth medium. The enzyme is

localized at the cell membrane and in the cytoplasm (63, 87, 93, 96).

### 3. Filamentous Fungi

Filamentous fungi, particularly *Aspergillus* sp., are good producers of exoglycosidases and used in industry to obtain pectic and hemicellulase enzyme preparations (61, 97, 98). These preparations are widely used in fruit juice processing and winemaking, mainly to improve juice clarification and yield. In addition to their main activities, they contain several other enzyme “side activities” including glycosidases.  $\beta$ -Glucosidase and  $\alpha$ -arabinofuranosidase are often the most abundant, followed by  $\alpha$ -rhamnosidase, while  $\beta$ -apiosidase is rarely detected (10) (Table 1). The production of  $\beta$ -apiosidase by *A. niger* appears to be inducible because, unlike  $\beta$ -glucosidase, which is a constitutive enzyme in fungi, it requires the presence of a carbon source inducer such as apiin (a trihydroxyflavone-apiosyl (1 → 2) glucoside) (99). Enzyme preparations shown in Table 1 differ notably in their glycosidase activity levels. Furthermore, these levels vary greatly from one batch to another, as current pectinase enzyme preparations are formulated by producers as a function of their main activities.

The production by fungi of endoglycosidase, capable of hydrolyzing disaccharidic conjugates of flavor compounds, has to date been the subject of only one paper. An *A. niger* strain was shown to produce such an enzyme (an endo- $\beta$ -glucosidase) when cultured on rutin as the sole carbon source (100).

## V. ENZYME ASSAY METHODS

The substrates used may be composed either of a mixture of glycosides isolated from fruits and plants by selective retention on hydrophobic adsorbents (2, 12), or of purified and synthesized natural glycosides (6, 35, 101, 102). Alternatively, artificial *p*NP-glycoconjugated substrates are often used.

Glycosidase activities can be determined by two techniques:

1. Direct analysis of glycosides by chromatographic techniques (TLC, HPLC, GC) (2, 5, 6, 19, 35, 48, 51).

Before GC analysis, a derivatization step, generally involving the silylation and trifluoroacetylation of glycosides, is carried out in order to obtain their volatile forms.

2. Analysis by colorimetric or chromatographic (TLC, HPLC, CPG) techniques of aglycone or sugar moieties (monosaccharides or disaccharides) released from glycosides (2, 5, 48, 51, 103). In the case of aglycone liberated by enzymatic hydrolysis from natural glycosides, the volatiles are recovered from the enzyme assay before GC analysis, by either liquid-liquid extraction with a solvent or selective retention on hydrophobic adsorbents (2, 6, 12). A colorimetric assay of monoterpenes (aglycones) liberated from sugars has also been proposed (104).

*p*NP-glycoconjugated substrates are widely used as the standard for assaying glycosidase activities using mainly colorimetric techniques owing to their ready availability (except for certain disaccharidic substrates) and the simplicity of the analysis. Often, this analysis does not reflect the catalytic characteristics of enzymes, owing to the presence of multiple forms of glycosidases and, in some cases, the narrow aglycone specificity (see Sec. VI.C).

## VI. FOOD-PROCESSING PROPERTIES OF GLYCOSIDASES

This section will examine the properties of enzymes, focusing on the specific conditions encountered in the processing of fruit juice and derived beverages. In particular, three important parameters influencing flavor release will be discussed: the effect of pH; aglycone and sugar specificity of glycosidases; and inhibition of activity by sugar and sugar analogues. A summary of the properties of  $\beta$ -glucosidase from some plants and microorganisms is given in [Table 2](#).

### A. Effect of pH on Activity and Stability

The optimum pH activity of plant  $\beta$ -glucosidase (55, 59) and endoglycosidase (51) is similar (5.0–6.0) to that of intracellular yeast  $\beta$ -glucosidase (63, 87, 93, 105). This value is generally lower (4.0–5.0) for extracellular yeast (63, 92, 93) and *Aspergillus* enzymes (10, 61, 106). The optimum pH of an extracellular endo- $\beta$ -glucosidase from *A. niger* was found to be unusually low (3.4) (100). Most  $\beta$ -glucosidases exhibit only 5–15% of their maximum activity in the pH range of fruit juices (2.8–3.8).

*A. niger*  $\alpha$ -arabinofuranosidase (62, 107) and  $\alpha$ -rhamnosidase (47, 108) possess similar pH optima to that of extracellular  $\beta$ -glucosidase from the same fungus, while the value for *A. niger*  $\beta$ -apiosidase is higher (5.0–6.0). (10, 99, 106). Both  $\alpha$ -arabinofuranosidase and  $\alpha$ -rhamnosidase exhibit >50% of their maximum activities in the pH range of fruit juices.

An important parameter that must be considered for technological applications is the stability of glycosidases in the acidic pH of fruit juices. Glycosidases differ notably in this respect ([Fig. 4](#)) (10).

$\beta$ -Glucosidases from grapes, *S. cerevisiae*, and *C. wickerhamii*, are not very stable in these conditions. For example, *C. wickerhamii*  $\beta$ -glucosidase was able to hydrolyse  $\beta$ -D-glucosides of monoterpenes in a wine only when the initial pH (3.0) was adjusted to 3.5 or higher (109). Only 10% of initial  $\beta$ -glucosidase activity from *S. cerevisiae* was observed after 90 min incubation (20°C) in a buffer at pH 3.0. (10). This may explain the large decrease in *S. cerevisiae*  $\beta$ -glucosidase activity during grape juice fermentation. In fact the optimum pH stability of the enzyme corresponds to the pH of yeast cells (6.0). This decrease is also observed for  $\alpha$ -rhamnosidase and  $\alpha$ -arabinofuranosidase activities from *S. cerevisiae* during juice fermentation (10, 80). A  $\beta$ -glucosidase from *C. peltata* was fairly stable at pH 3.5–6.0 (95). The enzyme from a mutant strain of *C. molischiana* was shown to be more stable at acidic pH than an enzyme from a wild-type strain (110,111). This difference could be explained by the difference in glycosylation of the relevant proteins.

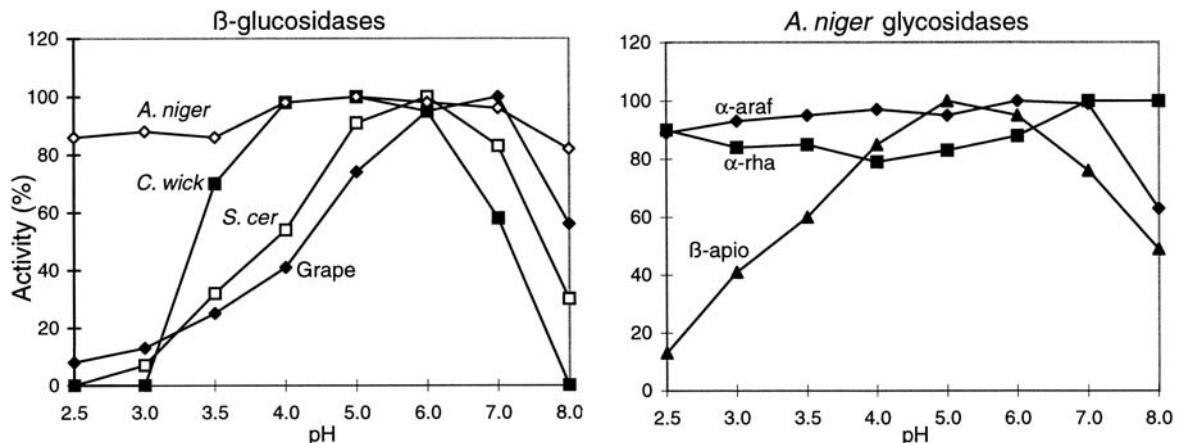

In contrast,  $\beta$ -glucosidase,  $\alpha$ -arabinofuranosidase, and  $\alpha$ -rhamnosidase from *A. niger* are remarkably stable over a pH range of 2.5–7.0 ([Fig. 4](#)) (10, 62, 106). The enzymes exhibit >80% of their maximum activity after 24 h of incubation in a buffer at pH 3.0. However, *A. niger*  $\beta$ -apiosidase was less stable at a pH < 4.0 (10, 106). The same trends were observed when the stability of *A. niger* glycosidases were monitored during grape juice fermentation at 20°C (pH 3.0)

<sup>a</sup>Temperature at which rapid inactivation occurs.

n.d., not determined; (i), intracellular; (e), extracellular.

**Figure 4** Effect of pH (phosphate-citrate buffer) on stability of glycosidases of *A. niger* (24 h, 30°C), *C. wickerhamii* (1 h, 30°C), *S. cerevisiae* (90 min, 20°C), and grape (24 h, 30°C). (From Ref. 10.)

(106).  $\beta$ -Glucosidase and  $\alpha$ -arabinofuranosidase activities remained practically unchanged after 7 days, while only 70% of initial  $\alpha$ -rhamnosidase and 50% of  $\beta$ -apiosidase activities were observed. This remarkable stability of extracellular *A. niger* enzymes is interesting for fruit juice processing and could be explained by the glycosylation of proteins (110, 112).

### B. Effect of Temperature

The optimum temperature activities of plant (54, 55) and yeast  $\beta$ -glucosidases (63, 89, 93, 95) is generally lower (45–50°C) than that (50–60°C) of *A. niger* enzymes (61, 106, 113). At the normal temperature (20°C) of grape juice fermentation, for example, glycosidases exhibit only 10–20% of their maximum activity.

Rapid inactivation of glycosidases occurs at temperatures > 50°C, (55, 63, 99, 113), although some filamentous fungal  $\beta$ -glucosidases are only inactivated at temperatures > 65°C (61). The pH of the medium plays an important role in the thermal denaturation of glycosidases. In general, glycosidases from filamentous fungi are more heat stable than those from yeasts and plants (61, 63).

### C. Aglycone and Sugar Specificity of Glycosidases

The hydrolysis of monoterpenyl diglycosides by exoglycosidases— $\alpha$ -arabinofuranosidase (48, 107),  $\alpha$ -arabinopyranosidase (50, 114),  $\alpha$ -rhamnosidase (48), and  $\beta$ -apiofuranosidase (99, 106)—is not significantly influenced by the structure of the aglycone moiety. This is

not very surprising since  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra of disaccharide glycosides show that the orientation of the terminal sugar is unaltered whether the monoterpenyl moiety is a primary or tertiary alcohol (35, 101).

The hydrolysis of monoterpenyl  $\beta$ -D-glucosides by plant (grape and almond; 2, 19, 55, 59, 115), fungal (yeast, *A. niger*; 10, 89, 115, 116), and bacterial (*B. polymyxa*; 117)  $\beta$ -glucosidases is, however, greatly influenced by the structure of the aglycone. Plant  $\beta$ -glucosidases showed a pronounced specificity and acted on  $\beta$ -D-glucosides of primary alcohols (e.g., geraniol, nerol, and citronellol) but not on those of tertiary alcohols (e.g., linalool,  $\alpha$ -terpineol, linalool oxides) which, when hydrolyzed, can give rise to potent volatils. This shows the limitations in flavor recovery with plant endogenous  $\beta$ -glucosidases in fruit juice processing.

The aglycone specificity of  $\beta$ -glucosidases from *S. cerevisiae* and *B. polymyxa* resembled grape and almond  $\beta$ -glucosidases more than microbial enzymes from *Aspergillus*, *Candida*, *Debaryomyces* spp. The latter were able to catalyze the hydrolysis of both monoterpene primary and tertiary alcohol  $\beta$ -D-glucosides.

The rate of hydrolysis of  $\beta$ -D-glucosides of monoterpene primary alcohols by various  $\beta$ -glucosidases was found to be higher than that of  $\beta$ -D-glucosides of tertiary alcohols (115, 116). These results are in general agreement with the catalytic activity of almond emulsin  $\beta$ -glucosidase on other primary and tertiary alkyl- $\beta$ -D-glucosides (118). It is interesting to note that the opposite results were obtained when the acid-catalyzed hydrolysis of these substrates was performed (119).

Furthermore, the configuration of monoterpenes has an effect on the rate of hydrolysis since diastereoisomeric monoterpenyl  $\beta$ -D-glucosides (linalool,  $\alpha$ -terpineol, and citronellol) and isomeric monoterpenyl  $\beta$ -D-glucosides (geraniol and nerol) are hydrolyzed at different rates by enzymes (115, 116). For example, geranyl- $\beta$ -D-glucoside was often hydrolyzed at a higher rate than neryl- $\beta$ -D-glucoside.

The  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra of  $\beta$ -D-glucosides of monoterpene primary and tertiary alcohols differ in the orientation of the  $\beta$ -D-glucopyranosidic linkage (35, 101), which may partly explain differences observed in enzymatic hydrolysis. The conclusion reached from these results is that the source of the  $\beta$ -glucosidase can influence the pattern of liberated aglycones and thereby the sensory properties of products.

Little work has been devoted to the determination of the affinity of  $\beta$ -glucosidases for glucosidic flavor precursors. Among the substrates tested (geranyl, neryl, and citronellyl  $\beta$ -D-glucosides), grape enzyme showed the highest affinity for geranyl- $\beta$ -D-glucoside (55). Additionally, differences were observed between two  $\beta$ -glucosidases isolated from grapes with regard to their affinity for monoterpenyl  $\beta$ -D-glucosides. Two  $\beta$ -D-glucosidases isolated from *A. niger* differed also significantly in their affinity toward geranyl  $\beta$ -D-glucoside and malvidin  $\beta$ -D-glucoside (participating in the red color; see Sec. VII.B) (103) and monoterpene tertiary alcohol  $\beta$ -D-glucosides (115). It is worthwhile to note that often multiple forms of glycosidases were detected in plants (53, 55, 120) and microorganisms such as fungi (61, 103, 106). This emphasizes the importance of the use of natural substrates to determine the catalytic properties of enzymes, as suggested by Hösel and Conn (120), instead of commonly used artificial substrates (*p*NP-glycosides).

With regard to endoglycosidase, the enzyme from grapes shows a broad specificity toward the sugar moiety of disaccharides (51). The enzyme is active against arabinofuranosyl, rhamnopyranosyl, and apiofuranosyl ( $1 \rightarrow 6$ ) glucosides from grapes. Arabinopyranosyl and xylopyranosyl ( $1 \rightarrow 6$ ) glucosides moieties from passion fruit (15) and tea leaves (5), respectively, are also substrates for the enzyme.

$\beta$ -Primeverosidase from tea leaves also shows fairly broad specificity toward disaccharide glycosides. Xylopyranosyl ( $1 \rightarrow 6$ ) glucosides and apiofuranosyl ( $1 \rightarrow 6$ ) glucosides are better substrates than arabinopyranosyl and arabinofuranosyl ( $1 \rightarrow 6$ ) glucosides (121).

Work carried out on other plant endoglycosides has mainly focused on the hydrolysis of flavonoid glyco-

sides. An enzyme from *Viburnum furcatum* was found to be very specific to the apiosyl ( $1 \rightarrow 6$ ) glucoside unit (122). Glycosides possessing rutinose and apiosyl ( $1 \rightarrow 2$ ) glucoside as sugar moiety were not substrates. In contrast, the latter was substrate for an enzyme from *Cicer arietinum* L. (123). An endoglycosidase from *Rhamnus* (124) and from *Fagopyrum esculentum* (125), however, showed, a broad specificity for flavonoid glycosides. Further work is needed to determine whether plants possess multiple forms of endoglycosidase differing in their catalytic activities towards glycosidic flavor precursors.

The broad substrate specificity of tea and grape endoglycosidases provides new challenges for the use of such enzymes through genetic engineering for flavor enrichment of fruit juices and other plant-derived products.

With regard to fungal endoglycosidase, an enzyme from *A. niger* was able to hydrolyze geranyl- $\beta$ -rutinoside (100). We have observed in our laboratory (data not published) that *Aspergillus* sp. can produce an endoglycosidase when specific carbon source inducers were present in the culture medium, in similar conditions to those described by Westlake et al. (126). However, the enzyme showed a distinct specificity for both the sugar and aglycone moiety of substrates. It was active on flavonoid rutinosides, such as rutin and hesperidin. Neither naringin, a flavonoid glycoside with rhamnosyl ( $1 \rightarrow 2$ ) glucoside as sugar moiety, nor monoterpenyl, 2-phenylethyl, or benzyl rutinosides was the substrate.

## D. Inhibition of Glycosidase Activities

### 1. Glucose Inhibition

An important constraint for flavor release in fruit juice processing is the inhibition of  $\beta$ -glucosidases by glucose. This inhibition is often of a competitive type and a common characteristic of these enzymes (10, 16, 127, 128). In contrast,  $\beta$ -glucosidase activity is not influenced by other sugars such as fructose, galactose, arabinose, mannose, lactose, and sucrose at the concentrations occurring in food products (95, 100).

Inhibition of  $\beta$ -glucosidase activity by glucose has long been known to be a major problem for enzymatic debittering of citrus juices by hydrolysis of naringin (108) and for efficient enzymatic saccharification of cellulosic material (61). Cellobiose, produced by the consecutive action of cellulases (exo and endoglucanases) on cellulose, can accumulate in the medium as the consequence of end-product (glucose) inhibition of  $\beta$ -glucosidase, which catalyzes the hydrolysis of cello-

biose. This leads to the inhibition of cellulase activities by cellobiose. Much attention has therefore been focused on the search for glucose tolerant  $\beta$ -glucosidase.

Intracellular  $\beta$ -glucosidases from yeast are generally very sensitive to glucose inhibition. Inhibition constants vary from 3.0 to 23 mM (63, 87, 93). During grape juice fermentation, both excreted and cell  $\beta$ -glucosidase of *S. cerevisiae* were found to be less sensitive to glucose inhibition (80, 81). Purified  $\beta$ -glucosidase from *S. cerevisiae* showed, however, a low value of  $K_i$  (6.7 mM) (105).

Some strains belonging to the genera *Candida* (92–95) and *Debaryomyces* (89) are able to produce glucose-tolerant extracellular  $\beta$ -glucosidase. *C. molischiana* extracellular enzyme (92) is strongly inhibited by glucose ( $K_i = 7$  mM), while that from *C. wickerhamii* ( $K_i = 230$  mM) (93) and particularly from *C. peltata* ( $K_i = 1400$  mM) (95) were distinguished by high resistance to glucose inhibition. Rosi *et al.* (89), after screening 317 yeast strains from 20 species, selected a *D. hansenii* strain producing a highly glucose-tolerant  $\beta$ -glucosidase.

Bacterial and filamentous fungal  $\beta$ -glucosidases are generally strongly inhibited by glucose, the inhibition constant being in the range of 0.6–10 mM (95, 113, 127–129). However, we recently demonstrated that the production of highly glucose-tolerant extracellular  $\beta$ -glucosidase from *A. niger* and *A. oryzae* is possible (129, 130). This involves an adaptive enzyme whose production was induced by using uncommon carbon sources in the culture medium. The highest production was obtained with quercetin (a pentahydroxyflavone) as the sole carbon source. In these conditions, two  $\beta$ -glucosidases were produced. The major  $\beta$ -glucosidase was strongly inhibited by glucose ( $K_i = 3.5$  mM) as is the case for *Aspergillus* enzymes (113, 127, 128). The minor  $\beta$ -glucosidase, however, was highly resistant to glucose inhibition ( $K_i = 953$  mM). The molecular weight of this enzyme is quite low (30 kDa) compared to that of most *Aspergillus* enzymes. To date only one strain of *A. niger* has been reported to produce (MW = 98 kDa) a constitutive enzyme which is not very sensitive to glucose inhibition ( $K_i = 543$  mM) (131).

Activity enhancement by glucose was observed for an intracellular  $\beta$ -glucosidase from *Streptomyces* sp. (132, 133) and from *Microbispora bispora* (134). Multiple forms of  $\beta$ -glucosidases have been observed in *Streptomyces* sp., but only one of these forms was found to display this particular behavior.  $\beta$ -Glucosidase activity from one strain was stimulated by up to 0.4 M glucose, with the maximum activation

occurring at 0.2 M glucose (132). That from another strain was activated only up to 0.2 M glucose concentration (133). The activity of both enzymes decreased at > 0.4 M glucose but the extent of this decline differed among the strains. No convincing explanations have emerged to account for this unusual behavior of the enzymes.

The activities of fungal exoglycosidases are not significantly affected at the usual glucose concentrations found in fruit juices (47, 135). The enzymes  $\alpha$ -arabinofuranosidase and  $\beta$ -apiofuranosidase were more resistant to glucose inhibition than  $\alpha$ -rhamnosidase (10). Glucose has been demonstrated to be a competitive inhibitor ( $K_i = 120$  and 350 mM) of fungal  $\alpha$ -rhamnosidase (66, 136).

Among plant  $\beta$ -glucosidases, those from grape (55) and almond (52) were resistant to glucose inhibition, with a  $K_i$  of 170 mM and 210 mM, respectively, while that from papaya fruit was more sensitive (11).

With respect to endoglycosidases, the enzyme from grapes showed a high  $K_i$  value (212 mM) (51). Glucose did not influence the activity of an endoglycosidase produced from *Aspergillus* sp. in our laboratory (data not published), which was found to be specific to flavonoid rutinosides as discussed previously. However, an *A. niger* endo- $\beta$ -glucosidase able to hydrolyze geranyl  $\beta$ -rutinoside was found to be sensitive to glucose inhibition ( $K_i = 40$  mM) (100). Furthermore, the common inhibition of glycosidases by their end product (sugar) was observed for fungal  $\alpha$ -rhamnosidase activity (66, 136). The inhibition with rhamnose was competitive, with a  $K_i$  of 1.2 and 1.75 M.

## 2. Glucono- $\delta$ -Lactone

This is one of the most powerful inhibitors of  $\beta$ -glucosidases. Plant (52, 55) and microbial  $\beta$ -glucosidases (63, 92, 93, 113, 137) are more strongly inhibited by this compound than by glucose. The high affinity of the compound for the enzyme has been explained by its structural analogy with an intermediate product in the enzymatic cleavage of  $\beta$ -D-glucosides (138). The inhibition is usually of the competitive type with  $K_i$  values often < 1 mM and applies equally to  $\beta$ -glucosidase from *Streptomyces* sp. ( $K_i = 0.44$  mM), the activity of which was enhanced by glucose (133).

Gluconolactone concentration may reach levels of 5–10 mM in grape juice and wine obtained from grapes contaminated by fungi, such as *B. cinerea* (56, 139). At these levels, grape (55), *S. cerevisiae* (80), *C. wickerhamii* (93), and *A. niger* (113)  $\beta$ -glucosidases are strongly inhibited. However, glucose-tolerant  $\beta$ -glucosidase

from *Aspergillus* strains, the production of which was induced with quercetin, displays 30% of its activity at 5 mM and 20% at 50 mM of gluconolactone (129, 130).

At high concentration gluconolactone is also an inhibitor of *A. niger*  $\alpha$ -rhamnosidase and  $\beta$ -apiosidase activities. For example, the former was inhibited by 50% and the latter by 85% with 100 mM gluconolactone (10). *A. niger*  $\alpha$ -arabinofuranosidase was unaffected at this concentration.

### 3. Miscellaneous Compounds

a. *Ethanol*. Generally, fungal  $\beta$ -glucosidase (80, 93, 100),  $\alpha$ -arabinofuranosidase (47, 135),  $\alpha$ -arabino-pyranosidase (47), and  $\beta$ -apiosidase (99) are weakly inhibited by 10% (v/v) ethanol which is the average value in wines. Inhibition often only occurs above 15% ethanol. However, *A. niger*  $\alpha$ -rhamnosidase was found to be more sensitive to ethanol, with a loss of 20–40% of activity at a 10% ethanol concentration, depending on the enzyme preparation (47).

An enhancement of particularly microbial  $\beta$ -glucosidase activity has been observed when *p*NP- $\beta$ -glucoside was used as substrate, which may be due to the glucosyltransferase activity of the enzyme (47, 87, 140). Conversely, the hydrolysis of *p*NP- $\beta$ -glucoside by grape (55, 59) and almond (59)  $\beta$ -glucosidases clearly decreased in the presence of ethanol. Grape  $\beta$ -glucosidase activity declined by 60% in 10% ethanol (55).

b. *Sulfur Dioxide*. At the usual levels (50–200 ppm) used in fruit juice processing and wine making to prevent oxidation, this compound was not found to cause an inhibitory effect on yeast  $\beta$ -glucosidase (80, 82) or *A. niger* endo- $\beta$ -glucosidase (100).

c. *Phenols and Polyphenols*. Phenols (141) and polyphenols (142) display an inhibitory effect on plant  $\beta$ -glucosidase. The affinity of phenolic inhibitor for the enzyme increases with increasing molecular size (142). Catechin, dimeric procyandins, and especially yellow oxidation products of catechin are powerful inhibitors of sweet almond  $\beta$ -glucosidase (143). Similarly, apple  $\beta$ -galactosidase is also inhibited by catechin, quercetin, and glycosides of quercetin (144). These polyphenols are either present in intact fruits or produced during fruit juice processing by oxidative reactions. To our knowledge, the effect of polyphenols on fungal glycosidase activities has not yet been studied.

d. *Cations*.  $\text{Ag}^+$ ,  $\text{Hg}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Fe}^{2+}$ , and  $\text{Fe}^{3+}$  were found to be inhibitors of plant and fungal glycosidases, the extent of inhibition depending

on the source of the enzyme (55, 63, 99). The strongest inhibition was often observed with  $\text{Ag}^+$ ,  $\text{Hg}^{2+}$ , and  $\text{Cu}^{2+}$ .

## VII. USE OF GLYCOSIDASES FOR AROMA ENRICHMENT

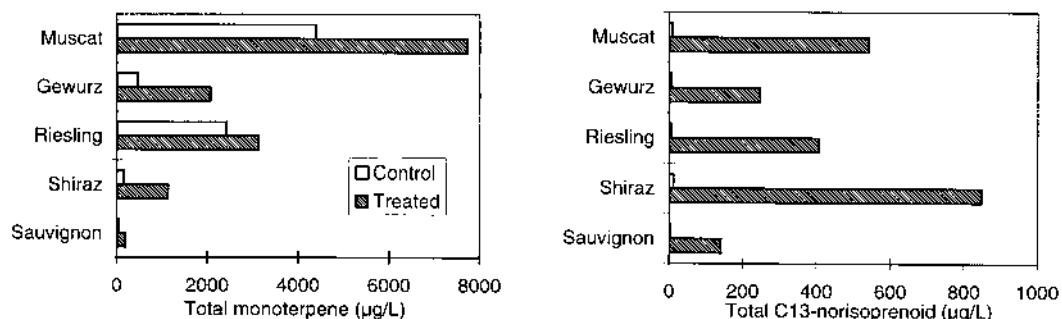

The use of glycosidases to release flavor compounds from glycosidic precursors, was initially examined in wines. Two major reasons for this are: (i) important flavor compounds in wines of *Vitis vinifera* cultivars are accumulated in grapes as flavorless glycoconjugates, and especially (ii) the glucose inhibition of  $\beta$ -glucosidase in available enzyme preparations, limits the use of glycosidases to media, like wine, containing trace levels of glucose (< 1 g/L). Nevertheless, because of the occurrence of flavor glycoconjugates in several fruits, enzyme applications have been found for fruit juices.

### A. Wine Flavor Enhancement

The amount of glycosidic flavor precursors decreases only slightly during grape juice fermentation (145). This phenomenon may be explained by the low levels of glycosidase activities exhibited by grapes (55, 56) and enological yeast strains (80), as discussed previously. Consequently, attention has been focused on the use of commercially available fungal enzyme preparations (pectinases, hemicellulases) containing glycosidase activities derived mainly from *Aspergillus* spp. Various enzyme preparations have been tested for flavor enhancement of wines from different cultivars by incorporating the enzymes either into the juice during fermentation or into the wine. Current regulations, however, do not allow the addition of enzymes into wine.

Muscat cultivars were often used as a model to test the effect of the enzyme treatment because of the abundance of monoterpenyl glycosides. The hydrolysis of these glycosides liberates highly odorous alcohols which can be detected by sensory analysis and easily analyzed by GC/MS. In general, the addition of enzyme preparations possessing glycosidase activities during wine making results in a significant increase in the concentration of monoterpenes,  $\text{C}_{13}$ -norisoprenoids, and shikimate derived compounds.

The total free monterpene concentration in the treated wines increased by several fold compared to control wines (Fig. 5) (10, 109, 146–152). The concentration of free monterpenes often exceeded their

**Figure 5** Total free monoterpene and C<sub>13</sub>-norisoprenoid concentrations in control and glycosidase treated wines.

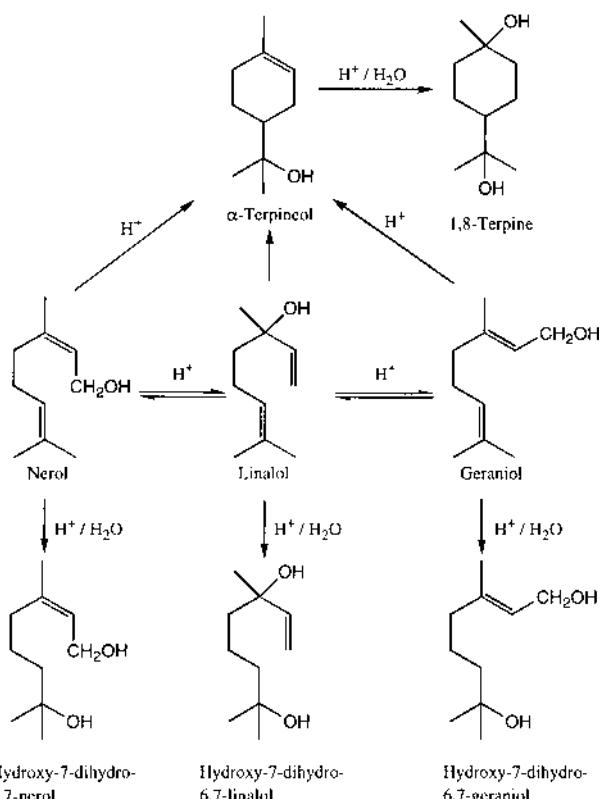

aroma threshold in wines made from varieties, such as Muscat and Gewürztraminer, in which large amounts of monoterpenes occur as flavorless glycoconjugates (2, 19, 109). These treated wines developed a more intense floral note owing to the abundance of monoterpenes. In nonfloral varieties, such as Sauvignon, Semillon, Shiraz, Greanche, Carignan, and Trajadura (10, 109, 148–152), the increase in monoterpenes is below the aroma threshold of these compounds. However, there is no information available about the effect of this increase on the flavor nuances that are sometimes detected in treated wines.

Among the monoterpenes, an increase was observed for geraniol, nerol, citronellol, linalool, furan, and pyran forms of linalool oxides,  $\alpha$ -terpineol, and monoterpene polyols (e.g., 8-hydroxylinalools, *p*-menthene-7,8-diol, exo-2-hydroxy-8-cineol). The highest increase often occurred for geraniol and nerol, which impart floral attributes to the wines (10, 146, 147, 151, 152).

The concentration of linalool, and linalool oxides, and some polyols often increased to a lesser extent because of the low activity of fungal  $\beta$ -glucosidase toward the relevant glycoconjugates. However, mono- and diglycosides of these tertiary alcohols are more prone to acidic hydrolysis in fruit juice than those of primary alcohols (35).

Citronellol concentration increased greatly in some enzymatically treated wines (Muscat). This could not be the consequence of the enzymatic hydrolysis of related glycosidic precursors since the glycosidic conjugates of this terpenol have not been detected in grapes (153). The increase was explained by the action of yeast (*S. cerevisiae*) reductase on geraniol and nerol, which were more abundant in the enzymatically treated wines (154–156). The production of citronellol was influenced by the yeast strain (155). The high amounts of this compound resulted in the perception of citrus attributes in the wines.

It is difficult to attribute the increase in concentration of each monoterpene directly to the enzymatic release from glycoconjugate precursors. The acid-catalyzed rearrangement of released monoterpenes occurs in grape juice and wine (Fig. 6) (36–38, 157), and some monoterpenes, as mentioned above, may be involved in yeast metabolism. The ideal way to determine the effect of enzymatic release from glycoconjugate precur-

**Figure 6** Acid-catalyzed rearrangement of monoterpenes.  
(From Ref. 157.)

sors is by direct quantitative analysis of monoterpenyl glycosides. However, this analysis requires reference glycosides which are not yet commercially available, such as certain monoterpenes. Furthermore, their synthesis, mainly for diglycosidic conjugates, is quite complex and leads generally to low yields (35, 101, 102).

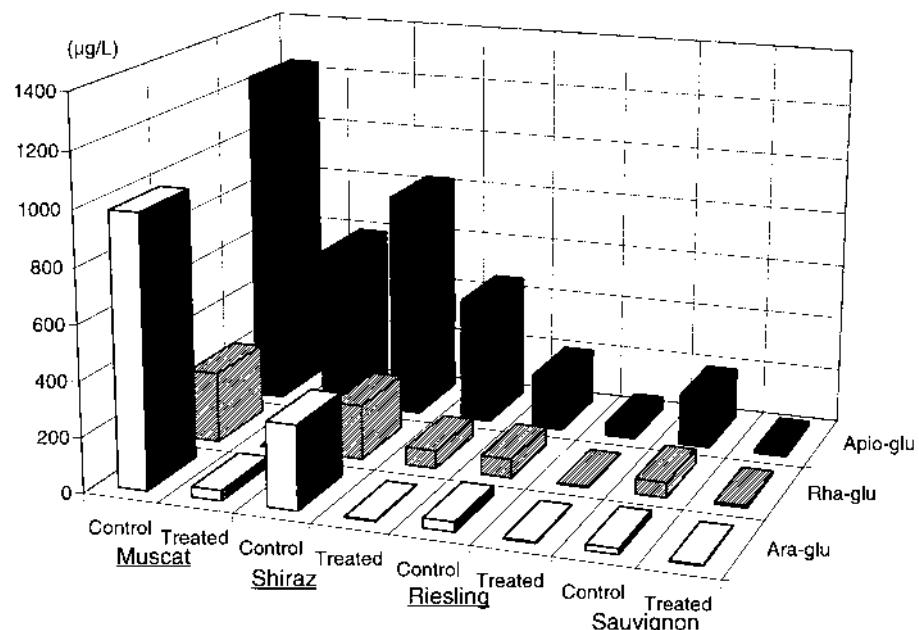

In our laboratory several monoterpenyl glycosides were synthesized (35, 101), which allowed us to quantify them in control and enzymatically treated wines (10, 109, 147). An enzyme preparation, rich in glycosidase activities, was added to grape juices from different cultivars before alcoholic fermentation. The glycosides hydrolysis was measured ~ 1 month after the completion of fermentation. The concentration of monoterpenyl arabinofuranosyl and rhamnopyranosyl glucosides decreased notably in treated wines, while apiosylglucosides decline less sharply (Fig. 7). This was due to the low levels of  $\beta$ -apiosidase activity compared to  $\alpha$ -rhamnosidase and  $\alpha$ -arabinofuranosidase activities in the enzyme preparation. With regard to monoglucosides, primary alcohol (geraniol and nerol)  $\beta$ -D-glucosides were almost totally hydrolyzed by exogenous enzymes (Fig. 8) (10, 109). In contrast, the level of tertiary alcohol (linalool) glucoside increased significantly in wines containing high levels of relevant disaccharidic conjugates. This accumulation is the result of the low activity of fungal  $\beta$ -glucosidase on tertiary

alcohol glucosides which are generated from diglycosides by the action of exoglycosidases.

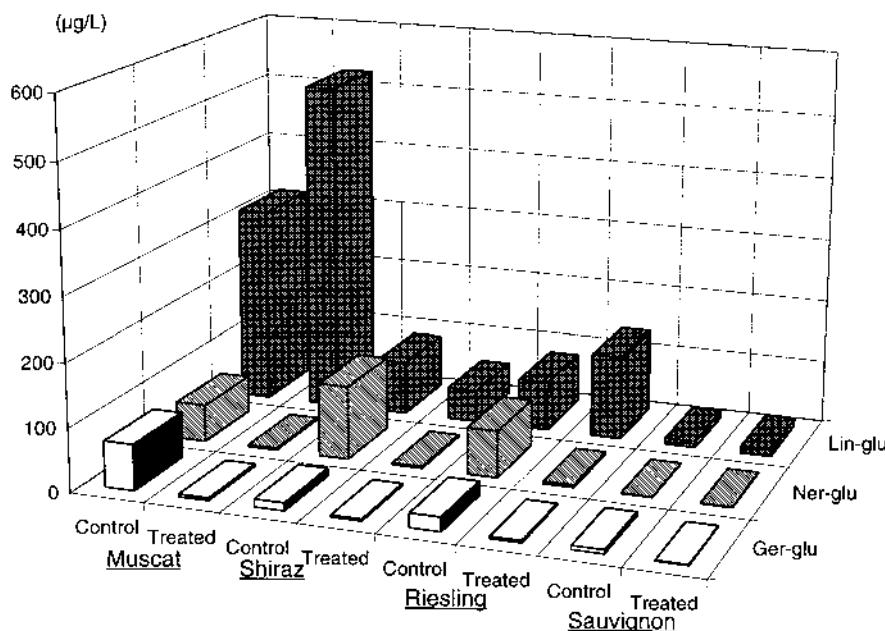

Fermentation trials with various Muscat grape juices, in the presence of different levels of glycosidase activities, showed that several hundred nanokatals of  $\beta$ -glucosidase,  $\alpha$ -arabinofuranosidase,  $\beta$ -apiosidase, and  $\alpha$ -rhamnosidase activities per liter of grape juice are needed to efficiently hydrolyze monoterpenyl glycosides (10, 109). These activities are much greater than those found in grape berries (55, 56) or produced by *S. cerevisiae* (80) during alcoholic fermentation.

Several C<sub>13</sub>-norisoprenoids that were barely detectable in control wines were nonetheless detected in the treated wines (Fig. 5) (10, 109, 147). This is not surprising as they occur mainly in glycoconjugated forms in grapes. These compounds are not often analyzed in glycosidase-treated wines, mainly because the references compounds are not commercially available. They are not specific to any grape variety, as was found for monoterpenes in Muscat cultivars, although some cultivars, such as Chardonnay (158, 159) and Shiraz (10, 109), do seem to contain larger amounts of C<sub>13</sub>-compounds.

In the enzymatically treated wines, the most abundant C<sub>13</sub>-norisoprenoids were often 3-hydroxy- $\beta$ -damascone, 3-oxo- $\alpha$ -ionol, and vomifoliol (10, 109, 147), as was also observed in the enzymatic hydrolysis

**Figure 7** Monoterpenyl diglycoside concentrations in control and glycosidase-treated wines.

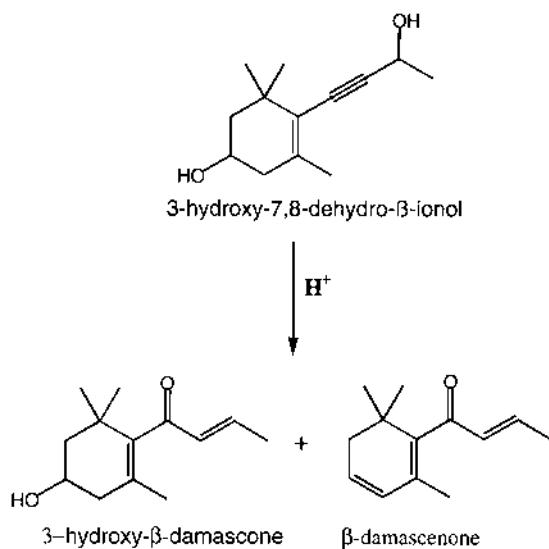

**Figure 8** Monoterpenyl glucoside concentrations in control and glycosidase-treated wines.

of grape glycosidic extracts. These molecules are odorless and are considered not to generate odor-active compounds by further reactions (42, 158). In contrast, 3-hydroxy-7,8-dehydro- $\beta$ -ionol, an acetylenic alcohol, detected in treated wines (10, 109) can generate a highly esteemed, flavorant,  $\beta$ -damascenone, along with a major product, 3-hydroxy- $\beta$ -damascone, at wine pH during storage through acid catalyzed reactions (Fig. 9) (42, 70, 158). A high concentration of  $\beta$ -damascenone, exceeding several fold its odor threshold, has been detected in an enzymatically treated wine 1 month after the end of fermentation (147). This can be explained by the fact that glycosidase treatment may have increased the concentration of an allenic triol which is known to rearrange much faster than aforementioned acetylenic alcohol to generate  $\beta$ -damascenone (158, 160).

$\beta$ -Damascenone, like other norisoprenoid flavorants, is generally produced in tiny amounts (in the range of ppt) (42, 158, 160) that are difficult to quantify by conventional GC/MS techniques. Nowadays, stable isotope dilution techniques are being used more and more because of their sensitivity and accuracy in quantitative analysis of trace flavorants.

Among the shikimate-derived volatiles, benzyl alcohol, 2-phenylethanol, vanillin, eugenol, and zingerone were often detected at higher concentrations in enzymatically treated wines (10, 109, 150). An enzymati-

cally treated white wine from a nonfloral grape variety (150) contained high levels of vanillin, which is a potent flavorant usually derived from wood used in wine aging.

**Figure 9** Products issued from 3-hydroxy-7,8-dehydro- $\beta$ -ionol by acid-catalyzed reactions in fruit juice and wine. (From Ref. 158.)

The increase in flavor compounds, using the same wine and at the same dosage of enzyme preparation, is strongly influenced by the enzyme preparations used (usually from 1 to 3 g/HL) (10, 151, 152). This can be explained by the different glycosidase activities of enzyme preparations, as mentioned previously. Furthermore, the vintage had an influence on the aroma enrichment of wine, which could be explained by differences in the biosynthesis of glycosidic precursors. It has also been found that enzyme preparations were more effective when added into wine instead of grape juice (10, 109, 151).

In addition to commercial pectinase preparations,  $\beta$ -glucosidase preparations have been used to enhance the varietal flavor of Muscat wines, including an immobilized endo- $\beta$ -glucosidase from *A. niger* (161), an immobilized  $\beta$ -glucosidase from *C. molischiana* (162, 163), and a  $\beta$ -glucosidase from *D. hasenii* (164). Monoterpene (geraniol, nerol, linalol, linalool oxides), benzyl alcohol, and 2-phenylethanol concentrations all increased in the treated wines. Since the authors only analyzed volatiles after enzymatic treatment, it is difficult to judge the extent of glycoside hydrolysis. Furthermore, the hydrolysis of disaccharidic glycosides was probably quite limited owing to the use of an unique activity ( $\beta$ -glucosidase).

Finally, an important aspect in the use of glycosidases is the prevention of any contamination of the grapes or fruits by molds. As previously mentioned, such contamination may lead to the inhibition of  $\beta$ -glucosidase activity by gluconolactone. This was observed when glycosidases were added to a wine made from mold infected grapes (personal communication). The diglycosides were effectively hydrolyzed by exoglycosidases in the treated wine, while the resulting monoglucosides were not hydrolyzed owing to gluconolactone, of which the presence in the wine was confirmed by analysis.

Sensory difference tests often distinguished between the control and enzyme treated wines (10, 109, 147, 152, 161, 162). The difference was clearly observed in wines whose flavor is monoterpene dependent (like Muscat and Gewürztraminer) even after 2 or 3 weeks of enzyme application, due to the enhanced floral attributes. For nonfloral varieties, which constitute the greatest volume of world wine production, the effect of glycosidases can be perceived usually after several months or more. Most of the liberated aglycones, especially those corresponding to the C<sub>13</sub>-norisoprenoids and monoterpene polyols, are flavorless but can generate odorous molecules during wine conservation. In contrast to the advances in our understanding of the

chemistry of aglycones (6, 36), very few data are available on their effect on the formation of odor-active molecules in normal wine storage conditions.

The role of aglycones, derived from grape glycosidic precursors, in the generation of important wine aroma descriptors has been shown in mimetic conditions (165). Indeed, some important key aroma descriptors (honey, tea, lime) of white wines were detected when a glycosidic extract from nonfloral varieties (Chardonnay, Semillon, Sauvignon) was subjected to an acid hydrolysis (pH 3.2) at elevated temperature (50°C, 4 weeks, under nitrogen) in order to accelerate the acid-catalyzed conversions that slowly occur during wine conservation. The contribution of glycosidic precursors to the characteristic aroma of an important red wine cultivar (Grenache) has been recently observed in our laboratory under similar conditions.

The volatiles responsible for the key aroma descriptors have not been identified yet, most probably due to the presence of trace quantities of important flavorants.

The rapid liberation of aglycones from glycoconjugates, through the use of exogenous glycosidases, can thereby accelerate the formation of odor-active volatiles during wine storage. In fact the glycosidic flavor precursors do undergo slow hydrolysis at wine pH during storage (35, 109, 145). For example, several Muscat wines prepared without glycosidase addition and analyzed after 18 months contained from 1.2 to 1.9 times more monoterpene in glycosylated form than in the free fraction (145). Bound forms of primary alcohols (geraniol and nerol) were 6–10 times more abundant than their free counterparts.

## B. Fruit Juices

Owing to the inhibition by glucose of the “key enzyme”  $\beta$ -glucosidase in the available fungal derived enzyme preparations, very little work has been devoted to flavor enhancement in fruit juices.

Treating mango and passion fruit juices with a yeast  $\beta$ -glucosidase from *Candida cacaoi* resulted in an increase in monoterpene concentrations (166). However, the increase was much lower than that due to acid hydrolysis. The immobilized enzyme (covalently bonded to sodium alginate beads) liberated fewer terpenols than the free enzyme. The addition of  $\beta$ -glucosidase from *C. molischiana* (immobilized onto Duolite A-568 resin) to apricot, mango, strawberry, peach, and apple juices yielded an increase in concentration of monoterpene alcohols (linalool,  $\alpha$ -terpineol, geraniol), benzyl alcohol, and 2-phenylethanol (162).

No differences were observed in the flavor released using free and immobilized  $\beta$ -glucosidase from *C. molischiana*. The immobilized enzyme was found to be quite stable under fruit juice conditions.

An *A. niger* endo- $\beta$ -glucosidase, immobilized onto acrylic beads or cellulose, increased the concentration of volatiles (linalool, benzyl alcohol and benzaldehyde) in passion fruit juice (161). In general, an aroma enhancement in the treated juice was observed (161, 162).

Although the volatile levels in fruit juices increased after the applications of  $\beta$ -glucosidase, two important parameters may have limited the efficiency of the process: (a) many flavor compounds occur in fruits as diglycosides which fungal  $\beta$ -glucosidases are, in general, unable to hydrolyze; (b) the fungal  $\beta$ -glucosidases tested are inhibited by glucose, which could therefore limit their action in fruit juices.

Because the authors only analyzed the volatile content of fruit juices and not the glycosides, the yield of hydrolysis cannot be evaluated. However, a paper reports how the amount of glycosides changes in a sweet wine (containing  $\sim 30$  g/L glucose) when fungal glycosidases were used in the wine-making process (147). The level of monoterpane diglycosides decreased notably in the treated wine, which may be explained by the action of exoglycosidases. The monoterpenyl- $\beta$ -D-glucosides produced were not hydrolyzed and therefore accumulated in the wine. This clearly indicates the inhibition of fungal  $\beta$ -glucosidase activity by glucose, which greatly limited the liberation of volatiles as confirmed by their analysis. In contrast, the hydrolysis of monoglucosides was very efficient when a dry wine was prepared using the same grape juice, enzyme dosage, and conditions (147).

## VIII. POTENTIAL ADVERSE EFFECTS OF ENZYME PREPARATIONS

Certain side activities of fungal enzyme preparations can be detrimental to fruit juice and wine quality owing to the formation of off-flavors and the decolorization.

### A. Off-flavor Formation

Hydroxycinnamic acids, such as *p*-coumaric and ferulic acids, occur mainly in bound forms in fruits. Quinic acid and/or glucosidic esters of these hydroxycinnamic acids have been detected in numerous fruits: apple, pear, apricot, peach, orange, grapefruit, strawberry,

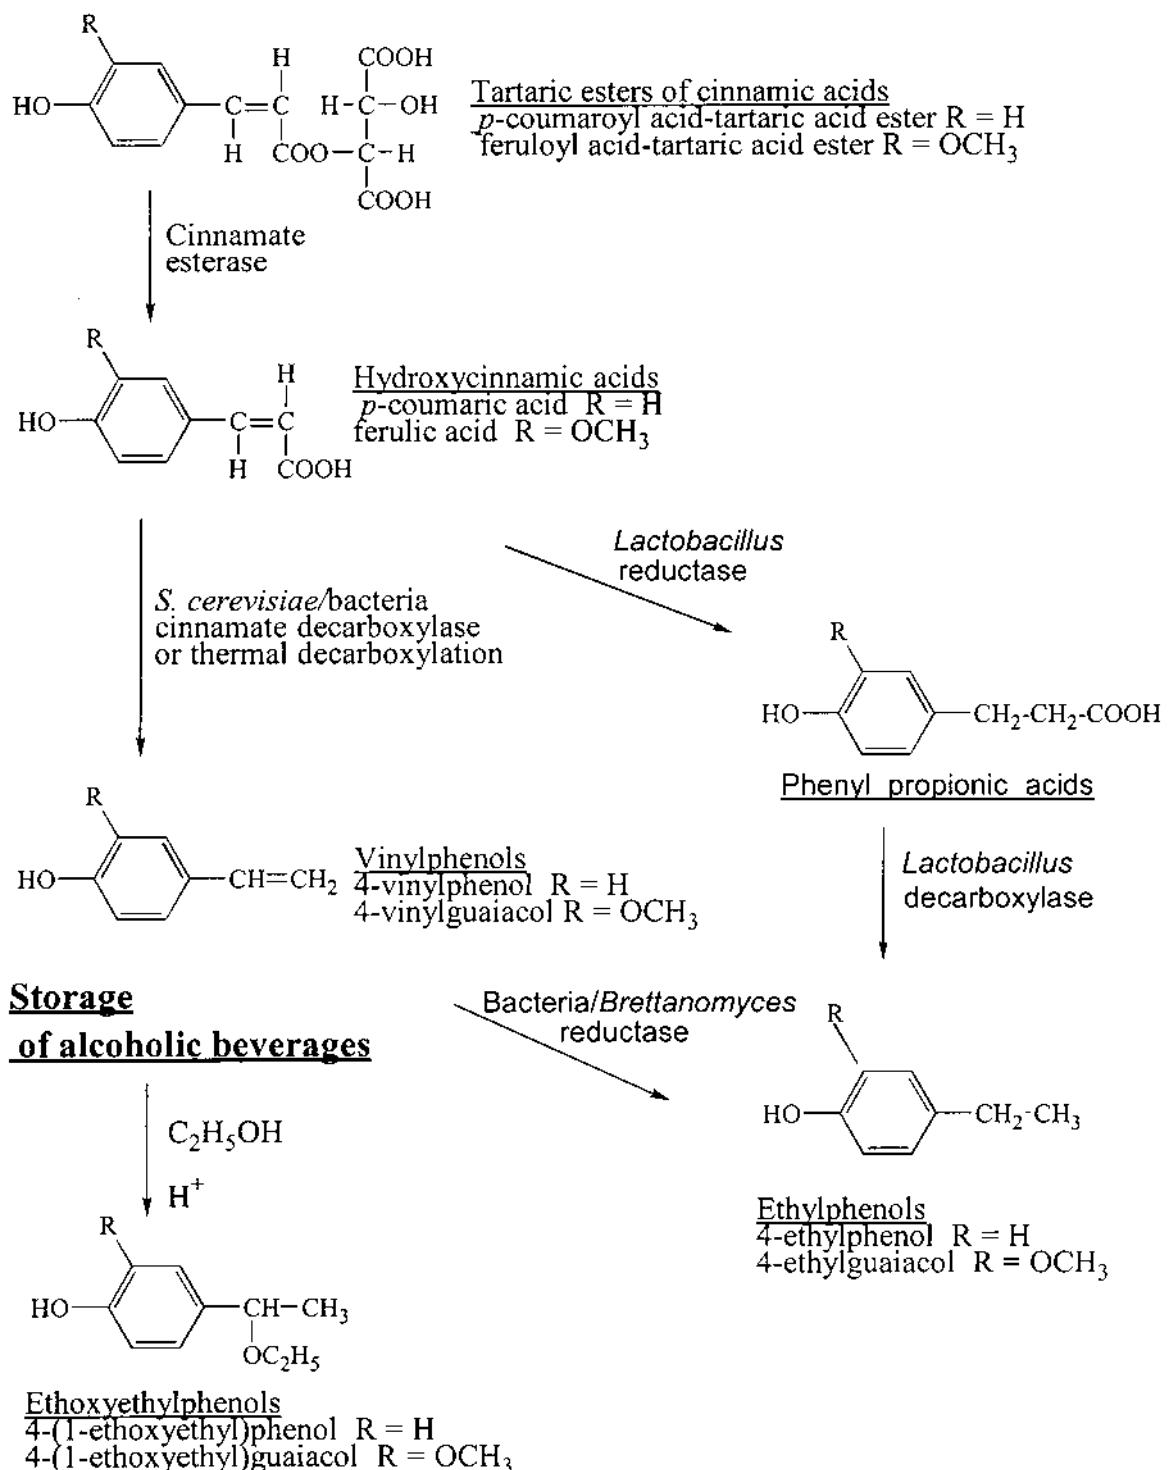

raspberry (167), while in grapes they are esterified with tartaric acid (167–169).

A large number of pectinase and hemicellulase preparations derived from *A. niger* used in fruit juice processing exhibit an cinnamate esterase as side activity which leads to the enrichment of the medium in free caffeic, *p*-coumaric, and ferulic acids (Fig. 10) (170–173). Free *p*-coumaric and ferulic acids can be converted to volatile high-flavorant *p*-vinylphenols, 4-vinylphenol, and 4-vinylguaiacol, respectively, by either nonenzymatic thermal (174) or enzymatic (yeast and bacteria) decarboxylations (175–179) (Fig. 10). These vinylphenols possess low detection thresholds (<100 ppb in water) (174, 179) and spicy and medicinal odors, and they contribute positively only at low levels to the flavor of food products (180–182). Accordingly, the increase in the concentration of hydroxycinnamic acids precursors of these volatiles due to enzyme treatments can have an important consequence to the flavor of the products.

4-Vinylguaiacol (or *p*-vinylguaiacol) generated from ferulic acid through nonenzymatic decarboxylation during orange and grapefruit juices processing and storage contributes to the development of the major detrimental off-flavor (old fruit, rotten flavor) in these products (174). It has been shown that the rate of 4-vinylguaiacol formation during orange juice storage was closely dependent on the amount of free ferulic acid (183).

A phenolic off-flavor is perceived in fermented products (beer, cider, wine) when aforementioned volatile phenols are present at high levels (171–173, 181, 184). The wines made from grape juice, that was initially spiked with some pectinase preparations rich in glycosidase activities contained exceedingly high levels (> 770 ppb) of vinylphenols, masking the pleasant fruity and floral odors which were generated by hydrolysis of glycosidic flavor precursors (109, 171, 172). It was demonstrated recently that the high concentration of volatile phenols detected sometimes in wines was due to the consecutive action of cinnamate esterase activity from enzyme preparation and decarboxylase activity from yeast (*S. cerevisiae*) (171–173) present in the majority of enological strains (175). Consequently, particular attention is now being directed to develop an enzyme preparation without cinnamate esterase activity and to select yeast strains with low activity toward hydroxycinnamic acids (185). Since the 1970s, pectic enzyme preparations have been widely used in wine making mainly to improve clarification and juice yield, and the problem of off-flavors has been sometimes observed without explanation (186).

## Fruit juice processing and fermented products

**Figure 10** Some volatile phenols formation pathways during processing and storage. (Courtesy of C. Flanzy, Oenologie: fondements scientifiques et techniques, Tec-Doc, Paris, 1998.)

The formation of vinylphenols is found to be lower in red than white wines, and is explained by the inhibition of yeast decarboxylase activity by red wine polyphenols (187).

The high levels of vinylphenol and vinylguaiacol in wines dropped notably after 1 year of storage, while there was a simultaneous decrease of unpleasant odor (188). In the acidic pH of wine, these compounds were partly transformed into their corresponding ethoxyethylphenols by addition of ethanol (Fig. 10). Ethoxyethylphenols, at the levels found in wines, probably have no direct influence on flavor owing to their odor threshold (188).

Ethylphenols, 4-ethylphenol (woody, phenolic odor), and 4-ethylguaiacol (clovelike, smoky odor), which impart undesirable flavors to wine, beer, and cider are produced from 4-vinylphenol and 4-vinylguaiacol, respectively, through reductase activity from bacteria (176, 181) and more frequently from spoilage yeast, *Brettanomyces* (184, 189). The production of ethylphenols from hydroxycinnamic acids is possible by another pathway by *Lactobacillus*: firstly the double bonds of hydroxycinnamic acids were reduced, and subsequently the resultant phenyl propionic acids were decarboxylated (177, 178).

In addition to this off-flavor formation, fungal enzyme preparations cause the oxidation of C<sub>13</sub>-norisoprenoids belonging to the structure of 3-hydroxymegastigmanes when they are used in assays for the determination of the aglycone moiety of glycosides (190). High enzyme concentrations are employed to ensure the complete hydrolysis of glycosides. This oxidation, by altering the structure of polyol aglycones, prevents the generation of desired aroma compounds, such as  $\beta$ -damascenone (6). However, at the dosage used in wine making for flavor release, the fungal-derived enzyme preparations do not provoke such oxidations (10, 109).

## B. Decolorization Effect

Anthocyanins are among the most widespread natural pigments and responsible for the red, blue, and purple color of fruits (191, 192). They are composed of anthocyanidins glycosylated with mono- (usually glucose), di- or trisaccharides (193). Anthocyanidins become unstable and are readily converted to brown or colorless compounds when released from their sugar moiety (194, 195).

The hydrolytic activity of fungal enzyme preparations toward anthocyanins was reported as early as 1955 (194).  $\beta$ -Glucosidase (196, 197),  $\alpha$ -arabinosidase

(197, 198), and  $\beta$ -galactosidase (197, 199) from commercial enzyme preparations may potentially degrade anthocyanins. The decolorization effect of these enzymes has been reported for raspberry (200), strawberry (201), blackberry (202), and grape anthocyanins (197, 203, 204). Certain molds, particularly *B. cinerea*, which develop on fruits are also able to degrade anthocyanins as has been observed in strawberry juice (205), raspberry juice (206), and red wines (207, 208).

Only one in 26 enzyme preparations, used in fruit juice processing within the mean recommended dosage, degraded the anthocyanin- $\beta$ -D-glucoside (cyanidin-3-glucoside) and di- and trisaccharides of cyanidin (209). Six enzyme preparations acted on disaccharidic conjugates only at high doses.

Two of four pectic enzyme preparations employed in wine making caused a significant color loss in red wine making (204). The major anthocyanin (malvidin-3-glucoside) and its acylated forms (malvidin-3-gluco-sylacetate and malvidin-3-glucosylcoumarate) both decreased significantly. The degradation of acylated anthocyanins requires the consecutive action of two enzymes—an esterase and  $\beta$ -glucosidase (170).

Accordingly, the choice of fungal enzyme preparations for flavor enhancement in fruit juices and derived beverages should be made carefully. Glycosidases that are highly active on anthocyanins may have specific applications for the decolorization of some orange juices or wines containing low levels of anthocyanin pigments.

An anthocyanin- $\beta$ -glycosidase from *A. niger* has been partially purified and characterized (201). Two  $\beta$ -glucosidases that were isolated and characterized from an *A. niger* pectinase enzyme preparation differ mainly in their catalytic activity (103). The major one was highly active on cellobiose and geranyl-glucoside but only slowly degraded malvidin-3-glucoside. In contrast, the minor one was highly active in degrading malvidin-3-glucoside. Both enzymes were strongly inhibited by glucose. These two  $\beta$ -glucosidases were also observed in another pectinase enzyme preparation.

In rare cases, an oxidation of white wine color was observed in the enzyme-treated sample. This might be due to polyphenoloxidase activity from enzyme preparations or to the chemical or enzymatic oxidation of flavonoids released through the action of glycosidases.

Finally, as positive effect of glycosidases as biocatalysts, is their role in the detoxification of certain foods through the hydrolysis of cyanogenetic glycosides (210) and the debittering of citrus juices by hydrolysis of narigin (211). These topics are not of the subject of this chapter.

## IX. CONCLUSION AND FUTURE PROSPECTS

Major progress has been made during the past two decades in our understanding of the chemical composition of glycoconjugated flavor compounds in fruits and the biochemical characterization of glycosidases involved in flavor release. The utilization of exogenous glycosidases for aroma enrichment in fruit juices and particularly in wine processing has been clearly demonstrated.

Several approaches, through genetic engineering techniques, will doubtless be used in the near future to overcome, by using recently discovered glycosidases, the limitations (glucose inhibition, substrate specificity, pH effect) on the exploitation of the glycosylated aroma source in the processing of fruit juices and derived beverages as well as other plant-derived products. The newly identified enzymes, such as endoglycosidase, possessing a broad sugar specificity and low inhibition constant for glucose, together with highly glucose-tolerant  $\beta$ -glucosidases from *Aspergillus* sp. and yeasts (*Candida* and *Debaryomyces* spp.), represent important biotechnological challenges in flavor release processes.

The construction of fungal strains such as *S. cerevisiae* and *Aspergillus* sp. expressing these proteins, and/or relevant exoglycosidases involved in flavor liberation, may enable the production of "tailor-made" glycosidases without undesirable activities (such as esterase, anthocyanase, and oxydase). This would allow better control of flavor release in various processes through the use of immobilized enzymes, enzyme preparations, and recombinant yeast (*S. cerevisiae*) strains.

## ACKNOWLEDGMENTS

The author thanks his colleagues identified in the literature, and Professor Christian Ambid for his helpful discussion and advice.

## Entrapment of Biocatalysts by Prepolymer Methods

Takuo Kawamoto and Atsuo Tanaka

*Kyoto University, Kyoto, Japan*

### I. INTRODUCTION

Immobilization of biocatalysts which include enzymes, cellular organelles, microbial cells, plant cells, and animal cells is attracting worldwide attention. Immobilized biocatalysts are, in general, easier to handle and more stable than native counterparts, and they can be used either repeatedly in a long-term series of batchwise reaction or continuously in flow systems, which are useful and important features for practical applications of biocatalysts. At present, immobilized biocatalysts have contributed to a wide variety of fields including:

1. Production of useful compounds by stereospecific and/or regiospecific bioconversions.
2. Production of energy and reducing equivalent by biological processes.
3. Selective degradation or removal of pollutants.
4. Analyses of various compounds with high sensitivity and specificity.
5. Application to foods, such as hydrolysis of lactose of milk, alcohol fermentation, production of glucose from starch, and production of high-fructose corn syrup.
6. Utilization in medical fields, such as new types of drugs and artificial organs.

These processes require immobilization not only of single enzymes that catalyze simple reactions but also of multienzyme systems that mediate more complicated reactions.

There are various immobilization methods at present. In general, the immobilization methods can be classified as follows:

(a) carrier binding via covalent linkage, ionic bonds, physical adsorption, or biospecific binding; (b) cross-linking by using bi- or multifunctional reagents; (c) entrapment in gel matrices, microcapsules, liposomes or hollow fibers; and (d) combination of the above-mentioned methods (1, 2).

Of these immobilization methods developed hitherto, entrapment methods are the most promising because this method is applicable to the immobilization of not only single enzymes but also multiple enzymes, cellular organelles, microbial cells, plant cells, and animal cells.

The disadvantages of this method are: (a) high-molecular-weight substrates may not be able to access the entrapped biocatalysts, and (b) renewal of the carrier is difficult.

Among the entrapment methods, entrapment in gel matrices is the most widely used. Various types of gel materials, such as polysaccharides, proteins, and synthetic polymers, are now used to entrap biocatalysts. Because applications of immobilized biocatalysts are aimed toward a wide variety of bioreactions, including synthesis, transformation, degradation, or assay of various compounds having different chemical properties (3), it is desirable to entrap biocatalysts in gels of adequate physicochemical properties to satisfy the different demands in such a variety of applications. It is, however, difficult to select suitable gels for each pur-

pose among those prepared from natural polymers. Furthermore, it is not easy to modify natural polymers for the preparation of proper gel materials. As for synthetic materials, acrylamide and its analogs have been used widely as starting materials for gels. These monomers are, however, liable to inactivate biocatalysts in the polymerization and immobilization processes.

For these reasons, continuous efforts have been devoted to development of prepolymer methods which are new entrapment methods using synthetic prepolymers as starting materials for gels.

## II. PREPOLYMER METHODS

In the case of prepolymer methods, synthetic resin prepolymers are used as gel-forming starting materials for entrapment of biocatalysts. Specific features and advantages of prepolymer methods can be summarized as follows:

1. Entrapment procedures are very simple and proceed under mild conditions.
2. Prepolymers do not contain monomers which may have a negative influence on the biocatalysts to be entrapped.
3. The network structure and strength of gels can be regulated by the chain length and the content of the reactive functional groups of the prepolymers.
4. The physicochemical properties of gels, such as hydrophilicity–hydrophobicity balance and ionic nature, can be controlled by selecting suitable prepolymers which are synthesized chemically in advance in the absence of biocatalysts.

Several examples of the prepolymer methods are described below.

### A. Photocrosslinkable Resin Prepolymer Method

#### 1. Principle

In the case of photocrosslinkable resin prepolymers, the mixture of the prepolymer and the biocatalyst is gelled by radical polymerization of the prepolymer initiated by illumination with near-ultraviolet light for several min in the presence of a proper photosensitizer (initiator) such as benzoin ethyl ether or benzoin isobutyl ether.

#### 2. Prepolymers

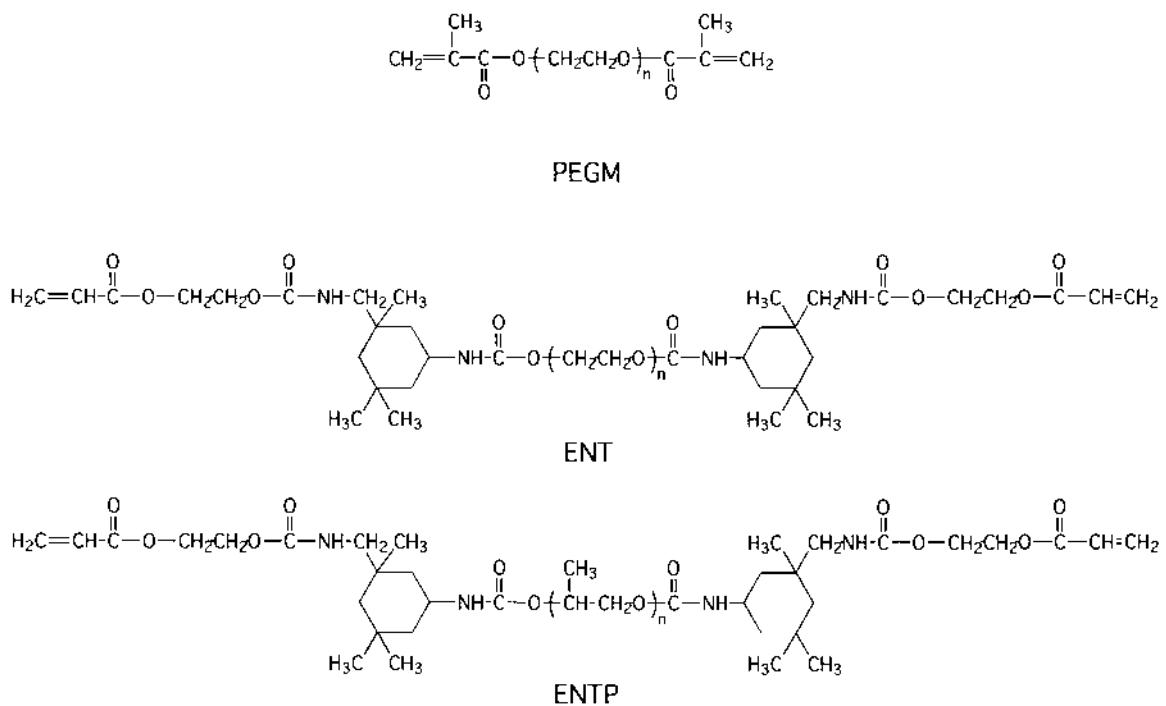

The structures of some typical photocrosslinkable resin prepolymers are shown in [Figure 1](#). The proper-

ties of the several prepolymers are summarized in [Table 1](#).

Polyethylene glycol dimethacrylate (PEGM) was synthesized with polyethylene glycol and methacrylate. ENT and ENTP were prepared with hydroxyethylacrylate, isophoronediisocyanate, and polyethylene glycol or polypropylene glycol, respectively. Each prepolymer has a linear skeleton of optional length, at both the ends of which are attached the photosensitive functional groups, acryloyl, methacryloyl, etc. PEGM (4–6) and ENT (7, 8) containing polyethylene glycol as the main skeleton are water-soluble and form hydrophilic gels, while ENTP (9) with polypropylene glycol as the main skeleton is water-insoluble and gives hydrophobic gels. By using polyethylene glycol or polypropylene glycol of different molecular weights, prepolymers of different chain length, PEGM-1000 to PEGM-4000, ENT-1000 to ENT-6000, and ENTP-1000 to ENTP-4000, can be prepared. Chain length of the prepolymers correlates with the size of network of the gels formed from these prepolymers. Prepolymers having ionic properties can also be prepared by introducing ionic functional group(s) to the main skeleton of prepolymers. An emulsion-type photocrosslinkable resin prepolymer, ENTE-1, was prepared in the following way. Hydrophobic polyvinyl acetate was coated with hydrophilic polyvinyl alcohol to be easily dispersed in an aqueous solution. Photosensitivity was introduced by the reaction with *N*-hydroxymethyl acrylamide in the presence of an acid catalyst. After neutralization, an emulsion-type photocrosslinkable resin prepolymer

**Table 1** Properties of Several Photocrosslinkable Resin Prepolymers

Prepolymer	MW of main chain	Property
PEGM-1000	~1000	Hydrophilic
PEGM-2000	2000	
PEGM-4000	4000	
ENT-1000	~1000	Hydrophilic
ENT-2000	2000	
ENT-4000	4000	
ENTP-1000	~1000	Hydrophobic
ENTP-2000	2000	
ENTP-3000	3000	
ENTP-4000	4000	
ENTE-1	—	Emulsion-type
ENTA-1	~2200	Anionic
ENTC-1	~940	Cationic

**Figure 1** Structures of typical photocrosslinkable resin prepolymers.

was obtained. ENTE-1 is useful when swelling of the gels is to be avoided (10). Photocrosslinkable resin prepolymers can be autoclaved at 120°C and stored in the dark.

Among these photocrosslinkable resin prepolymers, ENT and ENTP prepolymers are commercially available from Kansai Paint Co., Tokyo, Japan.

### 3. Procedures

Typical procedures for entrapment with photocrosslinkable resin prepolymers are as follows: 1 g of ENT-4000 or mixture of ENT-4000 and ENTP-4000 (ENT-4000 content is above 70%) is mixed with 10 mg of a photosensitizer such as benzoin ethyl ether. The mixture is melted by warming at 60°C. An adequate buffer, such as 50 mM potassium phosphate buffer (0.5 mL) is added to the molten mixture and mixed at 60°C. The molten mixture is cooled to 4°C, and 2 mL of solution or suspension of biocatalysts is added to the mixture. The obtained mixture is layered on a sheet of transparent polyester film framed ( $\sim 70 \text{ cm}^2$ ) with a plastic tape (thickness  $\sim 0.5 \text{ mm}$ ). The layer is covered with a transparent thin film to eliminate air and then illuminated with near-ultraviolet light (wavelength range 300–400 nm;

maximum intensity at 360 nm) for several minutes. The gel film formed is cut into small pieces and used as the entrapped biocatalyst.

Bead-type biocatalysts entrapped with photocrosslinkable resin prepolymers can also be obtained (11). Ten parts (by weight) of prepolymer are mixed with 0.08 parts of the initiator, 2 parts of 3% sodium alginate, 2 parts of distilled water, and 2 parts of the biocatalyst. The mixture obtained is dropped into 1.5% aqueous calcium chloride solution to form the beads. The beads thus formed are irradiated by near-ultraviolet light. After irradiating for 5 min, the entrapped biocatalyst beads obtained are washed with sterile water. For practical applications, the bead-type is often preferable to the cube-type or film-type.

Tube-type biocatalysts can be easily prepared by using ENTE-1. The inner surface of glass tubes (ID 2 mm) is silanized with vinyltriethoxysilane (10). ENTE-1 is mixed with photosensitizer and the solution or suspension of biocatalyst. This viscous mixture is injected at the top of each silanized glass tube to form a thin layer of biocatalyst-containing prepolymer on the inner surface of the tube. The tube is illuminated with near ultraviolet light for several minutes under an atmosphere of nitrogen to

complete the photocrosslinking of the prepolymer. The resulting tube-type biocatalysts can be used in continuous-flow systems to assay various compounds.

## B. Urethane Resin Prepolymer Method

### 1. Principle

The urethane resin prepolymer method is very simple and convenient, because isocyanate functional groups at both terminal ends of the urethane prepolymer (Fig. 2) react with each other only in the presence of water, forming a urea linkage and liberating carbon dioxide (12). Consequently, when the prepolymers are mixed with an aqueous solution or an aqueous suspension of biocatalyst, gels are easily formed within a few minutes and gelation is complete in 30–60 min.

### 2. Prepolymers

Structures of typical urethane resin prepolymers are shown in Figure 2, and the properties of the prepolymers are summarized in Table 2. Urethane resin prepolymers (PU) are synthesized from toluene diisocyanate and polyether diols composed of polyethylene glycol and polypropylene glycol or polyethylene glycol alone. Prepolymers with different hydrophilic or hydrophobic properties can be obtained by changing the ratio of the polyethylene glycol and polypropylene glycol in the polyether diol moiety of the prepolymers. For example, PU-2 to PU-4 with a high content of polypropylene glycol give relatively hydrophobic gels, while PU-1 and PU-5 to PU-11 with a high content of polyethylene glycol give hydrophilic gels, although all the prepolymers are water miscible (13, 14). The chain length and the content of isocyanate group of the prepolymers, which correlate to the size of network of the gels formed from these prepolymers, can also be changed.

Urethane resin prepolymers can be sterilized at 120°C under anhydrous conditions and stored in a desiccator.

Although these urethane resin prepolymers are not currently available commercially, Hypol having a similar structure can be obtained from W. R. Grace Co., Lexington, MA.

### 3. Procedures

Typical entrapment procedures with urethane resin prepolymers are as follows. The urethane prepolymer (1 g) melted by incubation at 50°C (if necessary) is cooled to 4°C and mixed quickly and well with 2 mL of aqueous solution or suspension of biocatalyst in a small beaker. When gelation starts after a few minutes of mixing, the mixture is kept at 4°C for 30–60 min to complete the gelation. The gel thus formed is cut into small pieces, washed thoroughly with the buffer, and used as the entrapped biocatalyst.

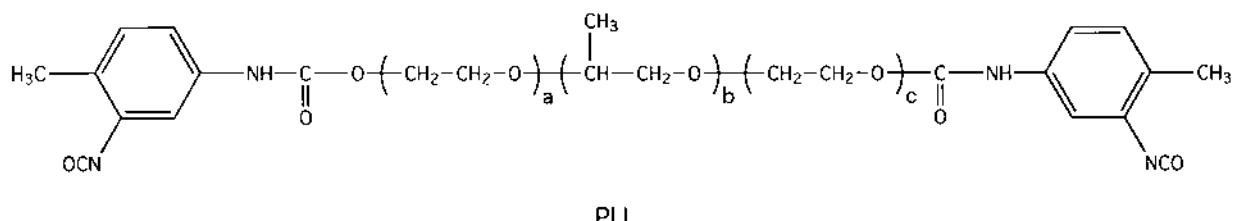

If the mixture, quickly and well stirred, is immediately layered on a glass plate framed with adhesive tape with the proper dimensions before the gelation starts, a film of entrapped biocatalyst can be obtained (15).

## C. Miscellaneous

Owing to the advantages of prepolymer methods mentioned above, continuous efforts have been devoted to develop new prepolymer methods.

Photosensitive resin prepolymers (PVA-SbQ) were also developed by Ichimura (16). Photosensitive resin prepolymers are derivatives of polyvinyl alcohol having styrylpypyridinium groups as photosensitive functional sites and polymerized by photodimerization with irradiation of visible or ultraviolet light. Hydrophilicity of the prepolymers can be controlled by changing the saponification degree of polyvinyl acetate.

Several prepolymers, such as polyvinyl alcohol (17), polyethylene glycol diacrylate (18), and polyethylene

<sup>a</sup>The remaining percentage (100-X) is polypropylene glycol.

glycol dimethacrylate (18, 19), are also useful gel materials for entrapment by radiation. In the case of 10% polyvinyl alcohol, 5–7 Mrad of radiation is sufficient to obtain rigid gels (17). The glass-forming prepolymers, such as polyethylene glycol diacrylate and polyethylene glycol dimethacrylate, are used for entrapment through radiation polymerization at low temperature. Entrapment can be carried out at -24°C with 10% prepolymer and a radiation of 1 Mrad (19). A mixture of polyvinyl alcohol and polyethylene glycol dimethacrylate is also applicable (18). This radiation method has several advantages such as possible application of a wide variety of prepolymers as gel materials and entrapment at low temperature. However, utilization of this method is limited because radiation apparatus is required.

Water-soluble linear polyacrylamide ( $MW\ 15\times 10^4$  to  $17\times 10^4$ ) partially substituted with the acyl-hydrazide group was synthesized (20). This prepolymer can be gelled and used for entrapment of biocatalysts in the presence of a crosslinking agent such as glyoxal, glutaraldehyde, or periodate-oxidized polyvinyl alcohol.

### III. BIOCATALYSTS ENTRAPPED BY PREPOLYMER METHODS

As described above, various kinds of prepolymers having different physicochemical properties have been

developed for the entrapment of different kinds of biocatalysts.

#### A. Enzymes

Examples of enzymes entrapped with prepolymers are listed in Table 3. Some enzymes listed in Table 3 have been employed for development or appraisal of new prepolymer methods. Not many reports are available concerning the applications of enzymes entrapped by prepolymer methods.

Lipases entrapped with hydrophobic photocrosslinkable resin prepolymers (ENTP-2000 and ENTP-4000) have been applied to the hydrolysis and ester exchange reaction of triacylglycerides. Production of cacao butter-like fat from olive oil and stearic acid or palmitic acid by enzymatic ester exchange reaction has been successfully achieved with ENTP-entrapped *Rhizopus delemar* lipase in an organic solvent system (21, 22). Entrapment markedly enhanced the operational stability of the enzyme. In the case of the hydrolysis of olive oil to glycerol and fatty acids, *Candida cylindracea* lipase entrapped with ENTP showed high activity (23). Entrapment also made it possible to use the enzyme repeatedly or continuously. PU-entrapped *Candida cylindracea* lipase was used for optical resolution of *dl*-menthol through enantioselective esterification in an organic solvent (24).

Enzymes entrapped with photocrosslinkable resin prepolymers were applied to the analyses of various compounds. Tubes entrapping glutamate decarboxyl-

Lysine decarboxylase	Photocrosslinking (ENTE-1)	25

ase (10) and lysine decarboxylase (25) were prepared with the emulsion-type photocrosslinkable resin prepolymer ENTE-1. These tubes were used in continuous-flow systems to measure the concentration of L-glutamate and L-lysine, respectively, in fermentation broths. Thin enzyme films, in which the enzymes were entrapped with photocrosslinkable resin prepolymers, were mounted on an oxygen electrode and used as enzyme electrodes (13). Several oxygen-consuming oxidases, such as choline oxidase and glucose oxidase, were employed for this purpose. These enzyme electrodes were found to be stable.

## B. Cells

Applications of immobilized cells are very attractive and important because cells possess multienzyme systems which mediate complex reactions (3). In the case of immobilization of cells, it is not necessary to extract the enzymes from the cells. This avoids inactivation of the enzymes during the time-consuming and expensive purification procedures, and makes it possible to use the enzymes under more stable conditions. However, immobilized cells have some disadvantages that should be considered for practical application:

1. Byproducts may be synthesized because the cells contain many enzymes, which may catalyze undesirable reactions. Selection of a strain, mutation, or proper treatment of cells, or genetic improvement of a cell line helps to overcome this problem.

2. The cell wall and/or cell membrane of intact cells often prevents substrates, products, and other reaction components from permeating into and out of cells. In this case, appropriate treatment of cells before or after immobilization is required to eliminate the barriers to permeability.

The immobilized cells can be kept in a growing state by appropriate supply of suitable nutrients. This type of immobilized cells (immobilized growing cells) is very advantageous. Immobilized growing cells serve as self-proliferating and self-regenerating biocatalysts. However, immobilized growing cells also have some disadvantages as follows:

1. Various nutrients and energy sources are required to maintain the cells in living or growing state(s), and yield of wanted products may be lowered by the consumption of substrates and/or products as nutrients or energy sources.

2. Products are liable to be contaminated by leakage of cells from carriers.

In spite of these disadvantages, cell immobilization is a key technology to construct an efficient bioprocess because immobilized cells have many attractive characteristics, as described above. For immobilization of cells, entrapment methods have been mainly used. Especially, other immobilization methods, such as carrier binding and crosslinking methods, are difficult to use for immobilization of living or growing cells. For entrapment of cells, prepolymer methods have been also widely used. Various types of cells have been entrapped by prepolymer methods.

## 1. Microbial Cells

Microbial cells are thought to be excellent biocatalysts due to high growth rate, insensitivity to shear force, and a relatively low cost for cultivation. Moreover, microbial cells can synthesize and secrete not only primary metabolites but also various secondary metabolites. Thus, various conditions of microbial cells—dried, untreated, resting, living, growing, etc.—have been entrapped by prepolymer methods and employed widely. Table 4 lists examples of microbial cells entrapped by prepolymer methods. Typical applications of entrapped microbial cells are described below.

Generation of ATP by using the energy of glycolysis is very important for the production of useful compounds by biocatalysts. Dried yeast cells entrapped by photocrosslinkable resin prepolymers were employed for the phosphorylation of adenosine with glucose as an energy source (26). Such ATP-generating systems can be combined with an ATP-requiring system in the same cells.

By using growing *Saccharomyces* cells entrapped with photocrosslinkable resin prepolymers, pilot-scale production of ethanol has been successfully carried out (27).

ENT- or PU-entrapped cells of *Rhodotorula minuta* var. *texensis* were successfully employed for the enantioselective hydrolysis of a *dl*-menthyl ester, giving optically pure *l*-menthol (28).

Entrapment in suitable gels renders microbial cells significantly tolerant against unfavorable effects of organic solvents. Applications of such entrapped microbial cells to bioconversion of hydrophobic or water-insoluble compounds are very important from a practical point of view. In these cases, introduction of organic solvents into reaction systems is essential to dissolve substrates and/or products. Various reactions have been successfully carried out by using microbial cells entrapped with prepolymers in water–organic cosolvent systems and in organic solvent systems (28, 29). However, it is very difficult for the entrapped cells to live in organic solvent. Recently, we have demonstrated that doubly entrapped baker's yeast, i.e., the yeast cells entrapped with urethane resin prepolymer (PU-6) after entrapment in calcium alginate, can maintain a living state during long-term stereoselective oxidoreduction in an organic solvent (30).

## 2. Plant and Animal Cells

Higher plants are important sources of numerous useful natural compounds such as pharmaceuticals, flavorings, and coloring materials, which have complicated structures and cannot be synthesized by microbial cells. Animal cells are also attractive biocatalysts for the production of vaccines and other bioactive peptides. For practical application of these cells, immobilization, especially, entrapment has received increasing interest as one of the most promising techniques. Entrapment of these cells has been carried out mostly with natural polymers such as alginate. As for prepolymer methods, cultured plant cells of *Lavandula vera* were entrapped with photosensitive resin prepolymer (PVA-SbQ) and used for production of blue pigments (31).

## C. Cellular Organelles

Cellular organelles have their own organized functions for metabolizing cellular substances. This means that these organelles are useful biocatalysts for carrying out well-organized multistep reactions when they are isolated intact and immobilized without the loss of their native characteristics. Prepolymer methods have proved to be suitable for the immobilization of organelles because the immobilization can be achieved by entrapment under mild conditions (32, 33). Only a few reports have been published; the kinds of organelles immobilized with prepolymer methods are summarized in Table 5.

## IV. EFFECTS OF THE PROPERTIES OF PREPOLYMERS

One of the advantages of prepolymer methods is easy preparation of gels having different properties by selecting suitable prepolymers which are synthe-

sized chemically in advance in the absence of biocatalysts.

### A. Chain Length

The chain length of prepolymers can be changed. For example, the chain length of ENT-1000-containing polyethylene glycol-1000 (average MW~1000) is ~10 nm, and that of ENT-2000 containing polyethylene glycol-2000 (average MW~2000) is ~20 nm.

In general, a looser network of gels prepared from longer-chain prepolymers increases the rate of diffusion of substrates and products through the gels. However, leakage of biocatalysts, especially enzymes with low molecular weights, sometimes becomes a significant problem with the gels which have a loose network (13). When invertase was entrapped with PEGM-1000 to PEGM-4000 (4) or PU of MW 2000–5000 (12), the apparent enzyme activity was highest in the case of the longest-chain prepolymer. A similar result was obtained when catalase was entrapped with ENT-1000 to ENT-6000 (8).

The loose network of gels is generally favorable to growth if the entrapped cells are allowed to grow inside gel matrices. When fungal spores (*Curvularia lunata*) were entrapped with photocrosslinkable resin prepolymers (ENT) and allowed to germinate and grow inside gel matrices, development of mycelia was abundant in gels formed from prepolymers of longer chain length, while the growth was inhibited in gels of tight network (34). Leakage of mycelia was often observed with gels prepared from longer-chain length prepolymer.

As described above, the chain length of prepolymers is an important factor affecting the activity of biocatalysts entrapped within the prepolymers. Prepolymer methods offer an easy selection of adequate chain length.

**Table 5** Examples of Cellular Organelles Entrapped by Prepolymer Methods

Peroxisomes or microbodies (methanol-grown <i>Kloeckera</i> sp.)	Photocrosslinking (ENT) Urea linkage (PU)	7 45

## B. Hydrophilicity–Hydrophobicity Balance

Bioreactions with hydrophilic substrates are generally carried out in aqueous solutions. Hydrophilic properties of gels are favorable for such reaction systems. On the other hand, proper organic solvents are suitable for bioconversion of hydrophobic compounds in terms of the solubility of the compounds and of shifting the reaction equilibrium to the desired direction. In such cases, hydrophobic gels favor the transformation of hydrophobic substances owing to high affinity of the compounds to the gels. One of the most representative examples is the successful ester exchange of triglycerides with *Rhizopus delemar* lipase in water-saturated *n*-hexane, indicating the need of organic solvent and the advantage of hydrophobic gels (21). In this case, hydrolysis of triglycerides was preferential when the concentration of water was high, and the hydrophilic gel-entrapped enzyme preparation exhibited only low activity. It was also found that the activities of the entrapped biocatalysts corresponded closely to the partition of the substrates between the gels and the external solvents (35).

Prepolymer methods, especially those with photo-crosslinkable resin prepolymers and urethane prepolymers, again offer easy selection of gels having an optional hydrophilicity–hydrophobicity balance by using different types of prepolymers or by mixing these prepolymers.

## C. Ionic Properties

Anionic or cationic property of gels has a significant influence on the apparent activities of gel-entrapped biocatalysts through an electrostatic interaction with the charged substrates. Furthermore, the optimum reaction pH may be shifted by using gels with proper ionic properties.

When choline oxidase entrapped with photocrosslinkable resin prepolymers was used as an enzyme electrode for assay of choline, the enzyme entrapped with an anionic prepolymer exhibited significantly higher activity. On the other hand, the enzyme entrapped with a cationic prepolymer showed markedly lower activity (13). The results can be explained by different affinity of the cationic substrate choline for the gels with different ionic properties.

Shift of the optimum pH was also observed in the case of the production of adenine arabinoside through transglycosylation by *Enterobacter aerogenes* cells entrapped with the photocrosslinkable resin prepolymers of different ionic characters (36).

## Genetic Immobilization of Enzymes on Yeast Cell Surface

Mitsuyoshi Ueda, Toshiyuki Murai, and Atsuo Tanaka

Kyoto University, Kyoto, Japan

### I. INTRODUCTION

Extensive studies have been conducted on various methods of immobilization of enzymes. Conventional methods for immobilization of enzymes through covalent bonds have some merits; the enzymes are immobilized through strong bondage, and dissociation is low in substrate or salt solution even at high concentrations. However, change in structure of the immobilized protein or in their characteristics often occurs owing to severe treatment and there are many difficulties in the determination of the immobilization reaction conditions. On the other hand, immobilization through ionic bonds does not share these disadvantages, but the enzymes are easily dissociated.

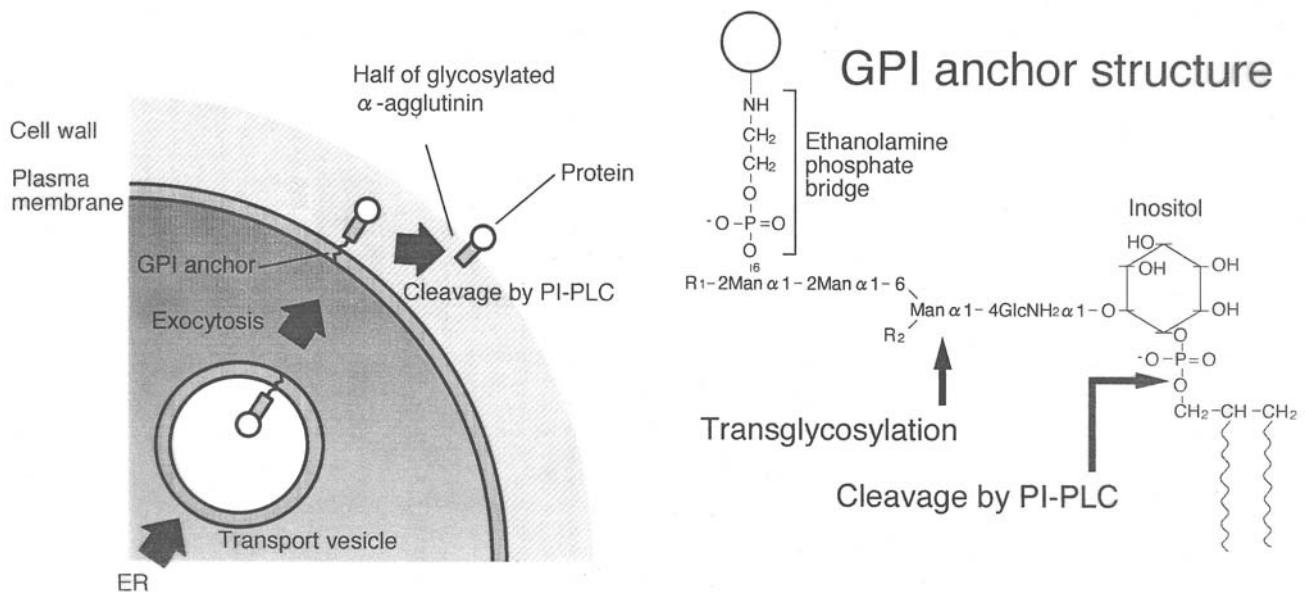

The genetic engineering method, combined with the immobilization method using cell surface as a carrier for immobilization of enzymes, overcomes the disadvantages of the above methods; enzymes are immobilized by a strong covalent bondage. They can be regenerated according to the activation of the promoter, and they are “naturally” immobilized on the cell surface. Immobilization of enzymes on cell surface saves tedious purification process of enzymes to be used in conventional immobilization. Expression of proteins on the cell surface of *S. cerevisiae* would offer more advantages than other microbial cells. First, since *S. cerevisiae* is widely used in industrial production of proteins and chemicals, enzyme-coated yeast cells could be used as novel

whole-cell biocatalysts, because surface-immobilized proteins are covalently linked to glucan in the cell wall, rendering them resistant to extraction. Second, as *S. cerevisiae* is generally regarded as safe (GRAS) for oral use, it can be used in food and pharmaceutical products.

The immobilized enzyme displayed on the cell surface is also regarded as a kind of a self-immobilized enzyme on the cell surface; this phenomenon is passed on to daughter cells as long as the plasmid or the integrated gene is retained by the cells. This immobilization system could turn or remake *S. cerevisiae* into a novel and attractive microorganism as a whole-cell biocatalyst by surface expression of various enzymes, especially when target substrates are not able to be taken up by the cells.

### II. PRINCIPLES OF GENETIC IMMOBILIZATION OF ENZYME ON YEAST CELL SURFACE

To immobilize protein on the cell surface of *S. cerevisiae*, molecular information of the native cell wall-anchored protein,  $\alpha$ -agglutinin, was utilized.  $\alpha$ -Agglutinin (1) is a mannoprotein involved in the sexual adhesion of mating-type  $\alpha$  *S. cerevisiae* cells with mating-type  $a$  *S. cerevisiae* cells.  $\alpha$ -Agglutinin has a glycosylphosphatidylinositol (GPI) anchor attachment signal (Fig. 1; Table 1), which is involved in anchoring cell wall proteins. This anchoring signal was combined with the

**Figure 1** Transportation system of cell surface proteins in *S. cerevisiae* and GPI anchor structure. ER, endoplasmic reticulum; PI-PLC, phosphatidylinositol-specific phospholipase C; GPI, glycosylphosphatidylinositol; Man, mannose; GlcNH<sub>2</sub>, glucosamine.

signal of the secreted enzymes using genetic engineering techniques. Figure 2 shows the general structure of the gene for cell surface immobilization of an enzyme (2). 3'-Half of  $\alpha$ -agglutinin contains a glycosylphosphatidylinositol (GPI) anchor attachment signal at the C-terminal end, like other cell surface proteins.

### III. GENETIC IMMOBILIZATION OF AMYLOLYTIC ENZYMES ON YEAST CELL SURFACE

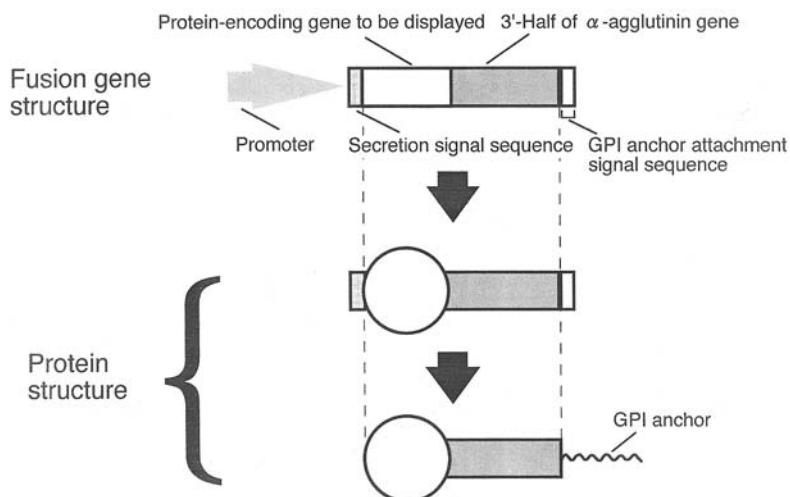

Although starchy materials are available in abundance as carbon sources for cultivation, wild-type

*S. cerevisiae* itself is unable to utilize starch. A number of strategies have been adopted for the construction of starch-utilizing systems, which include the addition of amylolytic enzymes in culture broth and the introduction of heterologous genes encoding amylolytic enzymes into yeast cells for secretive production of the enzymes. As one of strategies, glucoamylase (EC 3.2.1.3) from *Rhizopus oryzae* (3), an exo-type amylolytic enzyme cleaving  $\alpha$ -1,4-linked and  $\alpha$ -1,6-linked glucose effectively from the non-reducing end and/or  $\alpha$ -amylase (EC 3.2.1.1) from *Bacillus stearothermophilus* CU21 (BSTA) (4), an endo-type amylolytic enzyme cleaving  $\alpha$ -1,4-glycosidic linkage, were displayed on the yeast cell surface

(Fig. 3). The constructed strains immobilizing glucoamylase or glucoamylase and  $\alpha$ -amylase should be able to saccharify starch on its cell wall and assimilate the released glucose to proliferate and ferment.

#### A. Immobilization of Glucoamylase on Yeast Cell Surface Using a Multicopy Plasmid

##### 1. Construction of a Multicopy Plasmid

A plasmid pGA11 to immobilize glucoamylase on the yeast cell surface was constructed as a multicopy plas-

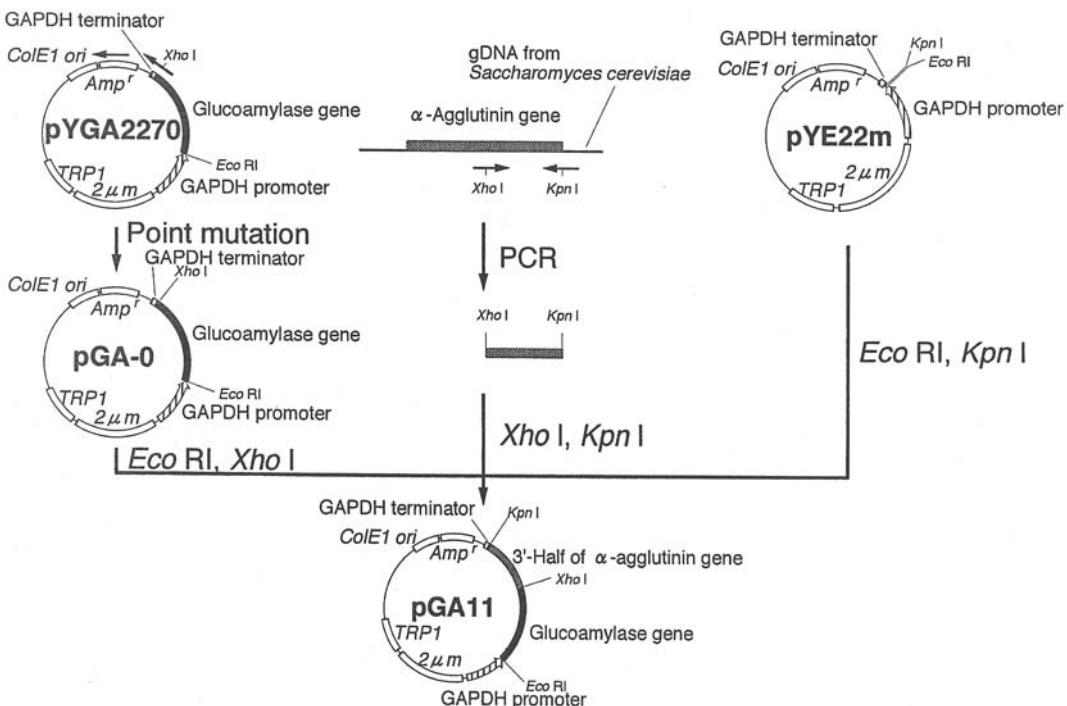

mid for expression of the glucoamylase/ $\alpha$ -agglutinin fusion gene containing the secretion signal sequence of the glucoamylase under the control of the *GAPDH* promoter (2). The plasmid pGA11 was constructed as follows (Fig. 4): an *Xba*I site was generated at the end of the glucoamylase coding region on the plasmid pYGA2270 (5) by site-directed mutagenesis (U.S.E. Mutagenesis Kit, Pharmacia Biotech. Co., Uppsala, Sweden) with the primers 5'-GCACCTG CCGCTGGCTCGAGAAATTAAATGC-3' and 5'-CTGTGACTGGTGACGCGTCAACCAAGTC-3' as mutation and selection primers, respectively. A DNA fragment containing glucoamylase coding region was isolated from the mutated plasmid by *Eco*RI-*Xba*I digestion. A DNA fragment of the  $\alpha$ -agglutinin gene (*AGα1*), containing 3'-half of the coding region encoding 320 amino acids of the  $\alpha$ -agglutinin and 446 bp of the 3'-flanking region, was prepared by PCR (primers, 5'-GTACCTCGAGCGCAAAGCTCTTTATC-3' and 5'-GCGGTACCTTGATTATGTTCTTCTT CTAT-3') with genomic DNA from *S. cerevisiae* MT8-1 (*MATA ade his3 leu2 trp1 ura3*). (6) as a template, followed by digestion by *Xba*I and *Kpn*I. These two fragments were substituted for the *Eco*RI-*Kpn*I section between the *GAPDH* promoter and the *GAPDH* terminator of the yeast expression cassette vector pYE22m. The resulting plasmid was named pGA11.

**Figure 3** Model of cell surface–engineered yeast assimilating starch or cellulose. E, amylolytic or cellulolytic enzyme(s).

##### 2. Detection of Glucoamylase Activity

The constructed plasmid was introduced into *S. cerevisiae* strain MT8-1 as a host cell. Yeast was precultivated in YPD medium (1% yeast extract, 2% peptone,

**Figure 4** Construction of the multicopy plasmid pGA11 for immobilization of glucoamylase on the yeast cell surface.

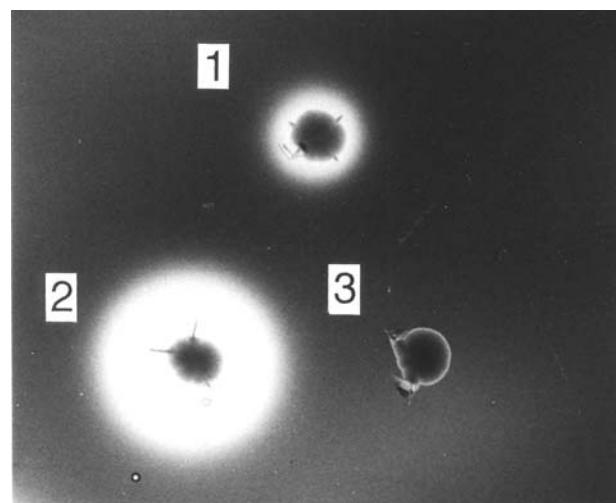

2% glucose). After cells were cultivated aerobically at 30°C in modified Burkholder's medium (containing 0.002% adenine sulfate, 0.002% L-histidine-HCl, 0.003% L-leucine, 0.002% uracil, and 1% casamino acids) to which 2% glucose was added as a carbon source, culture medium and cell pellets were isolated by centrifugation to measure the glucoamylase activities in both fractions. Cell growth in the culture broth was measured by absorbance at 600 nm. For measurement of glucoamylase activity (2), the substrate for glucoamylase reaction was prepared by adding soluble starch to boiling 20 mM sodium acetate buffer (pH 4.6) to give a concentration of 0.5%. After keeping 0.9 mL of the solution at 30°C for 5 min, 0.1 mL of enzyme solution was added and the mixture was incubated at the same temperature for 15 min. The reaction was stopped by boiling the mixture for 10 min and the concentration of glucose was determined using F-kit for glucose (Boehringer Mannheim, Mannheim, Germany). One unit of glucoamylase was defined as the amount of enzyme required to release 1 µmol glucose/min from starch. As a result, the cells harboring the plasmid pGA11 had only the cell-associated glucoamylase activity without secretion of the active enzyme (2).

The cell wall of *S. cerevisiae* mainly consists of glucan and mannoproteins. Glucan is composed of  $\beta$ -1,3- and  $\beta$ -1,6-linked glucose. Some mannoproteins seemed to be covalently linked with glucan, because they can be extracted by  $\beta$ -1,3- or  $\beta$ -1,6-glucanase. The localization of the glucoamylase protein and its association with cell wall was determined. Cells were harvested by centrifugation at 3000g and washed in cooled (0°C) buffer (10 mM Tris-HCl [pH 7.8], 1 mM phenylmethylsulfonyl fluoride [PMSF]). The cells, the buffer, and glass beads (diameter 0.45–0.50 mm) were mixed in a ratio of 1:2:1 wet-w/v/w in a glass tube and agitated vigorously, using a benchtop vortex mixer, for 5 min at 0°C. The cell wall fraction was recovered by centrifugation of the homogenate at 1000g for 5 min and was washed with the same buffer. Glucoamylase was extracted from this fraction in a two-step procedure. First, noncovalently bound proteins, and proteins bound through disulfide bridges, could be extracted from cell wall with hot sodium dodecyl sulfate (SDS). Following this, the SDS-treated cell wall was further digested with laminarinase ( $\beta$ -1,3-glucanase). To quantify the amount of the SDS-extracted and glucanase-extracted glucoamylase protein, intensities of signals from each fraction on the filter were measured

using antigucoamylase IgG and horseradish peroxidase protein A (2). The enzyme was almost extracted by glucanase.

The amylolytic activity was also detected by halo formation on an agar plate. Cells harboring the plasmid pGA11 or pYE22m, as a control, were inoculated on a plate of modified Burkholder's medium containing 2% glucose and 1% soluble starch. After incubation for 3 days at 30°C, the plate was stained with iodine vapor. Figure 5 shows that the cells harboring the plasmid pGA11 hydrolyzed starch and produced a halo strictly around the colony, while no halo formation was observed around the cells harboring the plasmid pYE22m. This indicates that the former cells obtained amylolytic activity owing to the expression of the glucoamylase/α-agglutinin fusion gene on the cell surface.

To know the properties of the anchored enzyme, thermal stability, optimal temperature, and optimal pH of the glucoamylase anchored on the cell surface were compared with those of the secreted free glucoamylase (7). The cell wall fraction of the cells harboring the plasmid pGA11 was suspended in 20 mM sodium acetate buffer (pH 4.6). The cells harboring the plasmid for expression of the glucoamylase without being fused to α-agglutinin were cultivated in modified Burkholder's medium containing 2% glucose as a car-

**Figure 5** Plate assay for detection of amylolytic activity. 1, *S. cerevisiae* with cell surface-immobilized glucoamylase (*S. cerevisiae* MT8-1/pGA11); 2, *S. cerevisiae* secreting glucoamylase; 3, *S. cerevisiae* MT8-1 as the control (*S. cerevisiae* MT8-1/pYE22m).

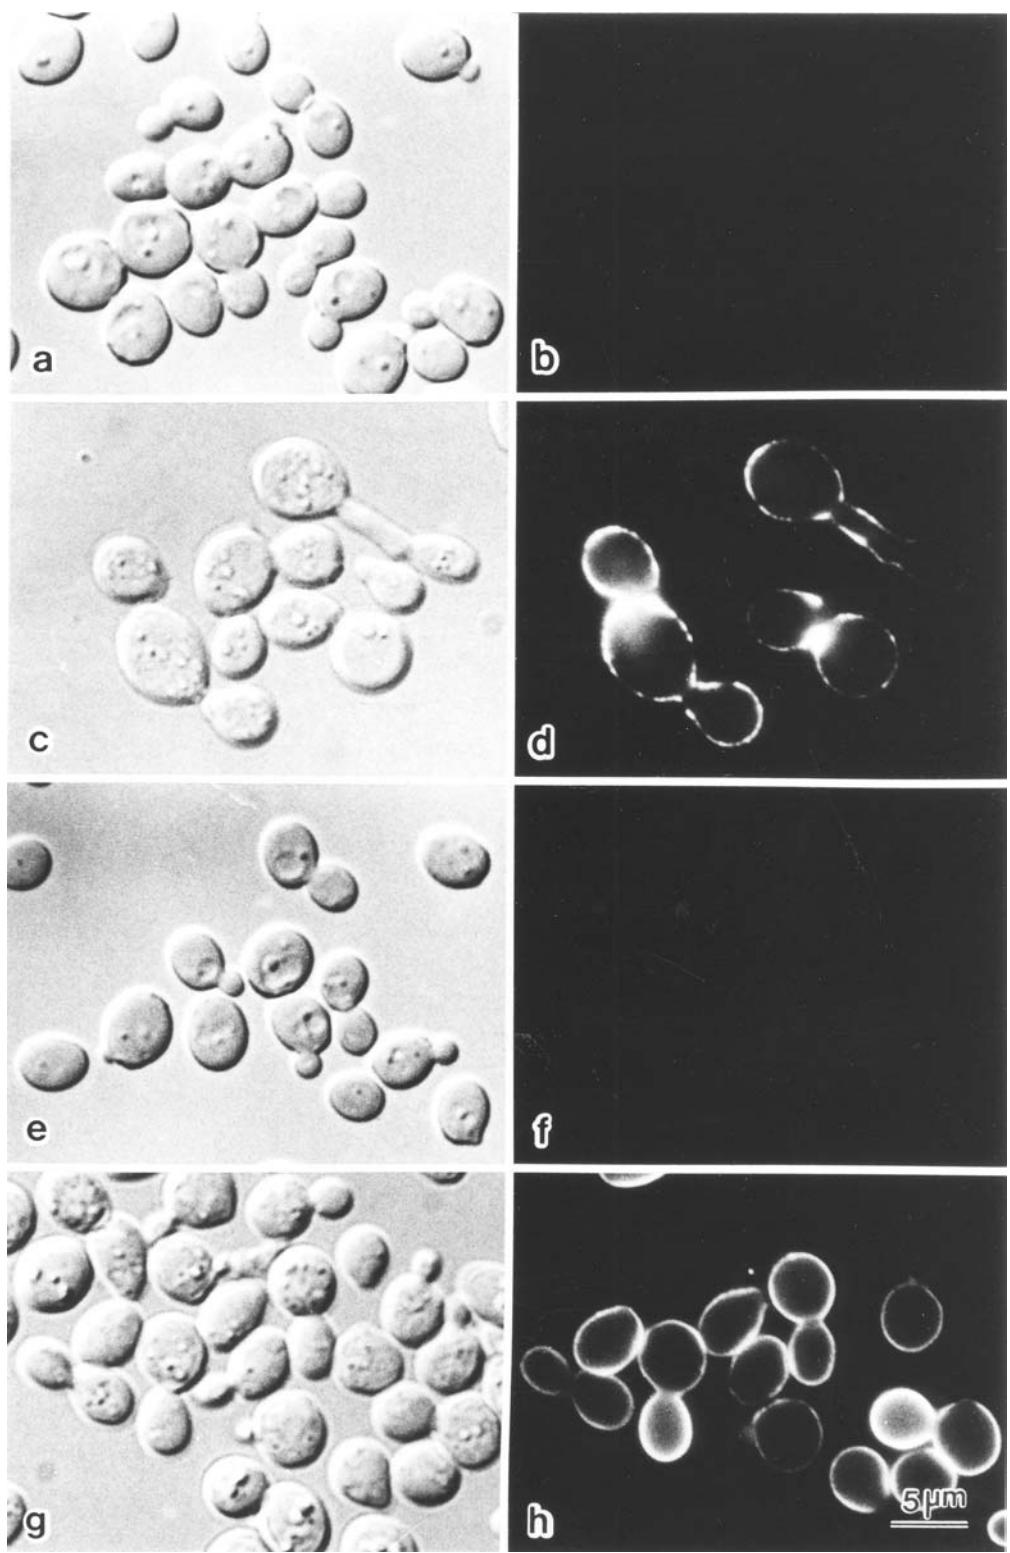

bon source at 30°C for 24 h, and the supernatant of the culture broth was used as the source of free glucoamylase. Free glucoamylase solution was prepared by dialysis of the culture supernatant in 20 mM sodium acetate buffer (pH 4.6) at 4°C. The glucoamylase activities in the cell wall suspension and the dialyzed supernatant were measured. The properties of the anchored glucoamylase examined were similar to those of the free glucoamylase, suggesting that the enzymatic function of the anchored glucoamylase was comparable to that of the free enzyme.

### 3. Microscopic Observation

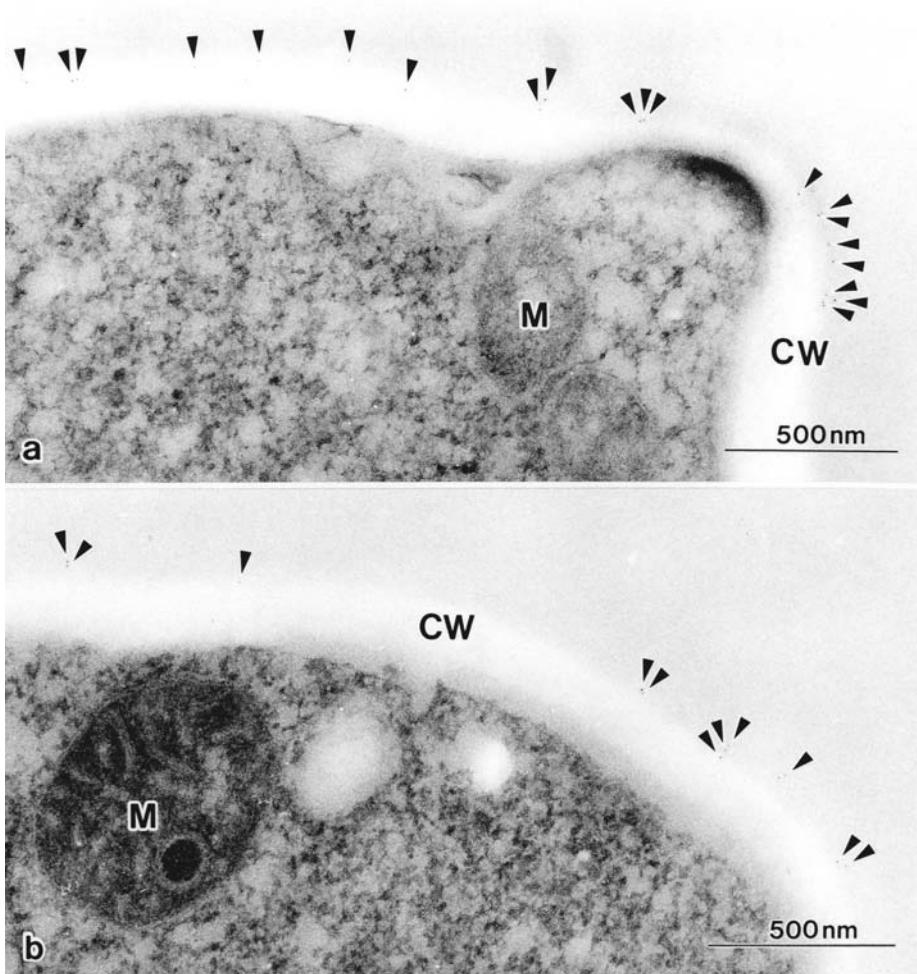

For immunofluorescence microscopy, immunostaining was performed as follows. As the primary antibody, the antibody against *R. oryzae* glucoamylase at the dilution rate of 1:1000 was used. Cells and the antibody were incubated at room temperature for 1.5 h. After washing of cells, the second antibody, fluorescein isothiocyanate (FITC)-conjugated goat anti-rabbit IgG diluted 1:300, was reacted with the cells at room temperature for 1 h. After washing, the image of cells was observed. Cells expressing the glucoamylase/α-agglutinin fusion gene were uniformly labeled, although not all the cells were equally intensively labeled. This is probably due to differences in expression levels among the cells. The cells harboring the control plasmid were hardly labeled (Fig. 6). For immunoelectron microscopy, yeast cells were fixed with 4% paraformaldehyde, and immunostaining was done as follows. The antibody against glucoamylase diluted 1:100, as the primary antibody, was incubated with cells at 4°C for 2 h. The second antibody, goat anti-rabbit IgG conjugating 5 nm gold diluted 1:40, was reacted with the cells at 4°C overnight, followed by fixation with 1% glutaraldehyde. Thereafter, embedding and microscopic observation were performed. Gold particles were detected on the surface of the cell wall of the cells harboring the plasmid pGA11. Few gold particles were detected in the case of the control cells (Fig. 7).

### 4. Assimilation of Starch

When cells were cultivated aerobically with 1% soluble starch as the sole carbon source, the cells harboring the plasmid pGA11 utilized starch and proliferated to reach an absorbance of ~ 10, which was the same level as in the case of the culture on 1% glucose.

**Figure 6** Immunofluorescent labeling of transformed cells. Normarsky differential interference micrographs (a, c, e, g) and immunofluorescence micrographs (b, d, f, h). a, b, e, f: *S. cerevisiae* MT8-1 harboring pYE22m (control); c, d: *S. cerevisiae* MT8-1 harboring pGA11; g, h: *S. cerevisiae* MT8-1 harboring pCMC11.

## B. Immobilization of Glucoamylase on Yeast Cell Surface Using an Integrative Plasmid

For the stable expression of enzymes on the yeast cell surface, a gene to be integrated into the chromosome of *S. cerevisiae* was constructed using the fusion gene of glucoamylase and C-terminal half of  $\alpha$ -agglutinin genes (8).

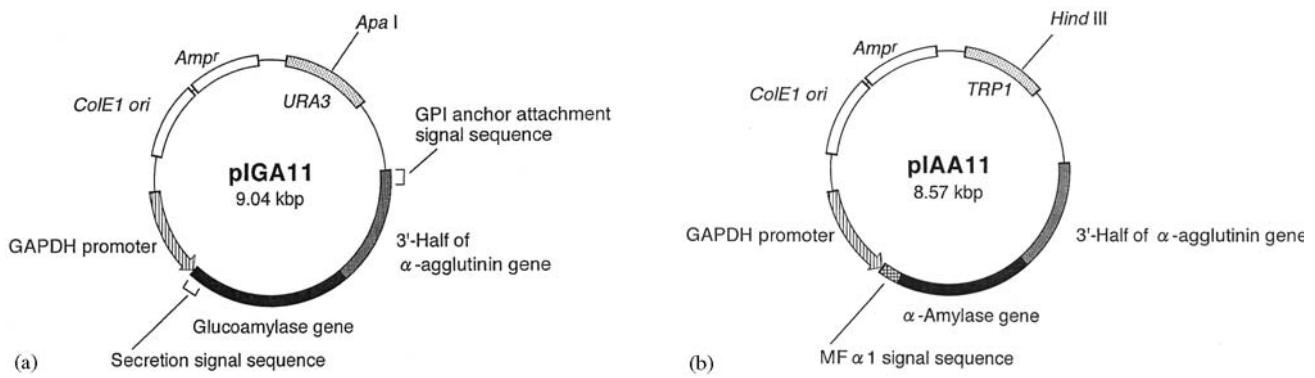

### 1. Construction of an Integrative Plasmid

An integrative plasmid for integration of the glucoamylase gene to the chromosome was constructed as follows (Fig. 8a): The yeast integration vector pRS406 (9) was digested with *Kpn*I and *Sal*I, treated with T4 DNA polymerase, and then self-ligated. The *Hind*III frag-

ment containing the glucoamylase/ $\alpha$ -agglutinin fusion gene excised from the plasmid pGA11 was inserted into the *Hind*III site of the self-ligated plasmid. The resulting plasmid was named pIGA11 as the integrative plasmid. The plasmid pIGA11 prepared was cut by *Apal* and introduced into *S. cerevisiae* MT8-1 strain, and the transformant obtained was named IGA strain. Integration of the fusion gene was confirmed by Southern blot hybridization analysis using a full-length fragment of *URA3* as a probe.

### 2. Stability of the Strain Harboring the Integrative Plasmid

Mitotic stability of the integrated exogenous DNA sequence after 120 h cultivation was estimated by com-

**Figure 8** Construction of integrative plasmids for cell surface immobilization of glucoamylase (a, pIGA11) and  $\alpha$ -amylase (b, pIAA11).

paring the number of colonies (cells corresponding to  $A_{600} = 10$ ) grown on a nonselective YPD plate with that grown on a selective SD (synthetic [S] medium [0.67% yeast nitrogen base without amino acid with appropriate supplements] containing 2% glucose) plate using the replica-plate method. As for IGA strain, the number of colonies on SD plate without uracil was  $\sim 97\%$  of that on YPD plate. When cultivation was repeated three times, the number of colonies of uracil nonauxotrophs was still 90%.

### C. Immobilization of $\alpha$ -Amylase on Yeast Cell Surface Using an Integrative Plasmid

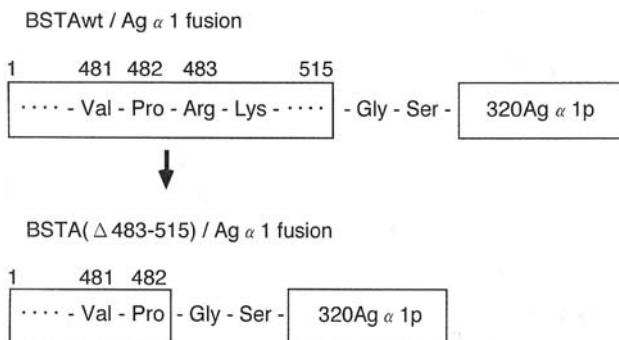

#### 1. Construction of an Integrative Plasmid

To express the  $\alpha$ -amylase gene from *B. stearothermophilus* CU21 (BSTA in *S. cerevisiae* and display the synthesized protein on its cell surface (8), the following DNA fragments were prepared (Fig. 8b). The prepro leader sequence of the  $\alpha$ -factor precursor (*MFα1*) was first fused to the  $\alpha$ -amylase gene. The prepro secretion signal sequence of the *MFα1* was amplified from the plasmid pLS01 by PCR, using the primers 5'-GCAGCTCGAGATGAGATTCTTCAATTTT-*ACTGC*-3' and 5'-TCTCTAGAACCCAAAGATAAC-CCCTTC-3'. pLS01 has a 1.7-kbp *EcoRI-EcoRI* fragment of the *MFα1* inserted at *EcoRI* site of pUC13 (10). The amplified fragment was cut with *XbaI* and *XbaI*, then ligated at the *XbaI* site with the  $\alpha$ -amylase gene fragment, which was amplified from pBR2.0A (4) by PCR using the primers 5'-CCTCTAGAGCCGCA-CCGTTAACGGCAC-3' and 5'-GCCTCGAGGCCA-GGCCATGCCACCAACCG-3' and digested with *XbaI* and *XbaI*. A DNA fragment of the  $\alpha$ -agglutinin gene (*AGα1*), containing 3'-half of the coding region encoding 320 amino acids of the  $\alpha$ -agglutinin and 446

bp of the 3'-flanking region, was prepared by the same method as the case of glucoamylase. These two fragments and *BamHI-XhoI* fragment of the GAPDH promoter were inserted into the plasmid pRS404 at its *BamHI-KpnI* site.

On the constructed plasmid, introduction of the *XbaI* site changed its corresponding amino acid sequence Lys-Arg to Ser-Arg, where Lys-Arg is the recognition sequence of the Kex2 endopeptidase to cleave  $\alpha$ -factor prosequence. Therefore, the site-directed mutagenesis was performed by PCR-based technique to change Ser-Arg to Lys-Arg. The resulting plasmid was named pIAA11. When the IAA strain harboring pIAA11 was cultivated in modified Burkholder's medium containing 2% glucose at 30°C for 24 h,  $\sim 60\%$  of the total  $\alpha$ -amylase activity was detected in the culture supernatant. This solubilization seemed to be caused by the proteolytic processing of the fusion protein.

The deduced amino acid sequence of the BSTA gene contains one possible processing site for the Kex2 endopeptidase, Val-Pro-Arg sequence, at amino acid residues No. 481–483. The Kex2 enzyme exhibits the substrate specificity toward each carboxyl site of Lys-Arg, Arg-Arg, and Pro-Arg sequences (11). Then, a Kex2-resistant BSTA/ $\alpha$ -agglutinin fusion protein was constructed by eliminating 33 residues from the C-terminus of the BSTA. The C-terminal truncated BSTA/ $\alpha$ -agglutinin fusion gene was introduced into *S. cerevisiae* (Fig. 9), using the integration plasmid pIAA12. For construction of the plasmid pIAA12, PCR was performed with primers 5'-GCAGCTCGAGATGAGATTCTTCAATTTT-*ACTGC*-3' and 5'-TCCTCGA-GCCAGGAACCCAAACCGAA-ACCG-3' and pIAA11 as a template, followed by *XbaI* digestion. The *XbaI* fragment of the plasmid

**Figure 9** Strategy for the construction of the C-terminal truncated BSTA/α-agglutinin fusion protein.

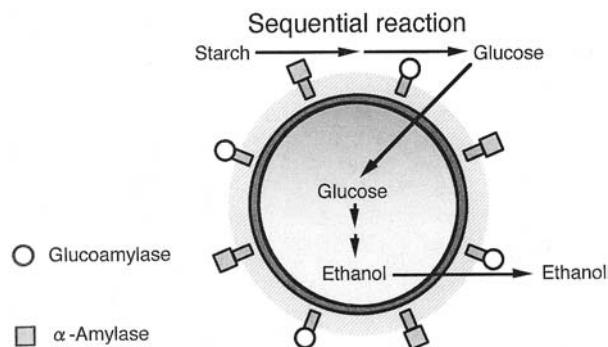

pIAA11 was substituted for this newly synthesized fragment to produce the plasmid pIAA12 to be immobilized without cleavage by proteases. Southern blot hybridization analysis was carried out to confirm the integration into chromosomal DNA. The obtained strain was named IAAΔ strain. The IAAΔ strain exhibited α-amylase activity only in the cell pellet fraction. This indicated that the genetic immobilization of α-amylase without leaking any detectable activity to the culture medium was performed by the elimination of the possible Kex2 enzyme processing site.

#### D. Coimmobilization of Glucoamylase and α-Amylase on Yeast Cell Surface

Coexpression of glucoamylase and α-amylase on the cell surface was expected to be effective for efficient assimilation of starch (Fig. 10). An *S. cerevisiae* strain was constructed in which glucoamylase/α-agglutinin gene and C-terminal truncated α-amylase/α-agglutinin gene were integrated into its chromosomes (8). The plasmid pIAA12 was cut by *Hind*III and introduced into the IGA strain harboring pIGA11. The cell of uracil and tryptophan non-auxotrophy was picked up and named IGA/IAAΔ strain. Integration of the fusion genes was confirmed by Southern blot hybridization analysis using *URA3* and *TRP1* as probes.

##### 1. Detection of Glucoamylase and α-Amylase

The strain IGA/IAAΔ exhibited both glucoamylase and α-amylase activities only in the cell pellet fraction. Immunofluorescent labeling and immunoelectron microscopy confirmed the location of both enzymes on the yeast cell surface. The colony of the IGA/

**Figure 10** Model of cell surface–engineered yeast coimmobilized with glucoamylase and α-amylase.

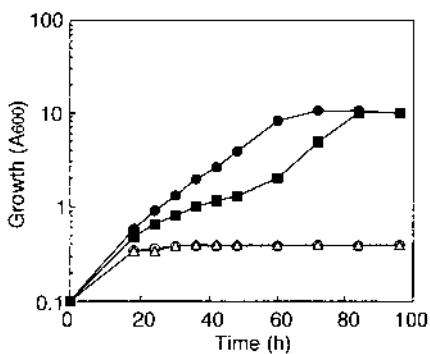

IAAΔ strain on a starch-containing plate, unlike that of the IGA/IAA strain, formed a small halo strictly around the colony as observed in the case of the IAAΔ and IGA strains, showing the expression of both glucoamylase and α-amylase on the cell surface. These results demonstrated that glucoamylase and α-amylase were coexpressed and coimmobilized on the cell surface of the same cell.

#### 2. Assimilation of Starch

The transformants were cultivated aerobically at 30°C in modified Burkholder's medium containing 1% soluble starch as the sole carbon source. The IGA and IGA/IAAΔ strains grew on starch and reached an absorbance of ~10 monitored at 600 nm, which was the same level as in the case of the culture on 1% glucose, although the growth on glucose of these strains was more rapid. No growth on starch was observed with the MT8-1 and IAA strains. The strain codisplaying glucoamylase and α-amylase, IGA/IAAΔ, grew faster than the glucoamylase-displaying strain, IGA (Fig. 11). This result demonstrated that the yeast strain armed with α-amylase in addition to glucoamylase had the enhanced ability to degrade starch by sequential hydrolytic reaction on the cell surface.

#### IV. GENETIC IMMOBILIZATION OF CELLULOLYTIC ENZYMES ON YEAST CELL SURFACE

Cellulose, consisting of glucose units linked together by β-1,4-glycosidic bonds, is the most abundant carbohydrate in the biosphere. An estimated synthesis rate of cellulose is ~4 × 10<sup>7</sup> tons/year. For a long-range

**Figure 11** Time courses of cell growth (absorbance at 600 nm) during aerobic cultivation in the medium containing starch as the sole source of carbon and energy. Symbols for strains: ○, MT8-1; ■, IGA; △, IAAΔ; ●, IGA/IAAΔ.

solution to resource problems of energy, chemicals, and food, cellulose is the most promising renewable carbon source that is available in large quantity. However, the yeast *S. cerevisiae* is unable to utilize cellulosic materials in spite of its versatility in industrial fermentation. The cell surface engineering system might be applicable. The genetic immobilization on the cell surface of yeast of carboxymethylcellulase (CMCase) from *Aspergillus aculeatus*, classified as endo-1,4- $\beta$ -D-glucan glucohydrolase (endoglucanase, EC 3.2.1.4), which cleaves the  $\beta$ -1,4-glycosidic linkage of cellulose (12) or/and  $\beta$ -glucosidase (1,4- $\beta$ -D-glucoside glucohydrolase, EC 3.2.1.21), an exo-type enzyme (13) from the same microorganism, was carried out. It was predicted that short-chain cello-oligosaccharides formed by the endo-action of CMCase would be converted quickly to glucose by  $\beta$ -glucosidase. However, *S. cerevisiae* lacks  $\beta$ -glucosidase activity and consequently is unable to utilize cellobiose as the carbon source. Thus, to construct an *S. cerevisiae* strain which is able to utilize cellulosic materials, it is necessary to endow it with  $\beta$ -glucosidase activity.

#### A. Immobilization of CMCase on Yeast Cell Surface

##### 1. Construction of a Multicopy Plasmid

A cDNA encoding Fl-CMCase of the fungus *A. aculeatus* with its secretion signal peptide was fused with the gene encoding the C-terminal half (320 amino acid residues from the C-terminus) of yeast  $\alpha$ -agglutinin (12). The constructed plasmid containing this fusion gene was expressed under the control of the *GAPDH*

promoter from *S. cerevisiae*. The multicopy plasmid pCMC11 to immobilize CMCase was constructed as follows (Fig. 12): An *Xba*I site was generated at the end of the CMCase coding region on the plasmid YEPM93R (14) by the PCR with the primers 5'-AGTACTCGAGCCCTGTACGCTGGCAGACCA-GT-3' and 5'-CGGTAGGTATTGATTGTAATTCT-G-3'. A DNA fragment containing CMCase coding region was isolated by *Eco*RI-*Xba*I digestion. A DNA fragment of the  $\alpha$ -agglutinin gene (*AGα1*), containing the 3'-half of the coding region encoding 320 amino acids of the  $\alpha$ -agglutinin and 446 bp of the 3'-flanking region, was prepared by the previously described method. These two fragments were substituted for the *Eco*RI-*Kpn*I section between the *GAPDH* promoter and the *GAPDH* terminator of the yeast expression cassette vector pYE22m. The resulting plasmid was named pCMC11.

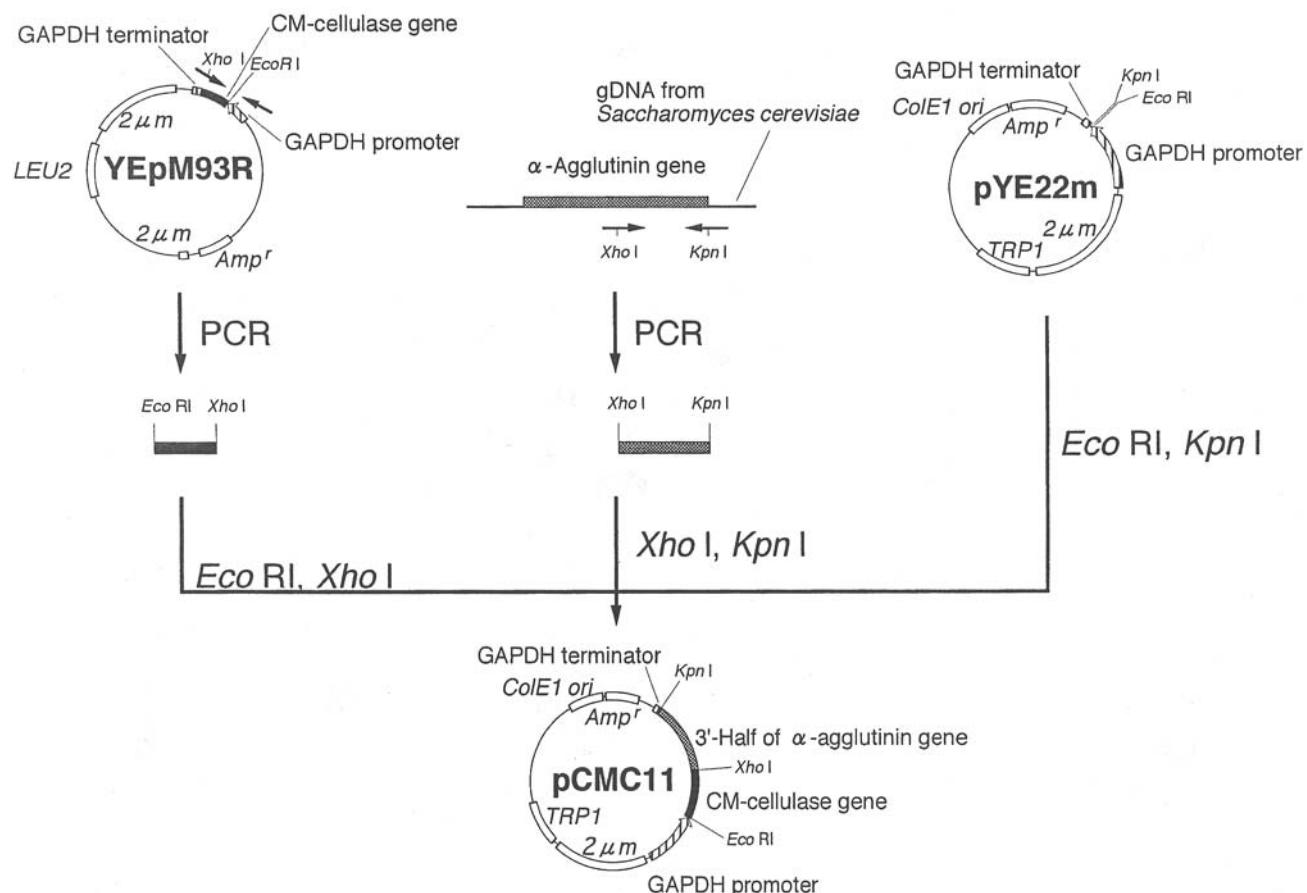

#### 2. Detection of CMCase

Cells were cultivated in SD medium (Sec. III.B.2) at 30°C for 24 h to the stationary phase. Culture medium and cell pellets were isolated by centrifugation to measure the CMCase activities in both fractions. The cells harboring the plasmid pCMC11 had the cell-associated CMCase activity without secretion of the active enzyme. The CMCase activity was stably maintained for 120 h at least. SDS and  $\beta$ -1,3-glucanase treatment indicated that the CMCase was covalently attached to the cell wall and immobilized by the genetic engineering techniques. A plate assay was carried out using Congo Red staining (15). The cells harboring the plasmid pCMC11 hydrolyzed carboxymethylcellulose and produced a halo strictly around the colony, while no halo formation was observed around the cells harboring the plasmid pYE22m (Fig. 13). Immunofluorescent labeling and immunoelectron microscopy confirmed the localization of CMCase/ $\alpha$ -agglutinin fusion protein on the yeast cell surface (Figs. 6, 7).

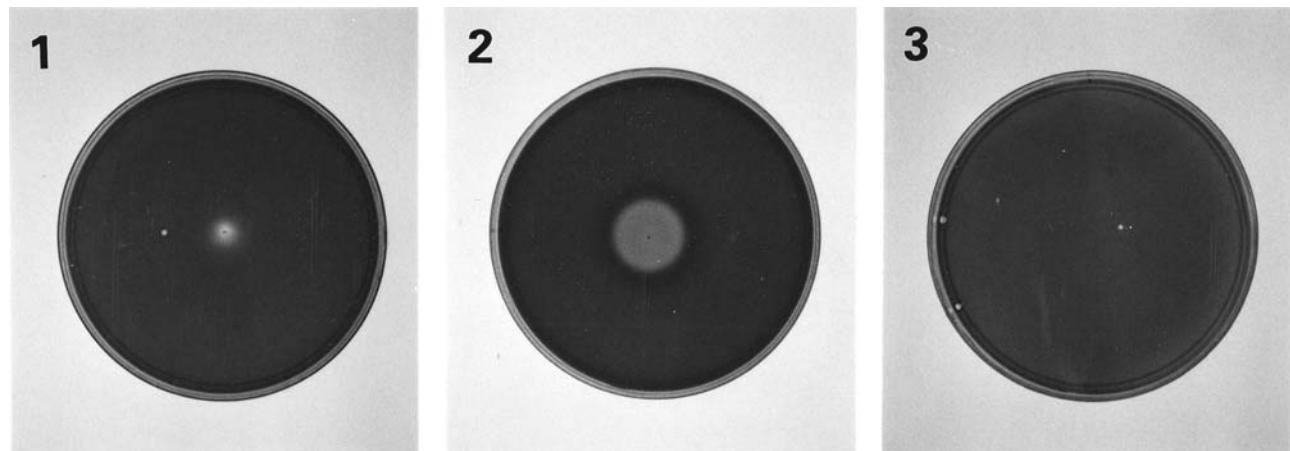

#### B. Immobilization of $\beta$ -Glucosidase on Yeast Cell Surface

##### 1. Construction of a Multicopy Plasmid

The DNA fragment composed of the *GAPDH* promoter and the secretion signal sequence of glucoamylase gene from *R. oryzae* was prepared by PCR (primers 5'-CCGAGCTCACCAAGTTCTCACACGGAACA-3' and 5'-GCCCGCGGCAGAACGAGCAAAGAAA-A-3') with the plasmid pYGA2269 (3) as a template, and then cut with *Sac*I and *Sac*II. The resulting *Sac*I-

**Figure 12** Construction of the multicopy plasmid pCMC11 for cell surface immobilization of CMCase.

**Figure 13** Plate assay for detection of CMCase activity. 1, *S. cerevisiae* with cell surface-immobilized CMCase (*S. cerevisiae* MT8-1/pCMC11); 2, *S. cerevisiae* secreting CMCase; 3, *S. cerevisiae* MT8-1 as the control (*S. cerevisiae* MT8-1/pYE22m).

*SacII* fragment, the *SacII-XhoI* fragment created by annealing two oligonucleotides 5'-GGAGATCTCCA-TGGC-3' and 5'-TCGAGCCATGGAGATCTCCGC-3', and the *XhoI-KpnI* fragment containing the 3'-half of the coding region encoding 320 amino acids of  $\alpha$ -agglutinin and 446 bp of the 3'-flanking region excised from the plasmid pGA11, were inserted into the sections of *SacI-SacII*, *SacII-XhoI*, and *XhoI-KpnI*, respectively, of the plasmid pRS404 (9). The resulting plasmid was named pICAS1. The plasmid pBG211 to immobilize  $\beta$ -glucosidase on the yeast cell surface was constructed as follows. The yeast high-copy vector pMH1 (15) was constructed by introducing the 2.14-kbp *EcoRI-EcoRI* fragment of PMT34(+3) (4) containing a part of 2  $\mu$ m DNA into the *AattII* site of the plasmid pRS403 (9). The *BglII-XhoI* fragment of the cDNA encoding  $\beta$ -glucosidase 1 (BGL1) from *A. aculeatus* was generated by PCR (5'-GTCGAGATCTCTGATGAACCTGGCGTTCTCT-3' and 5'-TTCACTCGAGCCTTGCACCTCGGGAG-CGCCG-3') with the plasmid pABG7 as the template, and substituted for the *BglII-XhoI* section of pICAS1, from which the *BssHII-BssHII* fragment was transferred to the plasmid pMH1 at its *BssHII-BssHII* section. The resulting plasmid was named pBG211 (Fig. 14) (14).

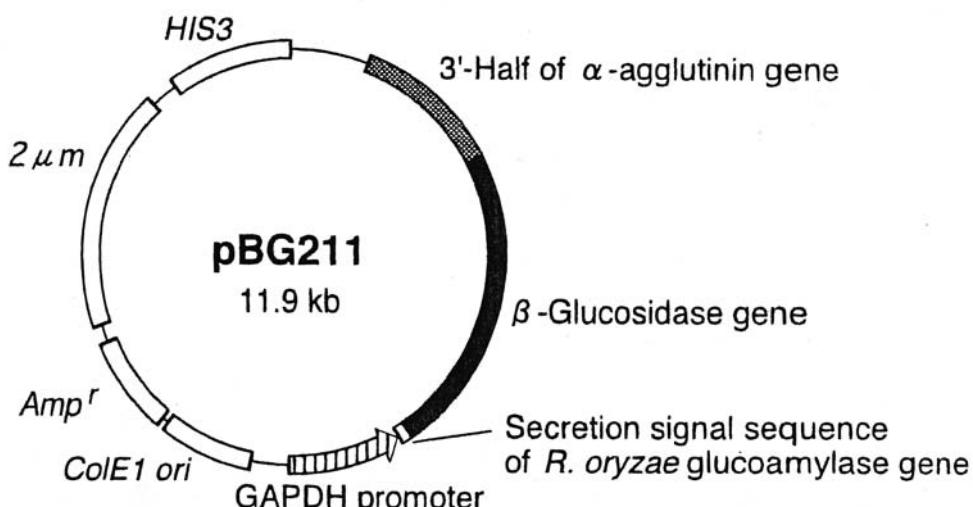

## 2. Detection of $\beta$ -Glucosidase

Yeast harboring pBG211 was precultivated in YPD medium and cultivated aerobically in the S-medium to which 2% glucose, 1% cellobiose, or 0.5%

cellooligosaccharides was added as the sole carbon source. The cello-oligosaccharides contain  $\sim$  11% (w/w) cellobiohexaose, 29% (w/w) cellopentaose, 33% (w/w) cellotetraose, 17% (w/w) cellotriose, 4% (w/w) cellobiose, and  $< 1\%$  (w/w) glucose.  $\beta$ -Glucosidase activity was measured as follows (16): The reaction mixture was composed of 0.1 mL of 1.7 mM *p*-nitrophenyl- $\beta$ -D-glucoside in 0.1 M sodium acetate buffer, pH 5.0, and 0.1 mL of enzyme solution. After incubation at 37°C for 10 min, *p*-nitrophenol released was measured spectrophotometrically as an increase of absorbance at 400 nm (molecular extinction coefficient, 17,700 M<sup>-1</sup> cm<sup>-1</sup>). One unit of the enzyme activity was defined as the amount of enzyme that released 1  $\mu$ mol of *p*-nitrophenol from the substrate per minute. Immunofluorescence microscopy was performed the same as in other cases.

## 3. Analysis of Saccharides

For thin-layer chromatography of cello-oligosaccharides, aliquots (1  $\mu$ L) of the culture supernatants were spotted on a silica gel 60F254 TLC plate, and developed twice with 1-butanol-pyridine-water (70:15:15, v/v). Sugars were detected by the diphenylamine-aniline method; the detection reagent, consisting of 4 mL aniline, 4 g diphenylamine, 200 mL acetone, and 30 mL 85% phosphoric acid, was sprayed on the plate, which was then heated at 105°C for 30 min.

**Figure 14** Construction of the multicopy plasmid pBG211 for cell surface immobilization of  $\beta$ -glucosidase.

### C. Coimmobilization of CMCCase and $\beta$ -Glucosidase on Yeast Cell Surface

#### 1. Construction of Cells for Coimmobilization of CMCCase and $\beta$ -Glucosidase

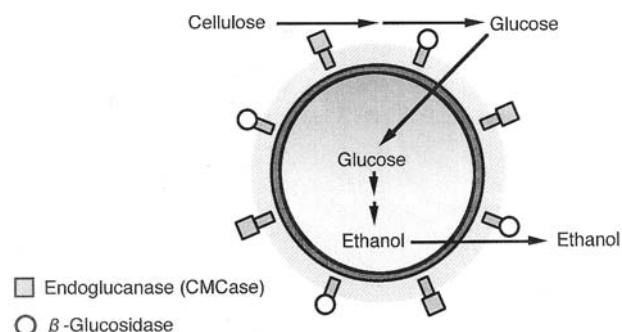

The plasmids pBG211 and pCMC11 described above were introduced stepwise into *S. cerevisiae* MT8-1. The resulting strain was named MT8-1/(pCMC11, pBG211) (13).

#### 2. Detection of CMCCase and $\beta$ -Glucosidase

To determine the location of CMCCase and  $\beta$ -glucosidase, yeast strains were cultivated in the SD medium (Sec. III.B.2) at 30°C for 24 h. The cells harboring the plasmid pCMC11, i.e., strain MT8-1/pCMC11 and strain MT8-1/(pCMC11, pBG211), had the cell-associated CMCCase activity, and the cells harboring the plasmid pBG211, i.e., strain MT8-1/pBG211 and strain MT8-1/(pCMC11, pBG211), exhibited the cell-associated  $\beta$ -glucosidase activity. Moreover, the cells harboring the plasmids pCMC11 and pBG211 showed both CMCCase and  $\beta$ -glucosidase activities. Strain MT8-1 itself exhibited neither of the activities. These results suggested that CMCCase and  $\beta$ -glucosidase proteins were efficiently synthesized and codisplayed on the cell surface in their active forms. MT8-1/(pCMC11, pBG211) cells were labeled by fluorescence with both anti-CMCCase IgG and anti- $\beta$ -glucosidase IgG, confirming again that these cells coimmobilized CMCCase and  $\beta$ -glucosidase proteins on their cell surface (Fig. 15).

#### 3. Assimilation of Cello-oligosaccharides

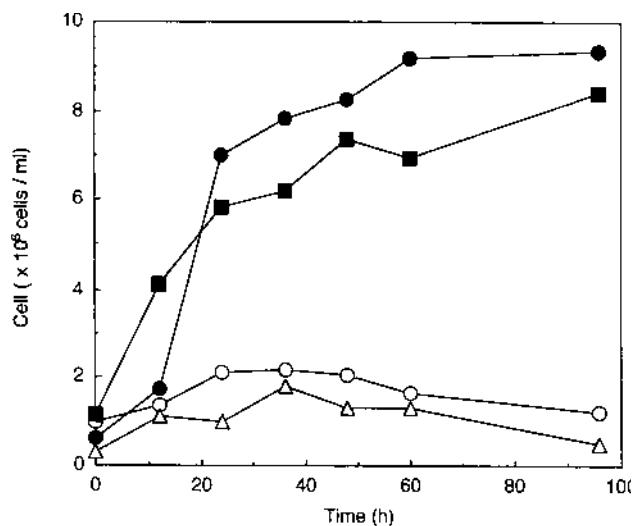

The transformants were precultivated in YPD medium and cultivated aerobically in S-medium (Sec. III.B.2) containing cellobiose as the sole carbon

**Figure 15** Model of cell surface–engineered yeast coimmobilized with CMCCase and  $\beta$ -glucosidase.

source. The strains MT8-1/pBG211 and MT8-1/(pCMC11, pBG211) grew on cellobiose and reached an absorbance of ~ 2, which was a little lower than that in the case of the culture on 1% glucose. No growth on cellobiose was observed with strains MT8-1 and MT8-1/pCMC11. No difference was observed between the growth curves of the strains MT8-1/pBG211 and MT8-1/(pCMC11, pBG211). These results showed that the  $\beta$ -glucosidase genetically immobilized on the cell surface endowed the yeast with the ability of cellobiose degradation and utilization. The transformants were precultivated in YPD medium and cultivated aerobically in S-medium supplemented with cello-oligosaccharides as the sole carbon source, and the cell growth was monitored by counting colonies that appeared on YPD plates on which aliquots of the culture broth were spread. The strains MT8-1/pBG211 and MT8-1/(pCMC11, pBG211) grew on cello-oligosaccharides employed (Fig. 16).

$\beta$ -Glucosidase was capable of degrading cello-oligosaccharides with glucose units of 2 to 6; the breakdown of cello-oligosaccharides by  $\beta$ -glucosidase seemed to be sufficient to sustain the growth of the yeast displaying this enzyme. The strain MT8-1/(pCMC11, pBG211), however, grew a little more rapidly than the strain

**Figure 16** Time courses of the cell growth during aerobic cultivation in the medium containing cello-oligosaccharides as the sole source of carbon and energy. Symbols for strains: ○, MT8-1; △, MT8-1/pCMC11; ■, MT8-1/pBG211; ●, MT8-1/(pBG211, pCMC11). Cell growth was monitored by counting colonies that appeared on YPD plates on which aliquots of the culture broths were spread.

MT8-1/pBG211, indicating that the yeast strain codisplaying CMCase and  $\beta$ -glucosidase had the enhanced ability to degrade cello-oligosaccharides. The degradation and assimilation of cello-oligosaccharides by the transformants were confirmed by thin-layer chromatography. The cello-oligosaccharides dissolved in the culture supernatants were gradually degraded and assimilated by the strains MT8-1/pBG211 and MT8-1/(pCMC11, pBG211).

The strain MT8-1/(pCMC11, pBG211) degraded cello-oligosaccharides more rapidly, especially cellopentaose (G5) and cellohexaose (G6), than the strain MT8-1/pBG211. This is probably due to the activity of CMCase displayed on the cell surface of the strain MT8-1/(pCMC11, pBG211). CMCase purified from *A. aculeatus* showed activity against G5 and G6 (17). Surely, it was confirmed that the strain MT8-1/pCMC11 degraded G5 and G6 among the cello-oligosaccharides employed, while the strain MT8-1 could not degrade any of the cello-oligosaccharides. These results gave evidence that the strain MT8-1/(pCMC11, pBG211) hydrolyzed the cello-oligosaccharides with synergistic actions of CMCase and  $\beta$ -glucosidase, the produced glucose being assimilated for proliferation.

## V. PERSPECTIVE

The immobilization of amylolytic and cellulolytic enzymes on the yeast cell surface may facilitate the utilization of starch and cellulose by yeast. In this system, the cell surface of yeast was used as a carrier for immobilization of enzymes, and the living whole cells were remade as a "cell biocatalyst." The modified strain was named "arming yeast" (18). This system turned or remade *S. cerevisiae* into a novel and attractive microorganism as a whole-cell biocatalyst by surface expression of various enzymes, especially when target substrates are not able to be taken up by the cells. Although a lot of methods for immobilization of enzymes have been developed to construct bioreactors with effective conversion of substrates, it is still difficult to maintain the enzyme activities over the long reaction period or to perform multistep conversions. The novel cell surface-engineered cells ("arming cells"), endowed with a rapid starchy and cellulosic material-utilizing abilities by immobilizing two amylases and cellulases on their cell surface, will be employed for efficacious fermentation of starchy and cellulosic materials.

Our cell surface engineering system has a possibility of being used to construct new functional yeast strains. This may contribute to resolution of many problems concerning environmental pollution and biomass conversion at the global level.

## VI. SUMMARY

We established the genetic system to immobilize enzymes as their active forms on the cell surface of yeast, *S. cerevisiae*. As a principle, a cDNA encoding enzyme with a secretion signal peptide was fused with the gene encoding the C-terminal half (320 amino acid residues from the C-terminus) of yeast  $\alpha$ -agglutinin, a protein involved in mating and covalently anchored to the cell wall. The constructed plasmid containing this fusion gene was introduced into *S. cerevisiae* and expressed under the control of the glyceraldehyde-3-phosphate dehydrogenase (GAPDH) promoter from *S. cerevisiae*. The activity and localization of the enzyme on the cell surface was biochemically demonstrated by subcellular fractionation and glucanase treatment. Appearance of the fused protein expressed on the cell surface was further confirmed by halo formation, unlike that of secretive enzyme, and immuno-fluorescence and immunoelectron microscopies. Arming cells displaying glucoamylase and  $\alpha$ -amylase, or carboxymethylcellulase and  $\beta$ -glucosidase, could assimilate starch or cello-oligosaccharides as the sole carbon source, although *S. cerevisiae* cannot intrinsically assimilate them. This technique endowed the cell with novel functions.

## Use of Immobilized Enzymes in the Food Industry

**Harold E. Swaisgood**

*North Carolina State University, Raleigh, North Carolina, U.S.A.*

### 1. INTRODUCTION

Most of the literature on immobilized enzymes has resulted from research and development during the past 40 years. A number of reviews have appeared (1–11) that discuss the preparation, characteristics, and uses of immobilized enzymes. Actual commercialization of immobilized enzyme bioprocesses has not occurred at a rapid pace in the food industry, perhaps owing to a natural reluctance to replace existing soluble enzyme processes and the fact that most of the industry involves low value-added products with small profit margins. Nevertheless, immobilized enzyme technology has gained acceptance in several areas. The most successful example is the production of high-fructose corn syrup using immobilized glucose isomerase, which is a unique product produced only with the immobilized enzyme.

### II. WHY USE AN IMMOBILIZED ENZYME?

The commercial success of an immobilized enzyme process requires the cost per unit of product to be less than that for a comparable soluble enzyme process or that a unique product can be produced with the immobilized enzyme that cannot be obtained with the soluble enzyme. Some possible advantages of an immobilized enzyme process as compared with use of

the soluble enzyme are listed in Table 1 (11). Because the same enzyme is used continuously, the amount of product obtained per unit of enzyme is much greater. For example, in the current commercial use of immobilized glucose isomerase 12,000–15,000 kg of dry product is typically obtained per kilogram of biocatalyst during its operational lifetime (J. Shetty, personal communication, 1999).

Precise control of the extent of reaction is a key advantage for many processes where a limited extent of reaction is desirable. Use of the immobilized form eliminates the need for a downstream enzyme inactivation step that could be harmful to the product. These considerations are important for processes involving protein modification or flavor generation. Even if precise control of the extent of reaction is not required, in many cases a downstream enzyme inactivation step is necessary because the commercial enzyme preparation may contain contaminating activities, e.g., proteinases, that over long periods can cause product deterioration. When the immobilized preparation is used, the short exposure time may not be detrimental.

Use of the immobilized enzyme in a bioreactor, for example, a fixed-bed or fluidized-bed reactor, allows it to be incorporated into a continuous automated bio-process. This feature greatly reduces the materials handling and, consequently, the labor costs. For example, Tanabe-Seiyaku Co. in Japan experienced a three-fold reduction in labor costs when they introduced the use of immobilized aminoacylase for L-amino acid

**Table 1** Some Possible Advantages of an Immobilized Enzyme Process as Compared with Use of the Soluble Enzyme

- 
1. Greater productivity per unit of enzyme
  2. Precise control of the extent of reaction
  3. Continuous operation and automation of the process is possible
  4. Materials handling is minimized
  5. Product does not contain the biocatalyst
  6. Enzyme activity may be stabilized
  7. A unique product may be produced
- 

production (4). Another example is the Valio process for producing hydrolyzed whey syrup using immobilized  $\beta$ -galactosidase. One of the largest whey-processing plants in the world, operated by Dairy Crest in northern Wales and using the Valio process, is fully automated and controlled by a microprocessor, thus requiring only two operators to be present at any one time (M. Harju, personal communication, 1999).

Immobilization can also result in stabilization of the enzyme activity. Such stabilization is especially true for proteinases because autolysis is prevented (12). Moreover, in many food processes, in order to limit microbial growth it is desirable to operate at temperatures where structural stability of proteins is marginal and thus most susceptible to proteolysis. In addition, the surface microenvironment of the support may stabilize the enzyme structure; for example, many sup-

ports have a polyol type structure that is known to stabilize proteins (13).

Finally, it may be possible to produce a unique product using an immobilized enzyme. Such is the case for production of high-fructose corn syrup using immobilized glucose isomerase. Recently, the potential to design functionality by limited proteolysis has been demonstrated (14, 15). However, this requires precise control of the extent of hydrolysis, but a downstream heat inactivation of the enzyme would also denature the polypeptides formed and thus destroy functionality. Use of immobilized proteinases would eliminate the required downstream enzyme inactivation; consequently, functional polypeptides could be produced that have unique properties in foods.

### III. ECONOMIC CONSIDERATIONS FOR AN IMMOBILIZED ENZYME BIOPROCESS

The commercial success of an enzyme process depends on its cost per unit of product balanced against the value added. The major factors that determine the cost of an enzyme process are listed in Table 2 (6, 11). For a soluble enzyme process, a major cost is that associated with its purification. The degree of purification must be balanced against the desirability of a high specific activity. Usually, costs escalate when additional purification is sought in the higher range of purity; however, higher specific activities mean less of

**Table 2** Major Factors That Determine the Cost of an Enzyme Process

---

Purification costs	Required specific activity Required removal of contaminating activities
Immobilization costs	Characteristics of the immobilization methodology Amount of enzyme loading
Operation stability	Enzyme stability Amount of enzyme leaching Resistance of the support to attrition
Regenerative capability of the biocatalyst	Number of times the activity can be regenerated Complexity of the regeneration procedure Capability of support regeneration
Upstream processing requirements	Complexity of the process Costs of substances added
Sanitation requirements	Frequency of required cleaning Complexity of the cleaning procedure

---

the enzyme preparation will be required in a process. The same considerations apply to an immobilized enzyme process. Preparations with higher specific activities will result in greater loading of active enzyme and higher activities of the biocatalyst; thus, a smaller bioreactor will be required for the same production rate.

Characteristics of the immobilization procedure are very important. In general, the fewer number of steps required, the lower the costs. However, a number of factors come into play, including the effect of the procedure on enzyme activity, the efficiency of immobilization (percent of the original activity that becomes immobilized), and the cost of the support.

The productivity of the biocatalyst, i.e., the amount of product per unit of biocatalyst per half-life, is a key economic parameter. Both the specific activity and the operational stability of the biocatalyst contribute to this factor. The higher specific activities of immobilized glucose isomerase biocatalyst currently in use have a much greater (10-fold) productivity than the original biocatalysts that were simply crosslinked whole cells (16; J. Shetty, personal communication, 1999). Most commercial immobilized enzymes have half-lives of months or even years and typically are operated through several half-lives. Some factors that contribute to the operational stability of the biocatalyst are the stability of the enzyme, the amount of enzyme leaching (desorption), and the resistance of the support to attrition. Enzymes immobilized by adsorption, such as on ion exchange supports, will exhibit a finite desorption rate that depends on environmental conditions, including enzyme characteristics, ionic strength, and temperature. Covalently immobilized enzymes will not leach from the support but the biocatalyst cannot be regenerated. The operational stability of the bioreactor is also affected by the presence of proteinases, either those in the feed stock or those produced by microbial growth. Thus, sanitation of the bioreactor is very important. For example, immobilized glucose isomerase bioreactors are operated at 60°C to control microbial growth.

Capability of regeneration of the biocatalyst can significantly lower the cost of the bioprocess per unit of product. Thus, if the support can be regenerated many times, even an expensive support can be economical. This feature would favor the use of an adsorption immobilization procedure over the use of a covalent bond. Nevertheless, a strong adsorption interaction is most desirable because less leaching would occur and the biocatalyst could be cleansed with stronger solu-

tions for removal of constituents adsorbed from the stock and for sanitizing the bioreactor.

## IV. IMMOBILIZED ENZYME PROCESSES THAT HAVE BEEN COMMERCIALIZED IN THE FOOD INDUSTRY

### A. Production of High-Fructose Corn Syrup Using Immobilized Glucose Isomerase

This industry has grown from the initial commercial production in 1970 by Clinton Corn Processing to become the largest industrial use of an immobilized enzyme process in the world (16, 17). Most recent data indicate that the global annual production of high fructose corn syrup is 10 million metric tons dry substance(ds) which is produced with 1500 metric tons of immobilized enzyme (J. Shetty, personal communication, 1999). Currently, the major producers of immobilized enzyme are Novo Industry A/S and Genencor. The Genencor immobilized enzyme is produced by adsorption of substantially purified enzyme on ion exchange resins, crosslinked with polyethyleneimine and glutaraldehyde, and granulated by extrusion. This immobilized enzyme typically has a productivity of 12,000–15,000 kg ds/kg and a half-life of 80–150 days (1920–3600 h) (J. Shetty, personal communication, 1999). The immobilized enzyme produced by Novo (Sweetzyme T) is prepared by crosslinking whole cell material from *Streptomyces murinus* with glutaraldehyde followed by extrusion (18). A typical bioprocess uses 1.5 m × 5 m fixed-bed bioreactors operated at 60–65°C to produce a 42% fructose isosyrup (16, 17). More than half of this isosyrup is converted to 55% fructose using fractionation technology. Future development of a thermostable enzyme may allow direct production of a 55% fructose isosyrup by performing the isomerization at 95°C because the equilibrium is shifted in favor of fructose.

### B. Production of Hydrolyzed Whey Syrups Using Immobilized $\beta$ -Galactosidase

The current commercial process, Valio Hydrolysis Process, was initiated in Finland in 1980 by Valio Ltd. (19). The biocatalyst, Valio IML, consists of a mold  $\beta$ -galactosidase (*Aspergillus oryzae*) adsorbed and crosslinked on a food grade resin (19, 20; M. Harju, personal communication, 1999). The major

product produced by Valio is a demineralized hydrolyzed whey syrup containing ~ 60% solids with 72% hydrolysis of the lactose, Valio Hydroval 80 (M. Harju, personal communication, 1999). Hydrolyzed whey syrups without demineralization and with 50% demineralization are also produced. Whey from cheese-making operations is received in a liquid form (6% total solids), pasteurized, passed through fixed-bed immobilized enzyme bioreactors for lactose hydrolysis, demineralized (if desired), and concentrated to ~60% total solids. The half-life and productivity of a typical bioreactor are 20 months and 2000 kg dry matter/kg enzyme, respectively. The annual production of hydrolyzed whey syrups by this process in Finland, the United Kingdom and Norway is ~ 5000–6000 metric tons.

Bioreactors containing  $\beta$ -galactosidase immobilized covalently on porous silica were developed at Corning Glass Co. (21) and used commercially (6, 22) in England (Specialist Dairy Ingredient Co.), the U. S. (Nutrisearch), and France (Union Laitière Normande). The Nutrisearch plant used the hydrolyzed whey for production of baker's yeast; however, this plant is no longer in operation. The only plant still in operation is the SDI plant in the UK owned by Dairy Crest; however, they currently use Valio IML as the biocatalyst.

In addition to production of whey hydrolysates, immobilized enzyme also has been used commercially to hydrolyze lactose in milk. The yeast (*Kluyveromyces lactis*) enzyme, with a pH optimum near 7, was entrapped in cellulose triacetate fibers in a process developed by SNAM Progetti for production of hydrolyzed lactose milk by a plant in Milan, Italy (6, 11, 17, 23). This plant, Centrale del Latte, has a minimum capacity of 8000 L/day (23). Snow Brand Milk Products in Japan also developed an industrial process for production of hydrolyzed lactose milk using the SNAM Progetti immobilized enzyme (23). The Japanese scientists also developed a bioreactor sanitation process, involving immersion in glycerol at 10°C, that allowed them to use 60 processing cycles without an increase in microbial load.

### C. Production of L-Amino Acids Using Immobilized Aminoacylase

This process for enzymatic resolution of D, L-amino acids was developed by Chibata and co-workers at Tanabe-Seiyaku Co. in Japan, and its commercialization in 1969 represented the first industrial use of an immobilized enzyme (6, 24–26). Chemically synthe-

sized acyl-D,L-amino acids are asymmetrically hydrolyzed to produce the L-amino acid and acyl-D-amino acid that are easily separated by differences in solubility. The acyl-D-amino acid is then racemized and passed back through the bioreactor for resolution. Bioreactors are prepared by immobilization of the enzyme from *Aspergillus oryzae* by adsorption on DEAE-Sephadex. A typical half-life of a bioreactor is 65 days at 50°C. Operating as a fixed-bed bioreactor, the productivity ranges between 13 and 46 kg amino acid/L/half-life, depending on the amino acid being produced. According to Uhlig (17), the annual production in 1988 was 1000 metric tons of Phe, Met, Tyr, and Val. The overall cost of amino acid production using the immobilized enzyme was 60% of that for use of the soluble form (24).

### D. Production of Specific Amino Acids

L-Aspartic acid has been produced from ammonium fumarate commercially in Japan since 1973 using immobilized L-aspartate ammonia lyase (aspartase) (EC 4.3.1.1.) prepared by entrapment of *Escherichia coli* cells in k-carrageenan (27). In 1988, ~ 1000 metric tons of L-aspartate was produced (17). The production of L-alanine from ammonium fumarate using two bioreactors with different immobilized cell preparations was successfully commercialized in 1983 in Japan by Tanabe Seiyaku Co. (28). The first bioreactor contained *E. coli* cells that were pH-treated to inactivate alanine racemase and fumarase activities and entrapped in carrageenan, and the second bioreactor contained pH-treated and glutaraldehyde-crosslinked *Pseudomonas dacunhae* also entrapped in carrageenan. Thus, the first bioreactor provided the aspartase activity while the second provided L-aspartate  $\beta$ -decarboxylase activity. This bioprocess represents the first industrial use of sequential bioreactors.

Because of its demand as a precursor in the production of aspartame ( $\alpha$ -L-aspartyl-L-phenylalanine methyl ester), various methods for enzymatic production of L-phenylalanine have been developed (29). Purification Engineering (Rhône Poulenc) (11,29) developed an immobilized enzyme bioprocess using phenylpyruvate as the starting material. A mutant of *E. coli* having exceptionally high activities of transaminases with the required specificities was immobilized by entrapment in a polyazetidine layer on Amberlite IRA-938 porous beads. Bioreactors typically exhibited a half-life > 8 months. A 600 metric ton per year plant was constructed (29).

Industrial processes for production of aspartame using immobilized enzymes also have been developed (10, 11, 30, 31). The process developed in Japan by Toya Soda Co. (30) utilized immobilized Thermoase (thermolysin) in a biphasic system to stereospecifically couple N-protected aspartate with D, L-phenylalanine methyl ester to give  $\alpha$ -aspartame after hydrogenolysis to remove the protecting group. The enzymatic process eliminates the need to protect and deprotect the  $\beta$ -carboxyl group of aspartate to prevent formation of the bitter isomer  $\beta$ -aspartame and allows use of the less expensive phenylalanine methyl ester racemate. The technology has been licensed to Holland Sweetener Co., a joint venture between Tosoh Corp. and DSM. More recently, another industrial process has been reported that uses enzymes in immobilized cells to make phenylalanine from cinnamic acid and ammonia followed by direct coupling to aspartate (31).

#### E. Production of 5'-Ribonucleotides

A market exists for 5'-ribonucleotides as flavor enhancers in foods and as precursors for pharmaceuticals. A process was developed in Germany by Keller and co-workers at Hoechst Aktiengesellschaft for hydrolysis of RNA using 5'-phosphodiesterase immobilized on oxirane acrylic beads (Eupergit C from Röhm Pharma) (32). Elimination of the necessity of fractionation of RNA and DNA was accomplished because DNA could not penetrate the matrix and thus was not hydrolyzed. In a pilot plant operation using crude nucleic acid feed stocks at 60°C, the immobilized enzyme was used continuously for 500 days with no detectable loss of activity and produced 10 metric tons per year (32). Earlier work in Japan also resulted in a process for production of 5'-ribonucleotides, including IMP, using a mixed bed of 5'-phosphodiesterase and 5'-adenylate deaminase immobilized on porous silica (33).

#### F. Production of Isomaltulose

Isomaltulose (*6-O-* $\alpha$ -D-glucopyranosyl-D-fructofuranose) is a natural component of honey with a sweetness one-third that of sucrose. However, it appears to be noncariogenic and it encourages the growth of *Bifidobacter*. Several processes for its commercial production using immobilized enzymes have been developed (34–36). Although only one enzyme, isomaltulose synthase, is required for conversion of sucrose to isomaltulose, normally whole cells were immobilized rather than incur the cost of purification. In the pro-

cess developed by Cheetham (34) in England, *Erwinia rhabontici* cells were entrapped in calcium alginate gels and formed into pellets by extrusion. The enzyme expressed by these cells was specific for sucrose and followed an unusual intramolecular mechanism in which both the glucose and fructose moieties remain enzyme bound (34). Operating as a fixed-bed bioreactor, the immobilized enzyme exhibited a half-life of 1 year and had a productivity of 1500 times its own weight in crystalline isomaltulose.

In another process developed at the South Germany Sugar Co. *Protaminobacter rubrum* cells were flocculated and crosslinked with glutaraldehyde (34, 35). Palatinit AG, a subsidiary of South Germany Sugar Co. and Bayer AG, used this process for commercial production of isomaltulose.

Using a similar procedure, except that the cells entrapped in calcium alginate gels were crosslinked with polyethyleneimine and glutaraldehyde, Mitsui Sugar Co. in Japan commercialized a process using *Serratia plymuthica* or *P. rubrum* cells (34, 36). The productivity of a fixed-bed bioreactor containing the immobilized *P. rubrum* enzyme was 260 kg/L of biocatalyst/half-life. The company initiated production with a 600 metric ton per year plant in Okayama, Japan.

#### G. Production of Invert Sugar (Hydrolysis of Sucrose)

Invertase immobilized by adsorption on ion exchangers (31) or covalently bound to a macroporous Plexiglas (17), Plexazyme IN (Röhm GmbH), has been commercialized in Europe for hydrolysis of sucrose obtained from sugar beets or cane sugar. The productivity of the Plexazyme IN bioreactor is 6000 kg dry weight/kg biocatalyst when producing a syrup with 90% conversion (17). Enzymatic hydrolysis of sucrose is less expensive than the HCl chemical process because of side reactions in the latter that lower the yield and decrease product quality. The annual production of invert sugar using immobilized invertase was 1000 metric tons in 1988 (17).

#### H. Production of Modified Triacylglycerols (Fats)

Chemically catalyzed interesterification results in random interchange of fatty acids among the three positions of the glycerol backbone. However, enzyme catalysis using a 1,3-specific lipase confines acyl migration to the 1- and 3-positions yielding a mixture of triacylglycerols not obtainable by any other means. Several commercial processes have been reported for

immobilization of lipase and its use for fat modification (37–40). Workers at Unilever (37, 39) immobilized lipases from *Aspergillus*, *Mucor* and *Rhizopus* spp. by adsorption from acetone, methanol, or ethanol solutions on inorganic matrices such as diatomaceous earth, hydroxylapatite, or alumina and used these preparations in fixed-bed bioreactors to interesterify shea oil or the mid fraction of palm oil. The substrates were dissolved in petroleum ether or hexane and passed through the bioreactor under carefully controlled water concentrations to maximize inter- or transesterification. Transesterification of the midfraction of palm oil with myristic acid produced a cocoa butter substitute from these less expensive starting materials (37). Scientists at Fuji Oil Co. Ltd, in Japan also have developed an immobilized lipase process for production of a cocoa butter-like fat using the palm midfraction as a starting material (41). Similarly, the triacylglycerols in shea oil or shea oleine have been modified by interesterification using these adsorbed lipases in two-phase systems (11, 38).

Tsukishima Kikai Co. (17, 42) developed a unique countercurrent two-phase multistage bioreactor for triglyceride hydrolysis using an immobilized thermostable lipase from a *Pseudomonas* sp. for production of glycerin and fatty acids. Workers at AKZO Chemicals (17, 43) also produced glycerin and fatty acids using a lipase from *Candida* sp. immobilized by adsorption on high-density polyethylene. The productivity of the CSTR bioreactor was 1100 kg of fatty acid/kg biocatalyst resulting in a cost that was competitive with the cost of steam splitting, and the product was of superior quality (43).

Eigtved (40), at Novo Industri A/S, developed an immobilized lipase bioreactor that could be used in a solvent-free system. Lipase from *Mucor miehei* was adsorbed from aqueous solution onto macroporous phenolformaldehyde resin and dried to a water content of 2–20%. The support has a relatively large particle size, allowing it to be employed with melted triglycerides in a fixed-bed bioreactor without excessive pressure drop. Operating to interesterify liquid fat (olive oil) at 60°C, the bioreactor exhibited a half-life of 3100 h and a productivity of 6.5 metric tons of modified triglyceride/kg of biocatalyst.

## V. FUTURE OPPORTUNITIES

A major factor driving the commercialization of an immobilized enzyme process is the ability to produce a product that cannot be produced by other means.

This may be the case for production of modified proteins designed for specific functionality in a food—for example, modification of the emulsifying, gelling, or foaming properties of a protein ingredient by limited proteolysis (14, 15, 44, 45). If the proteolysis is carefully controlled, large oligopeptides with native-like structure can be released that have more desirable functionality than the parent protein (14, 15). Use of an immobilized proteinase allows precise control of the extent of proteolysis without a downstream enzyme inactivation step such as a heat treatment. Because excellent functionality is destroyed by heat treatments that cause unfolding and aggregation, such a downstream process is often counterproductive. Another potential example is the alteration of the structural stability or gelling characteristics of a protein by limited crosslinking using transglutaminase as a catalyst (46, 47). As in the case with proteinases, use of immobilized enzyme avoids the need for a downstream enzyme inactivation step to prevent eventual gel formation and to stop reaction at the desired level of crosslinking.

Another major economic factor is the cost of enzyme purification and immobilization. Designing the enzyme for bioselective adsorption can minimize this cost. In the future, many enzymes will most likely be recombinant proteins designed with consideration of specific catalytic requirements such as specificity, thermal stability, pH optima, and cofactor requirements. In addition, it would not be difficult to design structures allowing ease of purification and immobilization. A number of fusion proteins have been genetically designed for this purpose. The cellulose-binding domain of *Cellulomonas fimi* exoglucanase has been fused to the gene for β-glucosidase allowing this fusion protein to bind to cellulose (48). Similarly, the starch-binding domain of *Aspergillus* glucoamylase was fused to β-galactosidase, resulting in a fusion protein that bound to starch (49). The streptavidin-biotin interaction represents an even stronger bio-specific interaction with a dissociation constant of the order of  $10^{-15} \text{ M}^{-1}$ . Genetic constructs have been prepared that allow expression of streptavidin-β-galactosidase (50), streptavidin-lipase (51), streptavidin-transglutaminase (52), and trypsin-streptavidin (53). Biotin can be covalently attached to a variety of supports using commercially available biotinylation reagents. Streptavidin-enzyme fusion proteins were purified and immobilized in one-step from crude recombinant cell lysates (50–53). Furthermore, the biotinylated supports can be regenerated and repeatedly used by desorption of spent enzyme and readsoption of fresh recombinant fusion enzyme (54).

*University College, Cork, Ireland*

### I. ADVANTAGES AND DISADVANTAGES

The advantages of enzyme analyses are numerous, as are the disadvantages. The advantages of using enzymes must therefore be weighed against the disadvantages for each application.

The benefits of using enzyme analyses include rapid assay times (relative to most analytical assays), low cost, inherent selectivity, and simplistic systems. The disadvantages include pH and temperature dependence, a limitation to primarily aqueous analysis, limited dynamic ranges, and relatively low stability. Thus, enzymatic analyses are confined to those areas where the advantages outweigh the disadvantages.

In recent years much work has been focused on overcoming the shortcomings mentioned above and hence widening the applicability of enzymes in analyses. It has been shown that pH and temperature dependence of enzymes is significantly reduced when immobilized; this is probably due to the enforced structure induced by immobilization (1). Thus, the use of immobilization can increase the ruggedness of most enzymatic assays. Several groups (2–4) have focused on the use of enzyme sensors in organic media. They found that when using organic solvents their sensors could still work well, but that the enzyme response was dependent on both the concentration and type of solvent. Such technology allows the detection of enzymatic substrates sparingly soluble in aqueous media

and enhances the thermal stability of the enzymes. Limited dynamic ranges can be extended through the use of diffusion limiting membranes (5). Gibson et al. (6) have employed polyelectrolyte backbones along with sugar alcohols to stabilize enzymes for extended periods of time, even at room temperature. Glucose oxidase was shown to have an operational stability for 5 months (7) when modified. With so much effort being focused on improving enzymatic analyses, the applications of the technology are likely to expand throughout the coming decade.

### II. METHODOLOGIES AND TOOLS AVAILABLE

In science, one of the main methodologies is standardization—to be able to compare different techniques or products to a standard. However, in a relatively new area such as enzymatic analyses, such standards are rare. McAtee et al. (8) have proposed a model for shelf life prediction of stabilized commercial enzyme assays. Being able to place a well-defined shelf life on a product would make it much more viable in the commercial marketplace. Boujtita et al. (9) have concentrated on making biosensors applicable to industrial needs. They compared different modes of production of renewable carbon paste electrodes and

found that they can produce high analytical quality sensors.

Enzymes can be coupled to a myriad of detection techniques; however, some are more appropriate to food analysis than others. Commonly used techniques include visible spectrophotometry, luminescence, fluorescence, amperometry, and potentiometry. Thus, development of the tools of these assay techniques has taken place. Examples of each system used in conjunction with food analysis are shown in Table 1.

For most food samples, some pretreatment would have to take place. Solid samples would generally be dissolved or the analyte extracted from them. This is particularly the case for optical detection systems where solid particles can seriously disturb the response. The importance of pretreatment cannot be underemphasized, even in an area such as enzyme analysis where the need for pretreatment is minimized. The strong pH, ionic strength, and temperature dependence of most enzymes means that any pretreatment must be carefully considered before being applied to enzymatic analysis.

In electrochemical analysis, a major challenge has been immobilization, to make the sensors reusable. Several techniques have been developed for immobilization, but generally speaking they can be classified into two major groups.

#### A. Adsorption or Physical Entrapment

This method has become more important in the last decade owing mainly to the development of hydrogels

(20) and sol-gels. Other methods include encapsulation of the enzyme within a growing polymer (21), entrapment behind membranes (22), encapsulation within gels (23), entrapment within carbon pastes (24), and passive adsorption of the enzyme on a suitable surface (25). Sol-gels have become important owing to the ease with which they are prepared and because they have controllable porosity, are chemically inert and physically stable, and can be produced at low temperatures under mild conditions (26). Another important property is that they can be produced as a bulk-modified electrode (27), providing simple renewal of surface by polishing, or as a coating of electrodes (28), where rapid responses are seen and a high enzyme loading can be achieved. This makes sol-gel-based enzymatic assays very versatile.

#### B. Covalent Binding

The use of glutaraldehyde as a crosslinking agent is perhaps the most common procedure in this area. This is due to the simplicity of the procedure. The three-dimensional structure produced allows a high enzymatic loading. Coupling to activated surfaces (29) produces a more reproducible surface coverage but at the expense of decreased enzyme loading. Other methods for covalent immobilization of enzymes include silanization (30) and multipoint covalent immobilization on epoxy-activated supports (31).

Each of these immobilization methods succeeds in making the associated assays reusable, but most decrease the activity of the enzymes and change their analytical performance such as pH optima, selectivity,

**Table 1** Direct Enzyme Assays Using Various Transduction Techniques

Analyte	Detection method	Enzyme	Dynamic range	Ref.
Cyanogenic potential	Absorbance at 510 nm/linamarin	Linamarase	0.5–40 mg/kg of HCN	10

and temperature dependence (1). Enzyme kits, of which there are a wide variety (32), ignore this problem and use enzymes directly in solution. However, this can make the assay expensive if the enzyme cannot be produced cheaply enough. Kits are available for a wide variety of analytes, but most require optical detection by eye or through a spectrophotometer. Thus, only colorless and fully soluble samples can be assayed with this technique, which makes food analysis difficult.

### III. TYPES OF ANALYSIS POSSIBLE

Enzymes are already used in a variety of assays of foods. These can be generally classified into three main areas—direct, indirect, and inhibition—as shown in Figure 1.

*Direct enzyme assays* use the specificity of an enzyme toward the analyte to determine the concentration of the analyte or enzyme. An example of this is a glucose assay, using glucose oxidase to oxidize the glu-

**Figure 1** Schematics of direct, indirect, and inhibition enzyme assays. Example system 1 (a) is a direct enzyme assay; system 2 (b) is an ELISA, an indirect assay; and example 3 (c) is an inhibition assay.

**Table 2** Summary of Sugar Analysis Through Enzymatic Methods

Analyte	Detection method	Enzyme	Application	Ref.
Glucose	Spectrophotometric	GOx <sup>a</sup>	Fruit juices, soft drinks, fermentation processes	33

<sup>a</sup>Galactose oxidase (GaOx).

cose in a sample and produce a measurable response. Table 2 shows a brief list of direct enzyme assays.

*Indirect enzyme assays* use enzymes as a label. This means that the assay uses only the catalytic properties of an enzyme to produce an easily measured response, achieving specificity through another molecule. An example of this type of assay is ELISA, where specificity is provided by antibodies but the finally measured signal is produced by an attached enzyme.

*Inhibition assays* use the inhibitory effects of certain molecules or ions on enzymes to quantify their presence in samples. Heavy metals are known to inhibit most enzymes but to different extents depending on the enzyme and metal ion involved. Organophosphorous and carbamate pesticides inhibit certain cholinesterases. Depending on the pesticide and enzyme chosen, the extent of inhibition varies.

### A. Direct Enzyme Analysis

Direct enzyme analysis is the simplest of the three areas. It can only be used to quantify substrates and enzymes, and is only practical when the products are readily measurable. Many modifications have been made to direct enzyme analysis, some to expand the applicability of the system, and some to overcome problems in the analysis.

#### 1. Simple Substrates Analysis

The main applications of this system are the assays of chemical components of foods, such as sugars (Table 2) and organic acids (Table 3). This is because there are many enzymes available for these metabolic compounds. Given the inherent instability of most

**Table 3** Summary of Organic Acid Analysis Through Enzymatic Methods

Analyte	Detection method	Enzyme	Application	Ref.
Lactate	Amperometry (0 V)	LOx <sup>a</sup> /HRP	Wine and yogurt	38

Inosine monophosphate	Amperometry (0.65 V)	IMPDH/NOx	Flavor enhancers	41

<sup>a</sup>Lactate oxidase (LOx); glutamate oxidase (GluOx); ascorbate oxidase (AscOx); urate oxidase (UOx); inosine monophosphate dehydrogenase (IMPDH); NADH oxidase (NOx).

enzymes, these analyses are performed with a reference of known analyte concentration. Such assays are rarely applicable to analytes not commonly found in metabolic processes. An example of such a rare assay is the organophosphate pesticide sensor. Using organophosphorus hydrolase, Mulchandani et al. (44) developed a biosensor for the determination of organophosphate pesticides with no crossreactivity with carbamates or other neurotoxins. They achieved a detection limit of 2  $\mu\text{M}$  for several common pesticides.

## 2. Enzyme Sequence Reactions

Systems employing a sequence of enzyme reactions can be used to increase the ease with which certain enzymatic products can be assayed. Peroxidase is frequently employed to detect the peroxide product of oxidase reactions at low applied potentials (45), thus avoiding electrochemical interferences that may be present in a sample. Difficulties with these systems include the possibilities that the optima for performance of the enzymes in the sequence may not be the same and that multiple enzymes decrease specificity. Such systems are therefore only used for important analytes such as sucrose (36) and aspartame (46) or to overcome major problems, such as electrochemical interference (45). Sucrose is hydrolyzed with the enzyme invertase, where the resultant glucose can be detected with glucose oxidase. Mutarotase is commonly added to such systems to speed up the conversion of  $\alpha$ -D-glucose to  $\beta$ -D-glucose.

## 3. Multianalyte Systems

With direct enzyme sensors it is relatively easy to produce multianalyte assay systems, which can detect a range of analytes simultaneously. The main advantage of this is that the analyst can build up an accurate picture of the current state of the food product or

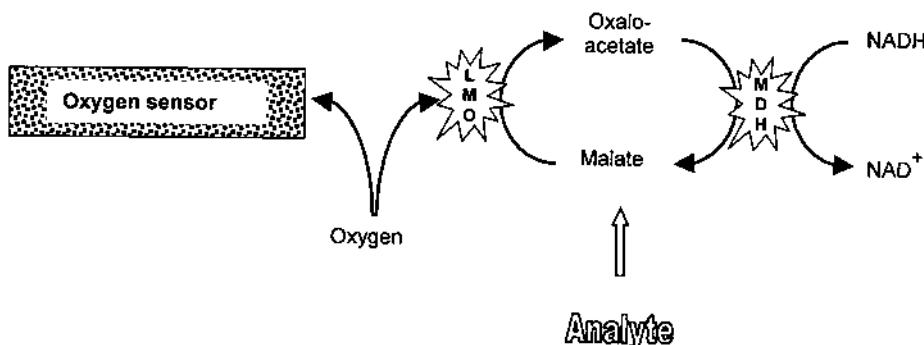

bioprocess. This is achieved by selecting the key analytes in a given system. To define the quality of wine, Miertus et al. (47) developed a multianalyte sensor for glucose, fructose and ethanol and for lactate, malate, and sulfite. The sensors were grouped in this way to allow different fermentation processes to be analyzed. The first group would allow monitoring of any alcoholic fermentation process, while the second could be used to monitor the malolactic fermentation processes in red wine.

## 4. Simple Enzyme Analysis

It is possible to detect the presence of an enzyme by exposure to its substrate. This system is employed in metabolic detection, where the metabolic action of bacterial enzymes indicates their presence in a sample. It is especially useful to determine the efficiency of sterilization procedures such as pasteurization. Swain et al. (48) used this type of assay to detect foodborne pathogenic bacteria.

## 5. Substrate Recycling

Another modification of the direct analysis method is substrate recycling (enzyme amplification). This process can dramatically enhance the sensitivity of enzyme assays but, as it uses multiple enzymes, it suffers from the same limitations as the enzyme sequence reactions described above. One example of this system is the detection of malate (49). In the presence of malate (analyte) and oxygen, lactate mono-oxygenase produces oxaloacetate. Malate dehydrogenase then converts this back to malate, where the sequence starts again (Fig. 2). While this simple procedure amplifies the response to malate, it also makes the assay strongly susceptible to interference from lactate. Table 4 describes examples of assays for miscellaneous food analytes using direct analysis.

**Figure 2** Schematic of a simple enzymatic amplification system for malate using an oxygen sensor.

**Table 4** Summary of General Food Analytes Through Enzymatic Methods

Analyte	Detection method	Enzyme	Application	Ref.

<sup>a</sup>Alcohol dehydrogenase (ADH); glycerokinase (GK); glycerol-3-phosphate oxidase (GPO); phospholipase D (PL); choline oxidase (COx);  $\alpha$ -chymotrypsin (CT)

## B. Indirect Enzyme Analysis Is Composed of Many Approaches

### 1. Immunoassays

The most commonly used indirect technique is ELISA, or enzyme-linked immunosorbant assay. An ELISA system can be designed to detect any molecule that can produce an immunogenic response, and many molecules that don't produce one on their own can be modified to generate a response. This makes the technique very versatile. While other biorecognition molecules are available, such as DNA, they are not generally coupled to enzymes. The enzyme labels are selected very carefully to fulfill defined parameters. The enzyme must be cheap, highly purified, easy to conjugate to antibodies, and have colorless substrates with a highly colored product. The main enzymes employed are horseradish peroxidase and alkaline phosphatase (55). They both meet the above requirements, but to different degrees. Given the versatility of ELISA, it is not surprising that a large number of food assays have been based on it. Primarily these have been focused upon the pathogenic bacteria and pesticides in foods, which can be difficult to detect using traditional techniques.

Bacteria analyzed by ELISA include *Listeria monocytogenes* (56), *Salmonella* sp. (57), *Escherichia coli* (58), *Staphylococcus aureus* (59), and *Bacillus cereus* (60). The popularity of the method is due to the sensitivity of the technique, which can yield results much faster than conventional techniques. Crowley et al. (61) developed a rapid immunosensor based on amperometric detection for *Listeria monocytogenes* in milk samples. The assay was performed in 3.5 h, which is an improvement over the 24 h needed to complete even the most rapid of traditional analysis. Abdel-Hamid et al. (62) developed a sensor for *E. coli* O157:H7 with a

limit of detection (LOD) of 100 cells/mL. Ivnitski et al. (63) have reviewed the different techniques used for bacteriological detection using immunosensors.

It can be difficult to detect the presence of pesticides using immunoassays. Owing to their small size, the antibodies are raised against pesticides conjugated to immunogenic carriers and may thus be of low affinity/selectivity. Keay and McNeil (64) used an amperometric immunosensor to detect atrazine. Polychlorinated biphenyls (PCB) are found throughout the food chain (fish extracts, clams, milk), and Bender and Sadik (65) produced an electrochemical immunosensor to detect for them. Dankwardt and Hock (66) reviewed the use of immunoassays to detect pesticides in foods and discussed the use of immuno-sensors.

Marine toxins are an area of increasing interest, as their incidence of outbreaks has been rising in recent years. Kreuzer et al. (67) developed an assay for okadaic acid in shellfish. This diarrhetic toxin was detectable down to a concentration of  $6 \times 10^{-13}$  M in a rapid time of 90 min, far better than any HPLC system for okadaic acid. Also, a rising issue in recent times has been the use of genetically modified (GM) foods. Brett et al. (68) have concluded that antibody-based assays are the natural detector for the presence of novel proteins from GMs. Van Duijn et al. (69) have used immunoblotting to detect the presence of CP4 synthase in GM soya. Thus, ELISA and immunosensors could become powerful tools in the confirmation of GM products in our foods.

### 2. Induced Bioluminescence

Another type of indirect enzyme analysis is the use of luciferase-encoded bacteriophage. The bacteriophage infect specific bacteria present in the sample and

cause them to bioluminesce by forcing them to produce luciferase. A major advantage of this system, unlike ELISA, is that it distinguishes between viable and non-viable cells. *Salmonella* sp. (70) and *Listeria* were assayed (71). Loessner et al. (72) produced a system for the detection of a variety of *Listeria* strains.

### C. Inhibition Enzyme Assays

There are two main groups of inhibition enzyme assays, pesticides and heavy metals.

#### 1. Pesticide Analysis

Since pesticides are not normally present in the food chain, there are few specific enzymes that can be used for their determination, although nonspecific inhibition of cholinesterase is commonly used (73). The determination of pesticides in food and water is a particular area of interest for biosensors. This is due to the function of pesticides to inhibit cholinesterases in pests (and possibly mammals). Organophosphates have been particularly well examined as they are toxic to mammals. Carbamates are less toxic to mammals but are not very soluble in water and thus accumulate in foods if incorrectly used. Cholinesterase inhibition is used for the determination of both these pesticides. Nunes et al. (74) used a sensor based on a low charge of cholinesterase to determine carbamates in food samples. As with all sensors of this type, the sample solutions must be exposed to the sensor prior to the analysis. This slows down the analysis time. Their sensor is usable only once (74). Overcoming this problem would reduce the cost per assay. Jeanty and Martin (75) used a reactivation sequence in their pesticide assay system. Based on flow analysis, their system showed good operational stability of 3 weeks and 6 months storage stability.

The inhibition of cholinesterases by both organophosphates, carbamates, and other neurotoxins causes problems for those who wish to measure just one class of pesticides. To achieve class specificity Mulchandani et al. (44) used organophosphorus hydrolase as described in the direct enzymatic assay section. Wang et al. (76) showed that a tyrosinase-based sensor could be inhibited by carbamates as well as other phenolic compounds. They also showed that tyrosinase did not require the lengthy exposure periods that characterize most enzyme inhibition assays. Perez Pita et al. (77) used this system in conjunction with a reversed micelle as the working medium. The advantages of this system include the increased solubility of the carbamates in

this medium and the low solubility of the enzyme, thus increasing the ease of immobilization.

#### 2. Heavy Metal Analysis

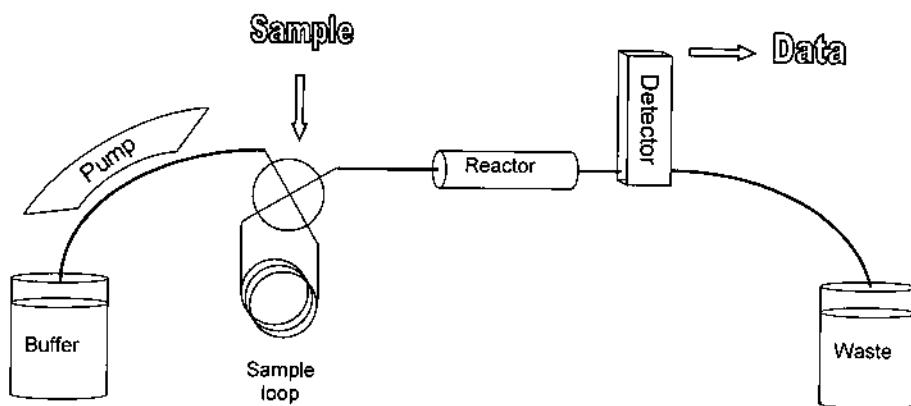

Fennouth et al. (78) compared the effectiveness of heavy metal salts at inhibiting the activity of lactate dehydrogenase. They found that they could detect the presence of heavy metals below the European norms, with the exception of lead acetate. They concluded that such technology could be applicable to metal contamination in foods. Bertocchi et al. (79) found that they could detect mercury levels in the 10–60 ppb range using enzyme inhibition. Volotovsky et al. (80) showed that additions of NaI to the sample improved the selectivity of their urease-based mercury sensor by decreasing the effects of silver.

## IV. ONLINE ANALYSIS

The use of enzymatic methods for continual and quasi-continual analysis is a challenge. Continual measurements require the enzymatic performance to be constant over a set period of time. Most enzyme assays cannot meet this challenge. A more applicable use would be quasi-continuous analysis, where samples are sent to an enzymatic detector at set time intervals. These intervals can be set by the need of the production process, but they are limited by the baseline recovery of the sensor. Flow injection analysis (FIA) provides a rapid means of sending a sample plug to a sensor, but after each analysis there is a recovery period when excess sample is washed away and the response returns to baseline (81). A simple flow injection system is shown in [Figure 3](#). Such systems have two major classes—where the enzyme is contained in a reactor and the product is detected downstream at a transducer, or where the enzyme is immobilized near the surface of the transducer. The needs of the fermentation industry have led to the development of flow injection sensors for sugars (82) and ethanol (83). The versatility of this technique led to its widespread use in enzymatic analysis (84, 85).

## V. QUALITY CONTROL

Production processes require quality control. The quality of food going to the consumer must always be assured. Traditionally this was performed by taking a sample and sending it to a remote laboratory. While this is successful for most samples, this was not always

**Figure 3** Schematics of a simple flow injection analysis system for use with an enzyme reactor or enzyme coated sensor (biosensor)

the case. Having remote laboratories means that the results are not instantaneous. It also means that unstable samples may have changed by the time they are analyzed. Enzyme-based systems, especially those incorporated within flow injection analyzers, overcome this problem. As the systems are small and of low cost relative to other automated analyzers, they can easily be fitted on-site. With the sensors fitted within the production process, a near instant reading can be achieved. Miertus et al. (47) developed a multianalyte sensor for quality control of red wine. By measuring a range of analytes simultaneously a picture of the true state of the product can be obtained. Since wine is liquid, there are few problems with sample pretreatment; however, there are problems with the matrix, which contains many potentially electroactive organic acids. Thus, any sensor hoping to measure in this matrix must address this problem. Minimal pretreatment was also required for a fish freshness sensor developed by Carsol et al. (86). The fish exudates were merely diluted in buffer and analyzed for the presence of inosine, inosine monophosphate, and hypoxanthine (K-value). Okuma et al. (87) developed a system to determine the initial stages of spoilage in chicken; as in the fish freshness assay, the system relies on the response of three analytes to show the spoilage. The markers selected, putrescine, cadaverine, and spermidine, allow an earlier assessment of the state of putrefaction of meat than the K-value. Kelly et al. (53) developed a sensor for the determination of L-lysine in heat-treated foods, but the breakdown of food proteins requires a hydrolysis step, which can be performed in 15 min. Thus, the pretreatment of the sample is the time-limiting step. The digestibility

of protein is of primary importance in determining nutritional quality. Hsu et al. (88) developed a multi-enzyme technique for estimating protein digestibility.

## Recent Advances in Enzyme Development

**Dominic W. S. Wong**

*U.S. Department of Agriculture, Albany, California, U.S.A.*

### I. INTRODUCTION

The important role of enzymes in food and food systems is aptly underscored by the description of some 60 enzymes in this handbook. These encompass all major six classes of enzymes—oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases—that catalyze various reactions contributing to the characteristic features and quality attributes of a particular food. Food scientists investigate the fundamentals of enzymology, extract the information obtained from biochemical studies, and apply them to the use and control of enzymes for preserving and producing better foods. Of the ~ 4000 known enzymes, only a handful of them are currently used in industry, ~ 45% are for food processing (Table 1). The future of enzyme technology foresees an increasing use of recombinant DNA technology and biotechnological processes for the discovery and development of novel enzymes and for better utilization of our food resources. Four research areas of emerging importance are described in this chapter: The study of extremophilic enzymes will change the landscape of our current knowledge on the use of enzymes; the rapid advances in developing novel techniques in protein engineering provide an ever increasing powerful tool for tailoring enzyme structural and functional properties; the ability to manipulate metabolic enzymes in biosynthetic pathways provides new opportunities for *in vivo* modification of food components; and the recent development of innovative approaches in the construction of artificial enzymes results in much improved catalytic activities,

and substantiates the potential of their future roles in enzyme technology.

### II. EXTREMOPHILIC ENZYMES

#### A. Search of Enzymes from Exotic Environments

A majority of the currently known ~ 4000 enzymes have been isolated from mesophilic organisms. In terms of microbial diversity, < 1% of the world microbial species have been identified and cultured in laboratories. These enzymes have evolved to function under a narrow range of pH, temperature, ionic strength, pressure, and chemical concentration, and are not optimized for performance under industrial conditions. Considerable efforts have been devoted to harvest organisms, mostly in the Eubacterial and Archaeal phylogenetic domains (1), that thrive in extreme environments for enzymes with industrial compatible properties. Major types of extremophiles include: thermophiles (found in hot spring, deep-sea thermal vents); psychrophiles (Arctic water, Antarctic Circle); acidophiles (geothermal sulfur-rich springs, coal deposits); alkalophiles (alkaline lakes, sewage sludge); halophiles (salt lakes, mines); and barophiles (deep-sea floor). Crystal structures are available for a number of thermophilic and psychrophilic enzymes, and some of these results provide the current information on factors that might stabilize them at extreme temperatures, compared with their mesophilic counterparts.

**Table 1** A List of Important Industrial Enzymes and Their Applications

$\alpha$ -Amylase
Conversion of starch to dextrins (liquefaction) in the production of corn syrup
Supplement to flour types low in $\alpha$ -amylase to ensure a continuous supply of fermentable sugar for yeast growth and gas production in dough making
Solubilization of adjuncts (nonmalt carbohydrate materials from barley and other cereal grains) used in brewing
Glucoamylase
Conversion of dextrins to glucose (saccharification) in the production of corn syrup
Conversion of residual dextrins to fermentable sugar in brewing for the production of "light" beer
$\beta$ -Amylase
Production of high-maltose syrup
Xylose (glucose) isomerase
Isomerization of glucose to fructose in the production of high-fructose corn syrup
$\beta$ -Glucanase
Breakdown of $\beta$ -glucans in malt and other raw materials to aid filtration of wort after mashing in brewing
Lipase
Enhancing flavor development and shortening the time for cheese ripening
Production of specialty fats with improved qualities
Production of enzyme-modified cheese/butter from cheese curd or butterfat
Papain
Used as meat tenderizer
Used in brewing to prevent chill-haze formation by digesting proteins that can otherwise react with tannic substances to form insoluble colloid particles.
Chymosin
Curding of milk by specific proteolytic action on $\kappa$ -caseins in cheese making
Microbial proteases
Processing of raw plant and animal proteins
Production of fish meals, meat extracts, texturized proteins, and meat extenders
Pectinase
Treatment of fruit pulp to facilitate juice extraction and for clarification and filtration of juice
Lactase
Additive for dairy products for individuals lacking lactase
Breakdown of lactose in whey products for manufacturing polyactide
Acetolactate decarboxylase
Reduction of maturation time in wine making by converting acetolactate to acetoine
(In the absence of the enzyme, acetolactate is oxidized to diacetyl that requires secondary fermentation to reduce it to acetoine)
Lysozyme
Antimicrobial preservative
Glucose oxidase
Conversion of glucose to gluconic acid to prevent Maillard reaction in products caused by high heat used in dehydration
Potential use to remove O <sub>2</sub> in food packaging for protection against oxidative deterioration
Cellulase
Conversion of cellulose wastes to fermentable feedstock for ethanol or single-cell protein production

Source: Ref. 24.

Protein stability can be expressed in terms of the free energy, associated with the micro- and macro-unfolding of the protein. Microunfolded represents qualitatively characteristics of the rigidity of the protein structure, and is associated with local, reversible, noncooperative unfolding reactions within

the folded state. Macrounfolded represents the stability of the macroscopic state of the protein molecules and the energy required for the protein changing from the native to the unfolded macroscopic state (2). Adjustment of conformational flexibility is a key step in the thermal adaptation of proteins.

Zavodszky et al. (3) compared both the macrostability (DSC and CD measurements) and microstability (hydrogen H/D exchange and FT-IR) of *Thermus thermophilus* (a hyperthermophilic microrganism) and *E. coli* 3-isopropylmalate dehydrogenase (IPMDH), and confirmed the correlation between enzyme activity and conformational flexibility. The thermophilic IPMDH has increased conformational rigidity as compared to the mesophilic counterpart, so as to stabilize the protein against heat denaturation. However, the two enzymes show similar conformational flexibility at their corresponding physiological temperature optima. This "thermometer effect" has been previously reported by Wrba et al. (4) on the study of D-glyceraldehyde-3-phosphate dehydrogenase isolated from *Thermotoga maritima*. Maes et al. (5) compared the crystal structure of triosephosphate isomeraes (TIM) from *Thermotoga maritima* with a series of nine known TIM from a wide variety of organisms, and did not find a common theme in the adaptive mechanism for the temperature scale.

Current structural investigations indicate that mesophilic and corresponding thermophilic proteins are virtually identical in structure with the difference in free energy of stabilization in the order of 5–15 kcal mol<sup>-1</sup> (6). This small energy difference is equivalent to only a few hydrogen bonds, salt bridges, or hydrophobic interactions (7). Proteins may have achieved increased thermostability by various combinations of these additional interactions. Delboni et al. (8) compared the crystal structures of six known thermophilic and mesophilic TIM enzymes, and found that hydrophobic stabilization contributes to the thermostability of the *Bacillus stearothermophilus* TIM. The enzyme shows increased hydrophobic packing with the smallest number of cavities and the total cavity surface area. The enzyme also has the largest hydrophobic surface area (314–534 Å) buried in the dimer formation compared with other TIM structures, with an energy gain of 7–13 kcal mol<sup>-1</sup>. It was also shown that the *B. stearothermophilus* TIM contains 13 prolines, exceeding all other TIM enzymes, suggesting that the large number of Pro residues are responsible for thermostability by decreasing the entropy of the unfolded state. Similar effects have been achieved by introducing disulfide bridges, for example, into subtilisin (9) and lysozyme (10).

The crystal structure of several psychrophilic enzymes has been elucidated, including that of  $\alpha$ -amylase (Antarctic *Alternomonas haloplancis*) (11), subtilisin (Antarctic *Bacillus* TA39 and TA41) (12), trypsin (Atlantic salmon, Antarctic *Paranotothenia magellana*)

(13), and triosephosphate isomerase (psychrophilic bacterium *Vibrio marinus*) (14). The Antarctic bacteirum *A. haloplancis* secretes a Ca<sup>2+</sup> and Cl<sup>-</sup>-dependent  $\alpha$ -amylase composed of 453 amino acids with a predicted Mr of 49,340 and a pI of 5.5 (15). The enzyme is synthesized as a preproenzyme comprised of a 24-residue N-terminal signal peptide, and a 192-residue C-terminal propeptide which contains features common to  $\beta$ -pleated transmembrane proteins (16). The amino acid sequence displays 66% similarity with procine pancreatic  $\alpha$ -amylase. It is characterized by a seven fold higher  $k_{cat}$  and  $k_{cat}/K_m$  values at 4°C and a lower conformation stability with the difference in free energy of 1.9 kcal mol<sup>-1</sup> (17). Homology modeling reveals several features responsible for the more flexible, heat-labile conformation of the psychrophilic  $\alpha$ -amylase: the lack of 12 surface salt bridges by replacement with Gln or Asn residues; substitution of 25 residues in the hydrophobic clusters of the porcine enzyme, causing a sharp decrease of the hydrophobicity and increase in flexibility; and deletion or substitution of 12 proline residues in loops or turns. These findings seem to substantiate the concept of local flexibility as an adaptation to thermal stability by extremophiles. The treatment of thermodynamic parameters of activation as a structure–function model accounting for local flexibility for acquiring high activity at low temperature has been described by Lonhienne et al. (18).

## B. Design Enzyme Stability

### 1. Immobilization

Until the advent of genetic modification, immobilization was routinely used for improving the stability of enzymes in industrial processing. Immobilization anchors the enzyme onto a suitable carrier such as agarose, alginate, gelatin, or polyacrylamide either by covalent coupling, adsorption, matrix entrapment, or encapsulation. The primary advantage of immobilization is to increase the stability of the enzyme, as well as convenience in separation and recovery, and reuse of the enzyme from the product mixture. In the manufacture of high-fructose corn syrup, glucose isomerase is immobilized by direct crosslinking of lysed cells with glutaraldehyde and extruded with structural support substances, such as gelatin and polyamine (19). Although not directly relevant to food applications, immobilization of enzymes has been shown to have higher stability in reactions carried out in water-miscible organic solvents (20). Apart from the conventional approaches, Stempfer et al. (21) engineered a

fusion protein of  $\alpha$ -glucosidase containing a hexa-arginine polypeptide stretch at the C-terminal end. The cationic peptide extension provides a strong, noncovalent attachment of the fusion protein to a polyanion matrix. Ureda and Tanaka (22) have constructed a genetic system to immobilize enzymes in their active and functional forms on the cell surface of *Saccharomyces cerevisiae*. The display of both CM-cellulase and  $\beta$ -glucosidase on the surface of *S. cerevisiae* results in digestion of cello-oligosaccharides as the sole carbon source. Likewise, coimmobilization of glucoamylase and  $\alpha$ -amylase on cell surfaces has been shown to digest soluble starch as the sole source of carbon for yeast growth (23).

## 2. Protein Engineering

With the advent of recombinant DNA technology, enzymes have been tailored by manipulating the genetic code to target specific amino acid substitutions. Site-directed or cassette mutagenesis is rapidly becoming a routine approach in many investigations. Subtilisin, lysozyme, trypsin, and amylases are among some of the most extensively studied enzymes as models for enhancing various enzyme properties (24). Considerable work has been conducted on the contribution of disulfide bridges to the stability of proteins by decreasing the conformational entropy in the unfolded state. In T4 lysozyme, a single change of Ile3  $\rightarrow$  Cys creates a disulfide bridge between the new Cys3 and the native Cys97, resulting in enhancement of stability against irreversible inactivation (25) as well as reversible thermal unfolding (26). Matsumura et al. (10) have shown that mutants containing three constructed disulfide bonds (3–97, 9–164, 21–142) exhibit an additive effect with  $\Delta T_m$  of 23.4°C higher than the wild type. However, mutants containing Cys90-Cys122 and Cys127-Cys154 are less stable due to the introduction of strains by the new bonds.

It has been known that salt bridges play an important role in protein stability. The introduction of His31-Asp30 in T4 lysozyme stabilizes the protein by 3–5 kcal mol<sup>-1</sup> (27). Engineering Ser38  $\rightarrow$  Asp and Asn144  $\rightarrow$  Asp at the N-terminal end of the helices B and J increases stability with  $\Delta\Delta G$  of 1.6 kcal mol<sup>-1</sup> (28). Some investigations indicate that the contribution to stability from an engineered salt bridge is very small ( $\sim$  0.1–0.25 kcal mol<sup>-1</sup>), which is largely offset by the entropic cost of localizing the ion pair on the surface of the enzyme (29). Van den Burg et al. (30) constructed a thermolysin-like protease mutant with a disulfide bridge (Asn60  $\rightarrow$  Cys with Gly8  $\rightarrow$  Cys), and several

mutations to increase the rigidity of the molecule, including Ala69  $\rightarrow$  Pro and Ser65  $\rightarrow$  Pro. The resulting mutant enzyme shows a dramatic increase in stability; it is 340 times more stable than the wild type in terms of the half-life time at 100°C. All these results suggest the importance of considering the balance between favorable and unfavorable factors involved in engineering structural changes.

## III. CREATING NOVEL ENZYMES BY DIRECTED EVOLUTION

In the use of rational design to engineer a protein's structural and functional properties, the change in the amino acid sequence is preconceived based on a prior knowledge of the structural and mechanistic details of the protein. In spite of some remarkable successes, prediction of the outcome of a particular amino acid substitution remains largely empirical, and explanations for the effects of site-directed mutagenesis are done in hindsight, simply because there is an enormous gap in our ability to correlate sequence structure and function. A novel approach based on the concept of combinatorial chemistry has revolutionized the way to engineering protein molecules. Initially, the concept of directed evolution was utilized in generating RNA molecules with novel binding and catalytic activities (31). Libraries of RNA can be generated by in vitro transcription of DNA by PCR with random priming. A selection step is applied to the RNA pool to isolate variants possessing the targeted function/property. The few selected RNA molecules are subjected to iterative cycles of amplification, mutation, and selection until the best-fit molecule is identified. The use of this concept for evolving proteins has been realized with the development of the DNA shuffling technique (32) and subsequent refining and expansion of this technique. The method involves random digestion of a pool of DNA sequences (typically amplified error-prone PCR products of a gene of interest) with DNaseI to a mixture of small DNA fragments. These fragments are reassembled by DNA polymerase, relying on self-priming of homologous end sequences, and in the process, recombination or crossover occurs by template switching. This DNA shuffling step is followed by selecting the recombinant libraries for the best combination of mutations yielding the targeted properties (33).

Modification and expansion of the original DNA shuffling concept have been continuously developed and reported. One of the adaptations, called family

shuffling, allows two or more related genes to be used as the starting genetic materials (34). This approach is based on the assumption that naturally occurring genes in a family of species are already enriched for functional diversity by selection in the natural evolution process. A simplified method for in vitro recombination, called staggered extension process (StEP) recombination, eliminates the steps of DNaseI digestion and reassembly of DNA fragments (35). The key to this method is to employ very short extensions in the PCR reaction, so that in the following cycle, denaturation will free the growing fragments to anneal to different templates. Kikuchi et al. (36) developed an effective family shuffling method using single-stranded DNA of two or more related genes to avoid the problem of homoduplex formation caused by the annealing of DNA fragments derived from the same gene.

In a greater deviation from the Stemmer's shuffling method, Coco et al. (37) developed a method called random chimeragenesis on transient templates, which involves separating the gene homologs into single-stranded DNA, digesting one strand into fragments which will align with the other strand as the template. Unhybridized flaps are removed, and gaps are filled to generate a full-length heteroduplexed gene. The parental template is destroyed by uracil-DNA-glycosylase treatment, and is replaced by a homoduplex strand during PCR. Ostermeier et al. (38) described a methodology, incremental truncation for the creation of hybrid enzymes, that creates hybrid gene libraries that are independent of sequence homology. Two parent genes are truncated incrementally and the fragments are fused pairwise to generate single crossovers. A more refined method, called sequence homology-independent protein recombination (39), allows the proper sequence alignment maintained between the parent genes in the hybrid sequence. A more recent development involves exon shuffling, which is based on the fact, that in nature, genetic recombination occurs by crossover in the intron regions to produce various structure genes (40). This approach had already been successfully utilized earlier by Kumagai et al. (41) to introduce lysozyme activity to  $\alpha$ -lactalbumin by engineering a hybrid protein by artificial exon shuffling.

Directed evolution as described above contains an in vivo step of expressing the gene variants in microorganisms. It requires an appropriate system for the transcription and translation of the DNA sequences to proteins for in vivo selection, while in the following step, the beneficial mutations are combined and subjected to in vitro mutagenesis and amplification for the next cycle. *E. coli* has been frequently used as a suitable

expression system, while yeast is the choice for working with eukaryotic genes. Various techniques have been developed to allow the generation of a library of protein molecules to be displayed (anchored) on the cell surface of bacteria (42), phage (43), or yeast (44) as a fusion protein. Currently, there are two cell-free systems developed for in vitro selection and evolution of proteins. Tawfik and Griffith (45) showed that in vitro transcription/translation apparatuses can be incorporated with single genes into reverse micelles, a cell-like compartment that links genotype to phenotype. In ribosome display, in vitro transcription and translation are performed on ribosomes, with a number of modification steps to retain the expressed protein on the ribosome after translation (46, 47). The ribosome-bound proteins are screened and reverse transcription and PCR of the mRNA produce the DNA sequence of the corresponding protein. Mutations in sequence can be introduced during amplification to generate a new population in the next cycle of protein synthesis and selection.

Directed evolution has been successfully employed in numerous investigations to engineer various aspects of structure-function properties of proteins and enzymes (48). However, the focus has been primarily on the improvement or alteration of existing properties. In a recent study, Alan R. Fersht's group created totally new catalytic functions in the transmutation of indole glycerol phosphate synthase (IGPS) to phosphoribosyl anthranilate isomerase (PRAI) (49). This was achieved by modification of the loops of IGPS that are differed from those in PRAI, followed by directed evolution. The final evolved enzyme loses its original IGPS activity, but acquires PRAI activity with  $k_{cat}/K_m$  value of  $4.8 \times 10^{-7} \text{ sec}^{-1} \text{ M}^{-1}$  which is sixfold that displayed by the wild-type enzyme. This study exemplifies the remarkable power of combining rational design and directed evolution in achieving novel structural and functional properties.

#### IV. METABOLIC ENGINEERING

Recombinant DNA technology has progressed rapidly so that foreign genes can be introduced or endogenous genes can be manipulated to redesign metabolic pathways in microbial, plant, and animal cells. For the field of agriculture and food, this means the ability of in vivo manipulation of enzymes to tailor the chemical composition and physical properties of various food components, to enhance characteristics suitable for food formulation and processing, to improve nutri-

tional values, to remove or reduce the level of anti-nutrients, or even to produce value-added nonfood products. The following description illustrates the application of metabolic engineering to change the quality characteristics of starch in cereal plants. The composition and molecular structure of starch have a direct impact on the rheological properties, such as gelatinization, swelling, viscosity, and retrogradation. With the current trend of developing more processed and formulated foods, the demand for specialty starches is increasing. The ratio of amylose to amylopectin has a significant impact on the physicochemical properties of the starch, and for some applications enriched fractions of either one is desirable. Currently, most waxy mutants that produce starches with little or no amylose are created by selective breeding in maize. However, controlling the degree of branching or the ratio of amylose to amylopectin can be realized only through the use of metabolic engineering. Introduction and expression of *Escherichia coli* glycogen branching enzymes into potato tubers showed an increase in branching degree of the amylopectin (50, 51). Lloyd et al. (52) introduced a chimeric antisense construct of two starch synthase isoforms (SSII and SSIII) into potato tubers, which led to accumulation of amylopectin with an increase in short-chain branching. Antisense inhibition of starch branching enzyme (isoform SBE A) in potato increases the average chain length of amylopectin and the level of phosphorylation (53). Suppression of both SBE A and B results in very high (~ 2.5 times) amylose potato starch containing insignificant levels of highly branched amylopectin, and sixfold increase in phosphorus content (54). Other targets for genetic manipulating of starch biosynthesis include (a) increased production or alteration of storage proteins, (b) changes in size and ratio of A and B starch granules, and (c) specialty carbohydrate products, such as cyclodextrins utilizing starch as substrate (55). All these can be achieved, as future investigations continue to reveal the complex interactions and mode of action of the various enzymes involved in starch synthesis.

Metabolic pathways often employ enzyme complexes to achieve multifunctional steps of catalysis in the formation of the final product via a number of intermediates. The concept of combinatorial chemistry can be applied to biological systems by combining, changing, or shuffling the genes in a biosynthetic pathway, resulting in a whole range of novel molecules and their variants (56). For example, in polyketide biosynthesis, the multifunctional polyketide synthase

enzyme complex catalyzes repeated Claisen condensation between acylthioesters (ketosynthase), followed by repeated reductive cycles comprising a ketoreduction (ketoreductase), dehydration (ketodehydratase), and enoylreduction (enol-reductase) on the  $\beta$ -keto group of the growing polyketide chain. After the chain has elongated through a fixed number of cycles, the polyketide product is released via the action of a thioesterase. Structural variability is introduced by variations of substitutions in the starter units, the extent of reduction, and the location of intramolecular ring closure (57). This natural process can be manipulated to produce designer polyketides by combinatorially expressing PKS subunits in modules, and a large repertoire of polyketides can be generated for screening for specific structure-function, including antibiotics and anti-cancer agents (58).

Recently, a wide range of structurally different carotenoids have been successfully synthesized by manipulating terpenoid pathways in bacteria and yeasts. To direct carotenoid biosynthesis in *Escherichia coli*, the terpenoid pathways need to be extended with expressing a number of genes, including phytoene synthase (for forming the C40 carotenoid phytoene), isopentenyl pyrophosphate isomerase (for the isomerization of isopentenyl pyrophosphate to dimethylallyl pyrophosphate which is the substrate for elongation), and geranylgeranyl pyrophosphate synthase (for forming geranylgeranyl pyrophosphate which is the substrate for phytoene synthase). A combination of these and several other genes for specific modifications of the phytoene chain were cloned into *E. coli* plasmids, resulting in the synthesis of eight different hydroxy derivatives of carotenoids, including 1-hydroxylycopene, 1, 1'-dihydroxylycopene, dimethylspheredene, 3-hydroxy- $\beta$ -zeacarotene, 7,8-dihydrozeaxanthin, 3- or 3'-hydroxy-7,8-dihydro- $\beta$ -carotene, and 1'-hydroxy- $\gamma$ -carotene (59). Using a similar approach, but combining it with directed evolution of phytoene desaturase and lycopene cyclase, Schmidt-Dannert et al. (60) were able to introduce six double bonds into phytoene for the production of the fully conjugated carotenoid, 3,4,3',4'-tetrahydrolycopene, and a unique cyclic carotenoid torulene.

## V. ARTIFICIAL ENZYMES

The idea of replacing enzymes with synthetic biocatalysts has long been an intellectual challenge. Miniature enzymes, devoid of polypeptide backbones, offer an attractive alternative for use in processing because

they are less prone to the effects of high temperature, extreme pH, and ionic strength existing in industrial applications. Cyclodextrins have proved to be the most popular host matrix for constructing enzyme mimics, usually with the attachment of one or more reactive groups, such as a pyridoxamine to the hydrophobic binding cavity to produce selectivity for transamination of ketoacids bound into the cavity (61). Examples also include the grafting of an imidazolylbenzoic acid moiety to achieve a chymotrypsin-like activity (62, 63). Another synthetic host that has been used quite extensively includes porphyrin or porphyrin-like structures as well as various macrocyclic compounds with built-in functions. For example, Fe<sup>III</sup> and Mn<sup>III</sup> (porphyrinato) complexes have been studied by several groups as superoxide dismutase mimics (64). Salvemini et al. (65) developed a Mn(II) bis(cyclohexylpyridine) macrocyclic complex that mimics superoxide dismutase catalytically and acts exclusively on superoxide, without interfering with other reactive species, such as nitric oxide, hydrogen peroxide, or peroxynitrite. An example of mimicking not only the important structural features but also the same chemistry as an enzyme was reported for the development of models of galactose oxidase, which oxidizes benzylic or allylic alcohols with O<sub>2</sub> to yield an aldehyde and H<sub>2</sub>O<sub>2</sub> (66). In the model, the derivatized Schiff base diimine-diphenolate ligands mimics the copper coordination in the natural enzyme involving two tyrosine phenolates, two histidine imidazoles, and exogenous H<sub>2</sub>O ligand.

Catalytic antibodies are currently the best-known enzyme mimics. These so-called abzymes are generated by screening a huge library of antibodies raised against transition state analogs for catalysts in a particular reaction of interest (67, 68). The many different reactions developed for catalytic antibodies include amide hydrolysis, ester hydrolysis, peptide cleavage, transesterification,  $\beta$ -elimination, cationic cyclization, Diels-Alder reaction, Claisen rearrangement, lactonization, and various chemical transformations. Esterolytic antibodies are the best characterized of the catalytic antibodies probably due to the fact that excellent transition state analogs are readily available. Several crystal structures of esterase-like antibodies have been published (69–73). All these abzymes, raised against phosphonate transition state analogs, act by stabilization of the oxyanion intermediate that results from general base-assisted or hydroxide attack on the substrate. The active site may contain a catalytic His or Ser-His dyad, and at least in one study on an abzyme with amide hydrolytic activity, a His residue at the bottom

of the antigen-binding site may be involved in nucleophilic catalysis (74). Applying directed evolution techniques to evolve a hydrolytic abzyme generated by the conventional method with immunization of the transition state analog, Takahashi et al. (75) produced a variant with six- to two-fold increases in the  $k_{cat}$  value.

An alternative approach of generating catalytic antibodies has been proposed by Brioulet et al. (76) using the properties of anti-idiotypic antibodies to generate an internal image of an enzyme-binding site. This approach follows the concept of idiotypic mimicry (77) in that antienzyme antibodies generated by animal immunization are screened for those that recognize (idiotypic) the enzyme active site. The selected antienzyme antibodies are used as immunogens to induce the production of anti-idiotypic antibodies which carry the imprint of the enzyme active site and are subject to enzyme activity screening. Crystallographic studies of anti-hen egg white lysozyme antibody complexed with an anti-idiotypic antibody suggest that the mimicking is functional, involving similar binding interactions rather than exact topological “images” (78).

Another technique known as molecular imprinting deals with a very similar concept in biological recognition. The overall approach is to allow a mixture of functional monomers (of either acrylate-, styrene-, or silica-based materials) to prearrange around the selected ligand by noncovalent interactions (79, 80). The resulting complexation is immobilized by polymerization of the monomers, and subsequent extraction (or dissolution) of ligand results in the development of an “imprint” within the polymeric structure. Plastic enzyme mimics could be produced by using template-containing analogs of substrates, transition state, or product of an enzyme reaction. Several studies used phosphonate derivatives to mimic the transition of carboxylic ester hydrolysis, and the results have been very moderate. In one study, phosphonic acid monoesters were imprinted using a polymerizable amidine derivative, and the catalysts were screened for activity (81). The hydrolysis reaction follows a typical Michaelis-Menten curve with saturation kinetics.

### I. INTRODUCTION

#### A. Reactions Catalyzed: Behavioral Anomalies

Catalase (hydrogen peroxide:hydrogen peroxide oxidoreductase; EC 1.11.1.6) catalyzes two different reactions and shows unusual features kinetically (1, 2). The first and best-known reaction is the decomposition of H<sub>2</sub>O<sub>2</sub> to give H<sub>2</sub>O and O<sub>2</sub>. This is called "catalatic activity" [Eq. (1)]. But catalase also oxidizes several H donors, such as methanol, ethanol, formic acid, and phenols with the consumption of 1 mole of hydrogen peroxide. This is called "peroxidatic-like" activity [Eq. (2)].

Which reaction predominates depends on the concentration of H donor and the steady-state concentration of H<sub>2</sub>O<sub>2</sub> in the system. In both reactions the active catalase-H<sub>2</sub>O<sub>2</sub> compound I is formed first. The decomposition step of H<sub>2</sub>O<sub>2</sub>, in which H<sub>2</sub>O<sub>2</sub> serves as H donor for compound I proceeds very rapidly ( $k \sim 10^7 \text{ M}^{-1} \text{ sec}^{-1}$ ), while peroxidatic-like reactions [Eq. (2)] proceed much slower ( $k \sim 10^2 - 10^3 \text{ M}^{-1} \text{ sec}^{-1}$ ) (3).

Another anomaly of catalase-catalyzed reactions is that catalase does not obey the expected order of reaction (Michaelis-Menten) shown by most enzymes.

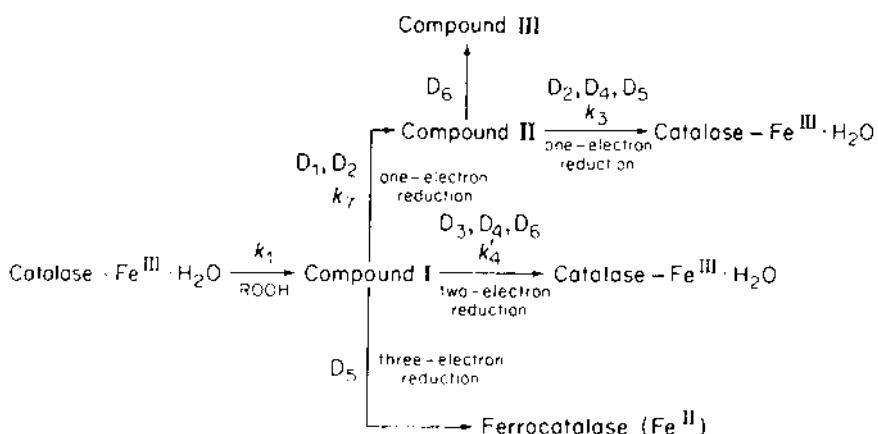

First, it is not possible to saturate the enzyme with substrate even as high as 5 M H<sub>2</sub>O<sub>2</sub>. Second, there is a rapid inactivation of catalase at H<sub>2</sub>O<sub>2</sub> concentrations above 0.1 M, because the active enzyme-H<sub>2</sub>O<sub>2</sub> compound I is converted to the inactive compounds II and III (Fig. 1) (4). Therefore, one cannot experimentally determine  $V_{\max}$  by saturating catalase with H<sub>2</sub>O<sub>2</sub>. As a result, the reactions must be performed at  $\sim 10$  mM H<sub>2</sub>O<sub>2</sub>. Successful and reproducible assays must be performed at catalase concentrations high enough so that the half-time ( $t_{1/2}$ ) for decomposition of the H<sub>2</sub>O<sub>2</sub> is 30 sec or less (4). Temperature changes have a low effect on rate of reaction ( $Q_{10} = 1.05 - 1.12$ ; about the same effect as on diffusion rates). Therefore, the activation energy,  $E_a$ , for conversion of H<sub>2</sub>O<sub>2</sub> to H<sub>2</sub>O and O<sub>2</sub> is  $\sim 0.60 - 1.7$  kcal mol<sup>-1</sup>. Conversion of H<sub>2</sub>O<sub>2</sub> to products initially (0–30 sec) follows a linear reaction (first order with respect to H<sub>2</sub>O<sub>2</sub> concentration) between 0.01 and 0.05 M H<sub>2</sub>O<sub>2</sub>.

The rate constant ( $k$ ) for the overall reaction is given by Eq. (3).

$$k = (2.3/\Delta t) \log[S_1]/[S_2] \text{ sec}^{-1} \quad (3)$$

where  $\Delta t = t_2 - t_1$  near the beginning of reaction (see above), [S<sub>1</sub>] and [S<sub>2</sub>] are H<sub>2</sub>O<sub>2</sub> concentrations at  $t_1$  and  $t_2$ , respectively. In studies with purified enzyme preparations the specific activity ( $k'_1$ ) is given by Eq. (4).

$$k'_1 = k/[E] M^{-1} \text{ sec}^{-1} \quad (4)$$

**Figure 1** Reactions of catalase with hydrogen donors. The Ds refer to the donors: D<sub>1</sub> is ascorbate or ferrocyanide; D<sub>2</sub> is phenols; D<sub>3</sub> is alcohols or formic acid; D<sub>4</sub> is nitrite; D<sub>5</sub> is azide or hydroxamine; and D<sub>6</sub> is hydrogen peroxide. (From Ref. 4.)

The  $k'_1$  for pure catalase from human erythrocytes is  $3.4 \times 10^7 \text{ M}^{-1} \text{ sec}^{-1}$ . This value permits estimation of the concentration of catalase in blood and tissues.

There are some problems in estimating the concentration of catalase because of molecular heterogeneity due to genetic origin (not all isozymes have the same specificity), conformational alterations due to -SH group oxidation or dissociation of the active tetramer (catalatic activity) into the dimer which has peroxidatic activity but not catalatic activity (6–8).

## B. Historical Aspects

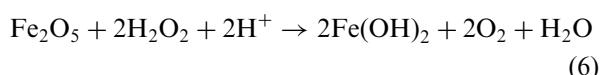

Catalase appears to be the first potential enzyme recorded (about 1812), based on the appearance of rapid bubble evolution when biological extracts were mixed with H<sub>2</sub>O<sub>2</sub>. The catalatic activity was regarded originally as an attribute of “protoplasm,” a term shared with other general catalysts such as platinum. In 1901, Loew introduced the specific name “catalase” (9). But the true nature of catalase was overlooked by the more prevalent discussion of the actions of metals in biological oxidation. Wieland (10) considered the initial oxidation reaction to be the transfer of hydrogen to oxygen to form peroxide, and the role of the metal was to remove the peroxide so formed. Warburg (11) considered that hydrogen peroxide was not formed during biological oxidation, but that the iron of the cells activated O<sub>2</sub> to react directly with substrates. Therefore, he did not consider special catalatic or peroxidative roles for the heavy metals in contrast to Wieland (10). Hennichs in 1926 (12) also failed to recognize that the prosthetic group of catalase contains

iron despite his partial purification of catalase. Willstätter (13) also doubted the function of iron in peroxidase.

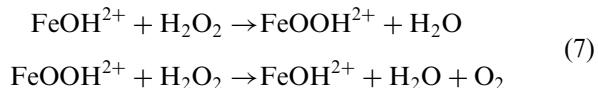

In 1930, Zeile and Hellström (14) prepared purer catalase from liver and demonstrated the hematin nature of the prosthetic group. The analogies between catalase and other hematin compounds were soon recognized (15–17). Bray and Gorin (18) postulated the reaction with iron of the hematin prosthetic group was probably that shown in Eq. (5). This was the first formulation of a catalytic role for quadrivalent (ferryl) iron.

Earlier, Manchot and Lehmann (19) reported that a pentavalent iron (Fe<sub>2</sub>O<sub>5</sub>) could perform a catalatic reaction [Eq. (6)].

But in enzymes, the theory of the enzyme-substrate complex formation was an alternate explanation to the free-radical hypothesis required by Eq. (6). Von Euler and Josephson's data (20) supported the idea that catalase formed a Michaelis complex with H<sub>2</sub>O<sub>2</sub>, with  $K_m$  of 0.025 M. Bonnichsen et al. (21) proved that the reaction velocity could be explained by the collision theory of reaction rates and strongly argued against the assumptions of chain mechanisms postulated earlier. At the same time Chance (22) discovered the primary compound (FeOOH<sup>2+</sup>) formed between catalase and H<sub>2</sub>O<sub>2</sub> (compound I; [Eq. (7)]), which then reacts with a second H<sub>2</sub>O<sub>2</sub> [Eq. (7)].

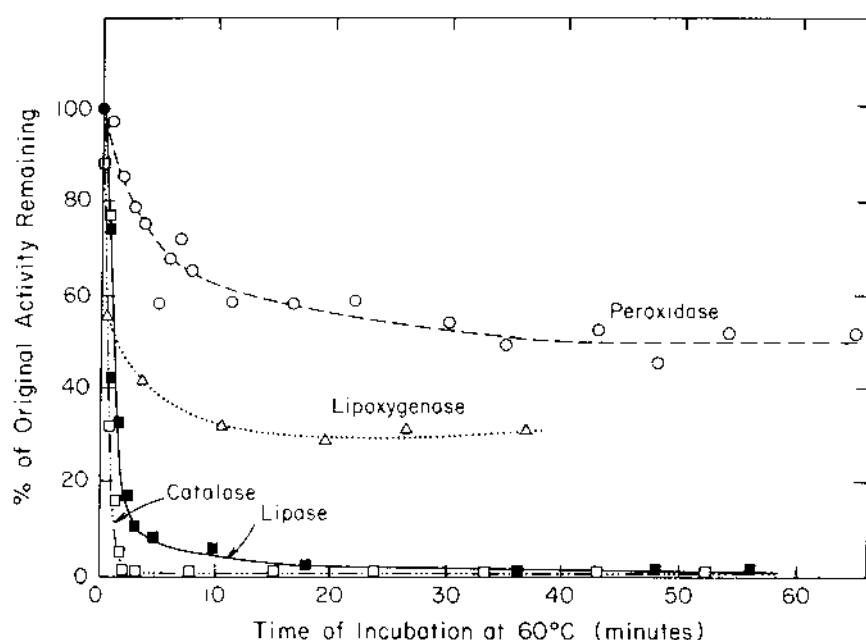

Chance's demonstration of the similarity between the catalytic and peroxidatic behaviors of the catalase compound I required a reexamination of the hypothesis that the biological role of catalase is in fact a peroxidatic one (23).

## II. IMPORTANCE OF CATALASE IN FOOD SCIENCE AND TECHNOLOGY

Catalase is widely distributed in nature. It is found in all aerobic microorganisms, and in all plant and animal cells. The catalase activity of mammalian cells varies. It is highest in liver and kidney and low in connective tissues. Catalase has been used in the food processing industry to determine the adequacy of blanching (70–105°C) of vegetables and fruits to destroy microorganisms and enzymes to preserve color, texture, flavor, taste, and aroma of the products when stored frozen up to 2 years. Early in the application of blanching for stabilization of frozen foods catalase was used especially for Birdseye peas (24–26), the best on the market. But catalase is much less heat stable than peroxidase (Fig. 2) (27), causing the U.S. Federal Drug

Administration some concern about whether catalase was the best enzyme to use. In 1949, Joslyn (29), based on his research from 1933 to 1945, concluded that loss of peroxidase activity paralleled the loss of enzymes responsible for off-flavor development in blanched frozen foods more closely than the loss of catalase activity. Neither catalase nor peroxidase has been shown to be directly involved in quality deterioration of frozen blanched foods. But it is easy to determine their activities and demonstrate the conditions required to inactivate them in the blanching process.

In the dairy industry, catalase activity is a sensitive and easily detected indicator of contamination of milk by neutrophil granulocytes. In biomedical research and medical clinics, catalase in liver, leukocytes, and erythrocytes has received substantial attention as to its role in oxidative metabolism and its protective role as a  $\text{H}_2\text{O}_2$  scavenger. In maize genetics, investigation of catalase has been extensively studied in relation to human acatalasemia. Severe cases of acatalasemia in humans indicate that the catalase activity is near zero, raising the question of how such individuals deal with the metabolic destruction of  $\text{H}_2\text{O}_2$ . Catalase activity has been used as a diagnostic predictor in some hematological disorders and in determining urinary tract infections.

**Figure 2** Rates of inactivation of catalase, peroxidase, lipoxygenase, and lipase in English green pea homogenates incubated at 60°C. (From Ref. 27.)

Following cold pasteurization of milk by H<sub>2</sub>O<sub>2</sub>, the residual H<sub>2</sub>O<sub>2</sub> is removed by addition of catalase. Catalase has been widely used in removing O<sub>2</sub> from the head space of several foods, including dried egg powder, fruit juices, and wines, to prevent enzymatic browning by polyphenol oxidase. It is also used in analytical determinations of O<sub>2</sub> and H<sub>2</sub>O<sub>2</sub> concentration in foods (30).

### III. MOLECULAR STRUCTURE

A large number of amino acid sequences of catalases are known, primarily deduced from the gene sequences. These include (based on entries listed in Swiss-Prot): *Aspergillus fumigatus* (*Sartorya fumigata*), *A. niger*, *Arabidopsis thaliana* (mouse ear cress), *Bacillus subtilis*, *B. firmus*, *B. stearothermophilus*, *Bacteroides fragilis*, *Bordetella pertussis*, *Bos taurus* (bovine), *Botrytis cinerea* (*Botryotinia fuckeliana*), *Brucella abortus*, *Caenorhabditis elegans*, *Campylobacter jejuni*, *Candida albicans*, *C. tropicalis*, *Cavia porcellus* (guinea pig), *Cucurbita pepo* (summer squash), *Deinococcus radiodurans*, *Desulfovibrio vulgaris* (strain Miyazaki), *Drosophila melanogaster* (fruit fly), *Emericella nidulans* (*Aspergillus nidulans*), *Glycine max* (soybean), *Gossypium hirsutum* (upland cotton), *Haemophilus influenzae*, *Helianthus annuus* (common sunflower), *Helicobacter pylori* (*Campylobacter pylori*), *Homo sapiens* (human), *Hordeum vulgare* (barley), *Ipomoea batatas* (sweet potato), *Lactobacillus sake*, *Listeria seeligeri*, *Lycopersicon esculentum* (tomato), *Micrococcus luteus* (*M. lysodeikticus*), *Mus musculus* (mouse), *Mycobacterium avium*, *M. bovis*, *M. intracellulare*, *M. tuberculosis*, *Neisseria gonorrhoeae*, *Nicotiana plumbaginifolia* (leadwort-leaved tobacco), *N. tabacum* (common tobacco), *Onchocerca volvulus* (*endobacterium*), *Oryza sativa* (rice), *Penicillium janthinellum* (*P. vitale*), *Phaseolus aureus* (mung bean), *Pichia angusta* (*Hansenula polymorpha*), *Pisum sativum* (garden pea), *proteus mirabilis*, *Pseudomonas aeruginosa*, *Ps. putida*, *Ps. syringe*, *Rattus norvegicus* (rat), *Rhizobium meliloti* (*Sinorhizobium meliloti*), *Rhodobacter capsulatus* (*Rhodopseudomonas capsulata*), *Ricinus communis* (castor bean), *Saccharomyces cerevisiae*, *Salmonella typhimurium*, *Schizosaccharomyces pombe* (fission yeast), *Secale cereale* (rye), *Solanum melongena* (eggplant), *Solanum tuberosum* (potato), *Triticum aestivum* (wheat), *Vibrio fischeri*, and *Zea mays* (maize).

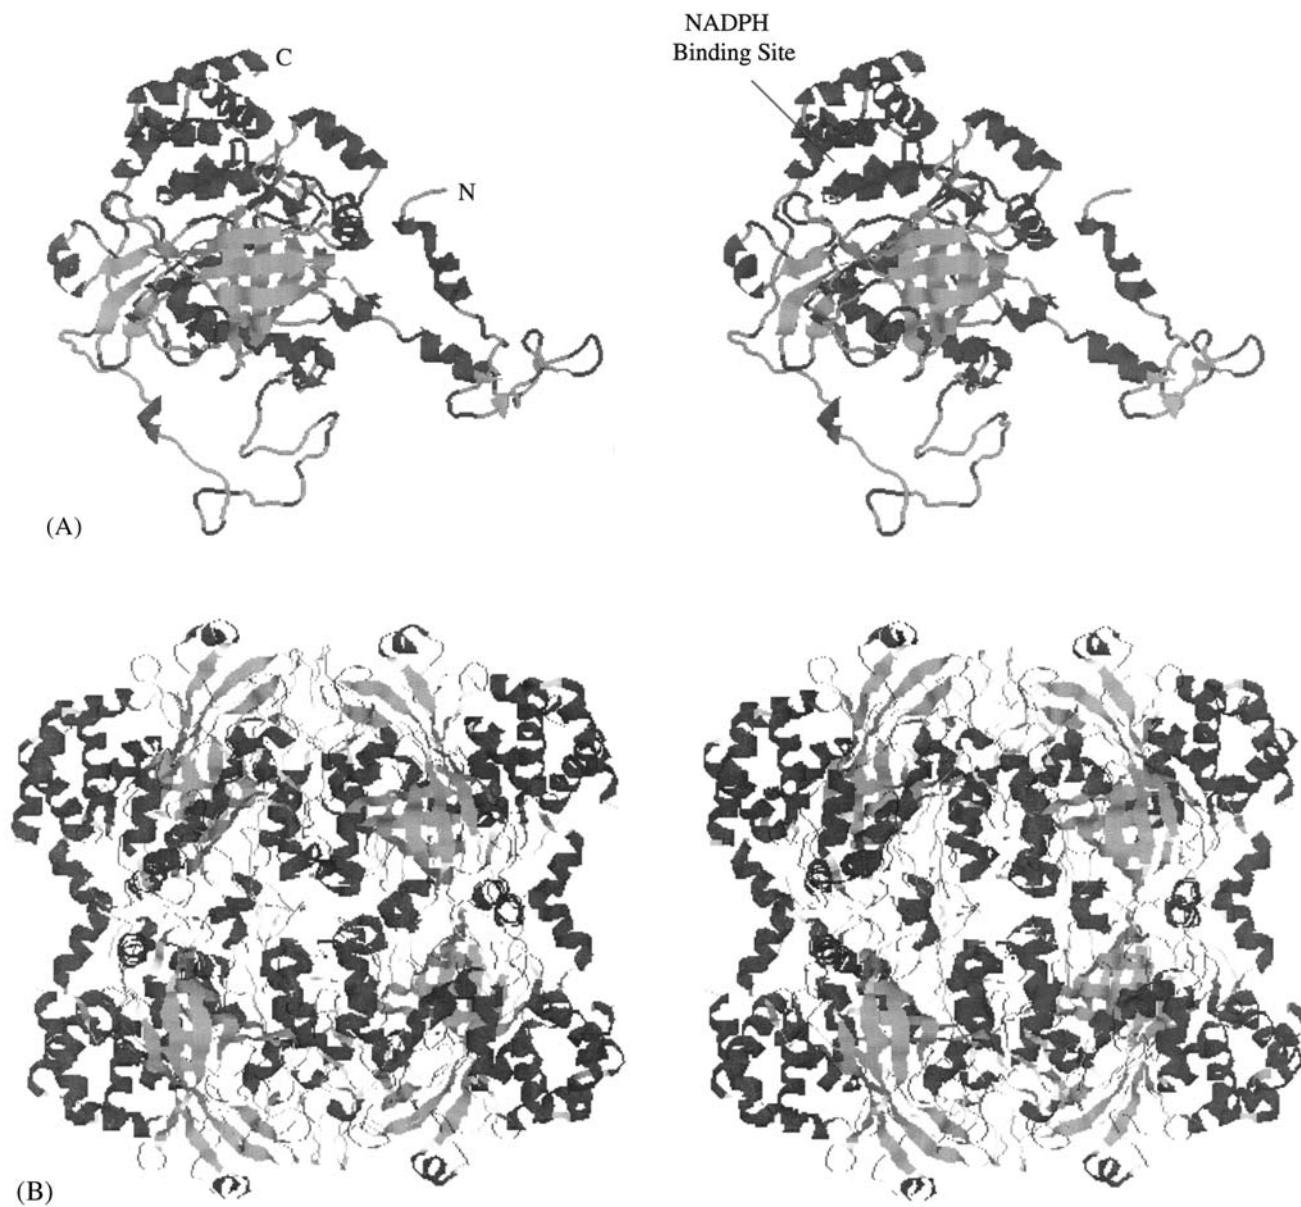

The primary structure of bovine liver catalase (BLC) subunit consists of 506 amino acid residues

with a prosthetic group. In the homotetrameric molecule, the four Cys residues in each subunit do not form disulfides (31). BLC belongs to a family that may be referred to as true catalases (or heme catalases), corresponding to homotetrameric, heme-containing enzymes with an  $\alpha + \beta$  fold, ubiquitously found in eukaryotes and also in many prokaryotes (32). These heme catalases have molecular weights (MW) in the range of 200–330 kDa. The other family of catalases consists of Mn-catalases that are nonheme hexameric enzymes with an all  $\alpha$ -fold, and are present only in prokaryotes (33).

An interesting group of bifunctional catalase-peroxidases have been identified in *Escherichia coli*, *Mycobacterium tuberculosis*, and *Synechococcus* sp. These KatG enzymes are phylogenetically related to eukaryotic ascorbate peroxidases and yeast cytochrome peroxidase forming class I of the plant peroxidase superfamily (34). The *E. coli* KatG enzyme (or hydroperoxide I, or HPI) is a tetramer of 84-kDa subunits and 2 protoheme IX groups, with a primary structure of 726 amino acid residues (35).

*E. coli* also produces hydroperoxidase II (HPII) which has been characterized as a monofunctional catalase containing a modified heme imparting a characteristic green color to the protein (36). It is a tetramer of identical 84-kDa subunits, each encoded by the *katE* gene, with a predicted sequence of 753 amino acid residues (37). The Cys residues in HPII do not have a catalytic role. Moreover, the highly conserved Cys438 is blocked with a unique hemithioacetal structure originated from a pyruvate modification (38).

Crystal structures of several catalases have been elucidated, including bovine liver, human erythrocyte, *Penicillium vitale*, *E. coli*, *Proteus mirabilis*, and *Saccharomyces cerevisiae*. The beef liver catalase subunit consists of four domains: an N-terminal section of 70 residues forms an arm extending from the globulin region and intersects with the neighboring subunits; the second domain (residues 76–320) forms a  $\beta$ -barrel consisting of two topologically similar, four-stranded antiparallel sheets; the third domain (residues 321–436), also known as the wrapping domain, is a long stretch of polypeptide chain forming an outer layer; and the C-terminal domain (residues 437–506) consists of four  $\alpha$ -helices on the external part of the molecule (32, 39–41) (Fig. 3A, B). In the tetrameric structure, most of the intersubunit interactions are confined to the N-terminal arm and the wrapping domain. The  $\beta$ -barrel and the C-terminal domain form a hydrophobic channel leading to the heme pocket which is  $\sim 20\text{ \AA}$  below the surface. Heme protein interactions involve

**Figure 3** Stereo view of beef liver catalase (A) subunit (PDB id 7cat) and (B) tetramer (PDB id 4b1c).

mostly van der Waals contacts between the heme vinyl and methyl groups and nonpolar side chains, and a few charge interactions between the heme propionyl groups and Arg and carboxylic acid residues. At the proximal side of the heme, Tyr357 provides a protein ligand (as ligand 5) with the Fe-phenolic oxygen distance of 1.9 Å. Ionization of the Tyr-OH is assisted by interactions with the guanidinium group of Arg353. On the distal side of the heme are the essential His74 and Asn147, with their  $N_s$  atoms at 4.3 Å and 6.2 Å

from the heme iron, respectively. The ligand 6 site on the distal side of the heme is unoccupied.

The tetrameric enzyme from human and bovine contains four molecules of tightly bound NADPH located toward the carboxyl ends of  $\alpha 5$  and  $\alpha 10$  helices (42, 43). However, the binding of NADPH is not essential for activity, but may function to prevent the formation of compound II, an inactive intermediate in the catalytic cycle (see below). The binding site shows relative affinities in the order of: NADPH > NADH >

$\text{NADP}^+ > \text{NAD}^+$ . The crystal structure of the fungal *Penicillium vitale* catalase is similar to that of the beef liver enzyme, except that there is an additional C-terminal flavodoxin-like domain (residues 520–670) (44, 45). This domain has an  $\alpha/\beta$  structure with a central  $\beta$ -sheet of five parallel strands and four helices around it, with a topology similar to that of flavodoxin (46). *Escherichia coli* catalase HPII, encoded by the *katE* gene, shows a very close structural relationship with other catalases. It differs from BLC in that the C-terminal domain of  $\sim 150$  residues is structurally flavodoxin-like (47). In addition, the N-terminal 60 amino acids increase the contact area between subunits. The crystal structures of *Proteus mirabilis* PR catalase and *Saccharomyces cerevisiae* catalase-A show that the bound NADPH has the same conformation as in BLC, and lacks a C-terminal domain equivalent to that found in *Penicillium vitale* (48, 49).

*Escherichia coli* catalase HPII exhibits an unusual absorption spectrum distinctly different from that of other catalases containing heme *b* (protoporphyrin IX). The heme prosthetic group of HPII is an unusual green chromophore derived from a member of the family of *d*-type hemes, which is also found in *Penicillium vitale* catalase. The structure has been characterized as having a configuration of a *cis*-hydroxy-chloin  $\gamma$ -spirolactone at the saturated pyrrole ring III of the macrocycle in the C-6 position, which may arise from heme *b* by a self-catalyzed epoxide formation on ring III followed by hydrolysis to the *cis* diol (50–52).

#### IV. REACTION MECHANISM

The overall reaction catalyzed by catalases involves the conversion of two moles of  $\text{H}_2\text{O}_2$  to yield water and oxygen as the final products. The substrate  $\text{H}_2\text{O}_2$  participates in both oxidizing and reducing activities, with a two-electron transfer in each process.

Step. 1. Two-electron oxidation of native ferric enzyme to catalase compound I, with the substrate  $\text{H}_2\text{O}_2$  reduced to  $\text{H}_2\text{O}$ :

Step 2. Two-electron reduction of compound I to native ferric enzyme, with a second molecule of  $\text{H}_2\text{O}_2$  oxidized to  $\text{O}_2$ :

#### A. Formation of Compound I

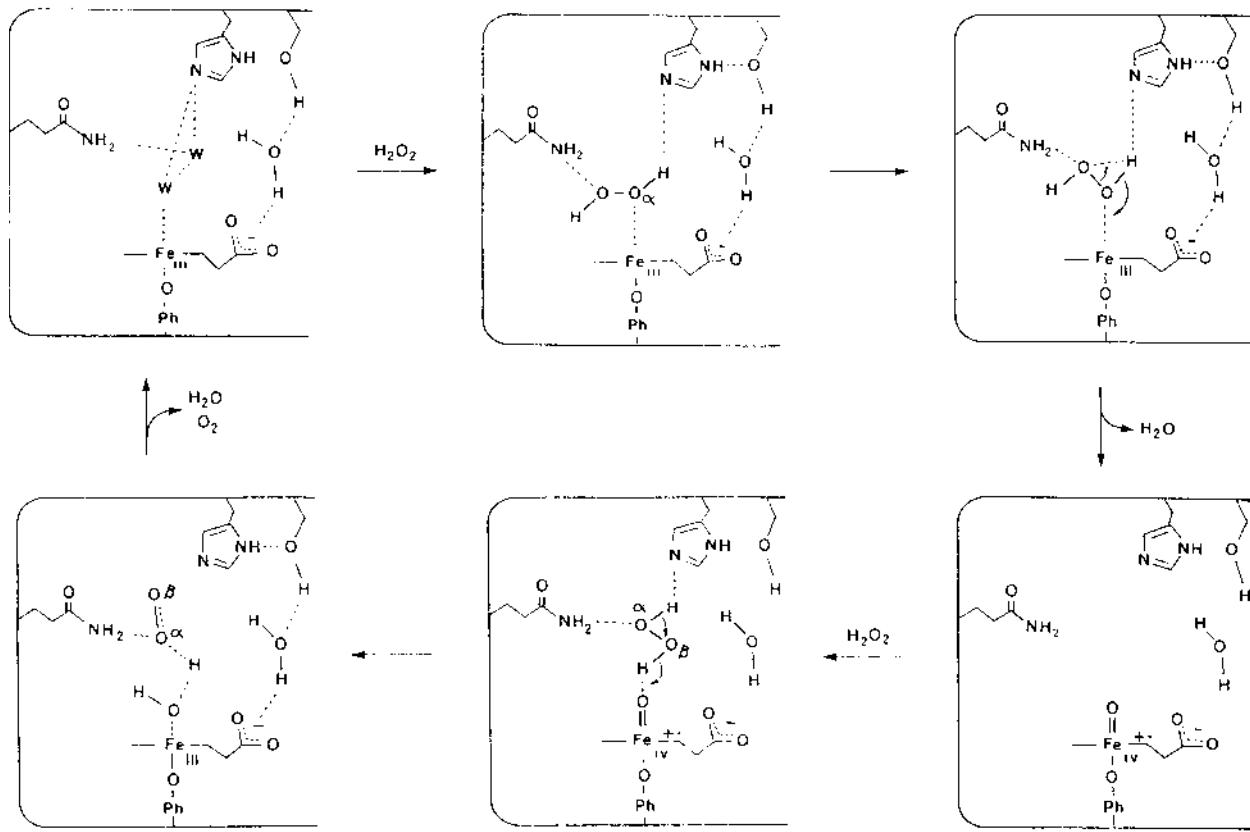

Compound I contains a  $\pi$ -cation radical of the heme structure of  $[\text{O} = \text{Fe(IV)}\text{porphyrin}]^+$  similar to that of compound I formed by horseradish peroxidase (HRP) (53). The rate constant for the formation of compound I with  $\text{H}_2\text{O}_2$  as substrate in the catalytic reaction is  $6 \times 10^6 \text{ M}^{-1} \text{ sec}^{-1}$  (54). Other hydroperoxide substrates, such as alkyl or acyl peroxides, can also be reduced to corresponding alcohols, albeit with much lower rate constants (Table 1).

Upon the binding of a peroxide molecule, two water molecules in the heme cavity are displaced for the substrate to form interactions with the enzyme. The peroxide  $\alpha$  oxygen interacts with the heme Fe(III) via electrostatic interactions, and with His74-N $\epsilon$  through hydrogen bonding (Fig. 4) (40). The net result is increasing acidity of the  $\alpha$ -proton and the weakening of the peroxide O $\alpha$ -H bond. The O $\alpha$ -O $\beta$  bond is further polarized by the formation of hydrogen bonding between the  $\beta$  oxygen and Asn147. Finally, a charge-relay system formed between His74-N $\delta$  and Ser113-O $\gamma$ , and the propionic carbonylic group of pyrrole III facilitates the transfer of the  $\alpha$ -proton from O $\alpha$  to O $\beta$  of the peroxide. The deprotonation of O $\alpha$  in turn enhances the interaction between O $\alpha$  and heme (Fe(III)), delocalization of the negative charge on O $\beta$ , and development of a

**Table 1** Rate Constants of Catalase in the Enzymatic Cycle

Substrate	Formation of Compound I $k_1 (\text{M}^{-1} \text{ sec}^{-1})$	Substrate	Reduction of Compound I $k_4 \text{ app} (\text{M}^{-1} \text{ sec}^{-1})$
HOOH	$6 \times 10^6$	HOH	$1.8 \times 10^7$
$\text{CH}_3\text{OOH}$	$8.5 \times 10^5$	$\text{CH}_3\text{OH}$	830
$\text{CH}_3\text{CH}_2\text{OOH}$	$2 \times 10^4$	$\text{CH}_3\text{CH}_2\text{OH}$	1020
$\text{CH}_3(\text{CH}_2)_2\text{OOH}$	$5.5 \times 10^3$	$\text{CH}_3(\text{CH}_2)_2\text{OH}$	6.5
$\text{HOCH}_2\text{OOH}$	$3 \times 10^4$	$\text{HOCH}_2\text{OH}$	1200

Source: Ref. 54.

**Figure 4** Reaction mechanism of catalase showing the formation and reduction of compound I. (From Ref. 70; adapted from Ref. 40.)

positive charge of the heme group, allowing the final transfer of the  $O_\alpha$  to the heme iron.

### B. Reduction of Compound I

In the second half of the cycle, catalase compound I reacts with a second molecules of  $H_2O_2$  to yield the native enzyme with generation of  $O_2$  and  $H_2O$ . However, compound I reacts poorly with other hydrogen donors, such as alcohol, hydroxylamine, or formic acid. Reduction of compound I occurs via a hydride transfer by abstracting the  $\beta$ -hydrogen by the heme ferryl oxygen (55). Deprotonation of the substrate's  $\alpha$ -proton is unlikely to occur because the His74 is less nucleophilic as the heme in compound I is positively charged. The  $\beta$ -hydrogen abstraction is stereospecific for the pro-R hydrogen in the oxidation of ethanol substrate (56). A hydride transfer facilitates the development of a double-bond character at  $O_\alpha-O_\beta$ , and the final transfer of the  $\alpha$  proton to the heme ferryl oxygen (Fig. 2).

### C. Formation of Compound II

Catalase can slowly form compound II by a two-step one-electron reduction of compound I under a steady low concentration of  $H_2O_2$  or with other special substrates, such as ferrocyanide and ascorbate. Catalase compound II is an inactive form in the catalytic mode of the enzyme. This is in contrast to HRP compound II, which is an active species produced by two sequential one-electron reductions of compound I with most of its substrates. The difference in the reactivities of compound II species of catalase and HRP is probably due to protein control of the accessibility of substrates to the heme group (57). In addition, the phenoxylate oxygen of the proximal Tyr residue provides more electron density to the heme iron than the His residues of HRP, and favors a two-electron transfer instead of a sequential addition of electrons (58).

The slow inactivation of catalase by its own substrate can be prevented by experimentally limiting the exposure to  $H_2O_2$ , or reducing the concentration of compound I. However, the primary inhibition of the

formation of compound II is provided by the enzyme's cofactor, NADPH, which has been shown to prevent and reverse the process (59). It has been suggested that the initial formation of compound II involves a compound II radical intermediate, and NADPH reduces both the iron and the free radical by a two-electron transfer (60, 61).

## V. MEASUREMENT OF CATALASE ACTIVITY

Catalase activity can be measured spectrophotometrically, manometrically, polargraphically, and titrimetrically. The best methods are the spectrophotometric and titrimetric methods. They will be presented below.

### A. Spectrophotometric Method (1, 2, 62)

Hydrogen peroxide has a molar extinction coefficient ( $\epsilon_m$ ) of  $52 \text{ M}^{-1} \text{ cm}^{-1}$  at 235 nm and its disappearance can be followed by continuous spectrophotometry when purified catalase preparations are used. As noted in paragraph 3 of Section I, 10 mM  $\text{H}_2\text{O}_2$  should be used in the catalase assay so as to avoid formation of inactive compounds II and III. Therefore, the time zero absorbance reading will be 0.520. This method is the easiest to perform, is sensitive, and is the best when purified catalase is used.

#### 1. Equipment Needed

UV spectrophotometer suitable for accurate measurements at 235 nm, connected to a high-speed recorder. Quartz cuvettes (10 mm light path).

#### 2. Reagents and Solutions

a. *Purity of Reagents.* Glassware, buffer, and substrate should be free from heavy metals, as they will cause decomposition of  $\text{H}_2\text{O}_2$ . Potential problems caused by metal impurities can be determined by a control containing an equivalent volume of phosphate buffer, pH 7.0, in place of the enzyme.

b. *Phosphate Buffer (50 mM, pH 7.0).* (1) Dissolve 6.81 g  $\text{KH}_2\text{PO}_4$  in water and make to 1 L. (2) Dissolve 8.90 g  $\text{Na}_2\text{HPO}_4 \cdot 2 \text{ H}_2\text{O}$  in water and make to 1 L. Mix solutions (1) and (2) in the proportion of 1:1.5 (V/V), pH 7.0.

c. *Hydrogen Peroxide (30 mM).* Dilute 0.34 mL of 30% hydrogen peroxide (freshly opened) with phosphate buffer, pH 7.0 (above) to 100 mL. (Smaller

volumes of reagents can be prepared by keeping the concentrations constant as given.)

d. *Sample of Catalase.* Prepared in the 50 mM, pH 7.0, phosphate buffer.

#### 3. Stability of Solutions

The phosphate buffers are stable as long as bacterial contamination is avoided; store at 2°C. Prepare the buffered  $\text{H}_2\text{O}_2$  solution fresh each day.

#### 4. Reaction

a. *Blank.* Place 1.00 mL of 50 mM phosphate buffer into a quartz cuvette. Add 2.00 mL catalase sample.

b. *Catalase Reaction.* Place 2.00 mL catalase sample into a quartz cuvette. Add 1.00 mL of  $\text{H}_2\text{O}_2$  solution (above). Mix rapidly (~ 5 sec) with a plastic paddle or by inversion three times using parafilm.

c. *Place in Spectrophotometer.* Record continuously for 30–60 sec. If a recorder is not available, take readings at 5- to 10-sec intervals. The temperature should be at 20–25°C.  $\Delta\text{Abs}/15 \text{ sec}$  should be no larger than 0.100 and not smaller than 0.020. If necessary, adjust concentration of enzyme solution to be within these limits and repeat the experiment.

#### 5. Calculation of Results

As noted earlier in Section I.A, the reaction approximates a first-order reaction. Therefore, the following relations can be used for a 15-sec or other interval of reaction time.

$$\begin{aligned} k &= (2.3/15 \text{ sec}) \log(A_1/A_2) \\ &= 0.153 \log(A_1/A_2) \text{ sec}^{-1} \end{aligned} \quad (8)$$

To calculate the catalytic concentration  $b$  of the sample ( $k/\text{L}$ ) or catalytic content  $Z_c/m_s$  of the sample (unit  $\text{k/g Hb}$ ) use:

$$b = (V/v)(2.3/15) \log(A_1/A_2) k/\text{L} \quad (9)$$

$$\begin{aligned} b &= (3/2)(2.3/15) \log(A_1/A_2) k/\text{L} \\ &= 0.23 \log(A_1/A_2) k/\text{L} \end{aligned} \quad (10)$$

where  $A_1$  is  $A_{235}$  at time = 0;  $A_2$  is  $A_{235}$  at  $t = 15 \text{ sec}$ ;  $V$  is total assay volume;  $v$  is enzyme sample volume in the assay mixture. The 3/2 is total reaction volume/enzyme sample volume (see Sec. V.4 above).

$$\begin{aligned} Z_c/m_s &= (2.3\alpha/15 \text{ Hb}) \log (A_1/A_2) \\ &= 0.153 \log (A_1/A_2) \text{ sec}^{-1} \times g \text{ Hb } (Z_c/g \text{ Hb}) \end{aligned} \quad (11)$$

where  $\alpha$  is the quotient of weight concentration of hemoglobin (Hb; unit g/L) in blood or erythrocyte sediment, and in the cuvette.

For a difference in absorbance of  $0.450 (t_0) - 0.400 (t_{15} \text{ sec}) \log (A_1/A_2) = 0.05115$ , the following relationship holds:

$$k = (2.3/\Delta t) \log (A_1/A_2) = (0.1175/\Delta t) \text{ sec}^{-1} \quad (12)$$

## 6. Precision, Accuracy, and Sensitivity

With values around  $300 \text{ k/g Hb}$ , a precision of  $\pm 10 \text{ k/g Hb}$  was found. The coefficient of variation is 2–3%.

## 7. Detection Limits

The limits of this method are set by the turbidity (of tissue homogenates) or by the hemoglobin content (of the hemolysate). Whenever low catalase activity of a sample does not permit dilution of at least 1:100 (i.e., activity in blood is  $< 20 \text{ k/g Hb}$ ), use of the alternative titration technique (below) is recommended.

## B. Titrimetric Method (62)

### 1. Method Design

The conversion of  $\text{H}_2\text{O}_2$  to products is measured by determining the  $\text{H}_2\text{O}_2$  left in the reaction after a certain time by back-titration with permanganate. Portions of the assay mixture are taken after 0, 10, 20, and 30 sec, and reactions are stopped immediately by addition of 1 M  $\text{H}_2\text{SO}_4$ .

### 2. Optimized Conditions for Measurement

See spectrophotometric method above (Sec. V.A). Titrimetric methods with incubation times  $> 30 \text{ sec}$  give only comparative values. Preparation of rate curves require time and effort, with a large series of measurements. Perborate, a stabler substrate than  $\text{H}_2\text{O}_2$ , is best for routine studies. The inactivation of the enzyme is somewhat slower than with  $\text{H}_2\text{O}_2$ . The results obtained with  $\text{H}_2\text{O}_2$  and perborate are of the same order of magnitude. The method of Feinstein (63) is suitable, insofar as the assay conditions are modified according to the recommended procedure of Bonnichsen (64) (i.e., 30 sec incubation time at pH 7.0 and  $20^\circ\text{C}$ ).

## 3. Equipment

Thermostatic water bath ( $20^\circ\text{C}$ ) with rotating shaking attachment.

## 4. Reagents and Solutions

a. *Purity of Reagents.* See remarks in Section V.A.3 under spectrophotometric method.

b. *Preparation of Solutions.* Use repurified water.

*Phosphate buffer* (50 mM, pH 7.0). See Section V.A.2.b under spectrophotometric method.

*Sodium perborate* (100 mM, pH 7.0). Dissolve 7.694 g  $\text{NaBO}_3 \cdot 4 \text{ H}_2\text{O}$  n ca. 20 ml of 2.4 M HCl, add ca. 400 ml of water, adjust pH to 7.0 with additional 2.4 M HCl and make to 500 ml with water.

*Potassium permanganate* (0.01 M). Dissolve 1.58 g  $\text{KMnO}_4$  in water and make 1 liter.

*Stability of solutions.* The phosphate buffer is stable as long as bacterial contamination is avoided; store at  $2^\circ\text{C}$ . The perborate solution is stable for several days at  $2^\circ\text{C}$ ; check titer with permanganate in each series of measurements.

## 5. Procedure

a. *Assay Conditions.* Incubation at  $20^\circ\text{C}$ ; final reaction volume 5.00 mL.

b. *Measurement.* The blank contains 1.00 mL phosphate buffer and 3.00 mL perborate solution. After preincubation for 10 min at  $20^\circ\text{C}$ , add 1.00 mL water; mix. Stop the reaction after 30 sec by addition of 3.00 mL of 1 M  $\text{H}_2\text{SO}_4$ . Mix.

The sample contains 1.00 mL phosphate buffer and 3.00 mL of perborate solution. After preincubation at  $20^\circ\text{C}$  for 10 min, 1.00 mL catalase solution is added; mixed. Stop the reaction after 30 sec by adding 3.00 mL of 1 M  $\text{H}_2\text{SO}_4$ . Mix.

The remaining perborate in the blank and sample is determined by titrating with permanganate solution.

To construct a rate curve, prepare several assay mixtures and stop the reactions at 10, 20, and 30 sec, respectively. The concentration of the enzyme solution should be such that after 30 sec not  $> 50\%$  and not  $< 10\%$  of the perborate is converted to product. If the catalase activity in the sample is low, the incubation time should be increased to 1 min, or even to 5 min.

## 6. Calculations

The rate constant ( $k$ ) for the overall reaction is given by:

$$k = (2.3/\Delta t) \log \frac{\text{titration vol for blank}}{\text{titration vol for sample}} \text{ sec}^{-1} \quad (13)$$

The specific activity ( $k'$ ) is obtained by dividing  $k$  by the molar concentration of enzyme [E].

$$k' = k/[E] M^{-1} \text{ sec}^{-1} \quad (14)$$

Owing to the progressive inactivation of the catalase the calculated  $k$  values for the various time intervals must be plotted and extrapolated to  $t = 0$ . The values obtained in this way for the rate constant  $k$  are somewhat lower than nonextrapolated values.

For comparative purposes the results can also be expressed in arbitrarily defined "units"—e.g., the number of millimoles of perborate decomposed under the standard experimental conditions related to mg wet weight of tissue (or g hemoglobin, etc.) ("perborate units") (62, 63).

## 7. Validation of Method

According to the type of sample, the relative standard deviation is 3–5%. The source of errors includes the titration of concentrated homogenates or blood samples (because of their low catalase activity). The endpoint is not sharp since the protein in the sample slowly reacts with permanganate. If the titration is carried out rapidly and always to the same endpoint (relative excess of  $\text{KMnO}_4$ ), the resulting error is small. A correction can be applied by titration of an additional control mixture containing no perborate or by deproteinization of the incubation reaction mixture with trichloroacetic acid. Oxidizable compounds (e.g., Tris) must not be used as components of buffers if catalase activity is determined by the titrimetric method.

## VI. PURIFICATION OF CATALASE

As reported in Section III, the amino acid sequence has been determined for 63 catalases, largely by gene sequencing. Individual researchers have developed their own methods for purification. In Methods in Enzymology, Vol II, 1955, detailed methods are given for purifying catalase from beef liver (65, 66),

horse and pig blood (64), bacteria [*Micrococcus lysodeikticus*] (67), and spinach leaves (68).

The purification procedure for spinach leaf catalase will be described here, as being more appropriate for food enzymology (69). Freshly harvested spinach leaves are washed in tap water and stored in a cold room at 2–4°C. The leaves are transferred to large stainless steel vats, covered with commercial acetone previously chilled to –15°C, and let sit for at least 2 h at this temperature. The cold, partially dehydrated leaves are very brittle and are easily reduced to small pieces with a large Waring-type blender. The blending is complete in 30–60 sec and the slurry is gravity-filtered in the cold; the filtrate is discarded. The residue is washed several times with portions of cold acetone (–4°C), and the resulting gray-green material is dried overnight in a ventilated hood.

The acetone powder is extracted repeatedly with ice-cold 0.1 M  $\text{Na}_2\text{HPO}_4$ , yielding a filtrate of Kat.f. ~ 50 and an inactive residue, which is discarded. The filtrate is half-saturated with solid  $(\text{NH}_4)_2\text{SO}_4$  and left overnight in the cold room (4°C). The precipitate, obtained by centrifugation at 0°C and containing all the activity, is redissolved in a small volume of 0.1 M  $\text{Na}_2\text{HPO}_4$ . This preparation, after clarification by filtration or centrifugation, has a Kat.f. of ~ 180. Three successive fractionations with 20%, 7%, and 20% saturated  $(\text{NH}_4)_2\text{SO}_4$  are carried out, the precipitates being saved in each instance. The product has a Kat.f. of ~ 920, shows a faint absorption band at 630 nm, and gives absorption peaks at 275, 330, 405, and 625 nm in a Beckman spectrophotometer.

The catalase solution is adjusted to pH 6.5 and made 0.1 M with respect to Na acetate by addition of the solid salt. Cautious fractionation with saturated  $(\text{NH}_4)_2\text{SO}_4$ , also adjusted to pH 6.5, yields several precipitates varying in Kat.f. from 1200 to 10,000. The most active preparations are dialyzed for 2 days in the cold against pH 7.14 phosphate buffer of ionic strength 0.1 and then subjected to preparative free boundary electrophoresis (18 mA, 330 volts, 4 h), yielding five fractions—three on the anodic side, one in the bottom cell, and one from the cathodic side. (Note: polyacrylamide gel electrophoresis should be used today.) The Kat.f. and spectrophotometric data for these fractions, as well as Kat.f.'s and all the other fractions in the preparatory scheme, are shown in Table 2.

The cathodic fraction of Kat.f. 23,600 gives needle-like crystals after concentration, dialysis against 0.1 M  $\text{Na}_2\text{HPO}_4$ , and addition of solid  $(\text{NH}_4)_2\text{SO}_4$  to ~ 12% saturation. These needles, when redissolved in

**Table 2** Kat.f. Values and Spectrophotometric Characteristics of Various Fractions of the Spinach Leaf Catalase Preparation

Fraction	Kat.f. <sup>a,b</sup>	$\frac{E_{280} \text{ nm}}{E_{405} \text{ nm}}$
1. $\text{Na}_2\text{HPO}_4$ extract of acetone powder	50	—
2. Ppt. of Fraction 1 insol. in 50% satd. $(\text{NH}_4)_2\text{SO}_4$ redissolved in 0.1 M $\text{Na}_2\text{HPO}_4$	180	—
3. Ppt. of Fraction 2 insol. in 20% satd. $(\text{NH}_4)_2\text{SO}_4$ redissolved in 0.1 M $\text{Na}_2\text{HPO}_4$ , sol. in 7% satd. $(\text{NH}_4)_2\text{SO}_4$	425	—
4. Ppt of Fraction 3 insol. in 20% satd. $(\text{NH}_4)_2\text{SO}_4$ redissolved in 0.1 M $\text{Na}_2\text{HPO}_4$	920	—
5. Ppts. obtained from adjusting Fraction 4 to pH 6.5, making 0.1 M with respect to Na acetate, then cautiously fractionating with solid $(\text{NH}_4)_2\text{SO}_4$	10,100	—
6. Electrophoretic fractions of redissolved Fraction 5		
Cathodic	23,600	1.54
Bottom cell	9,020	2.07
Anodic No. 2	12,100	2.07
Anodic No. 1	7,320	2.37
Anodic (top cell)	2,620	2.54

<sup>a</sup>  $k = 1/t \log_{10} A_0/(A_0 - x)$ , where  $k$  = 1st-order rate constant,  $t$  = time in min,  $A_0$  = mL permanganate used at zero time and  $A_0 - x$  = mL permanganate used at 3, 6, 9, and 12 min, respectively.

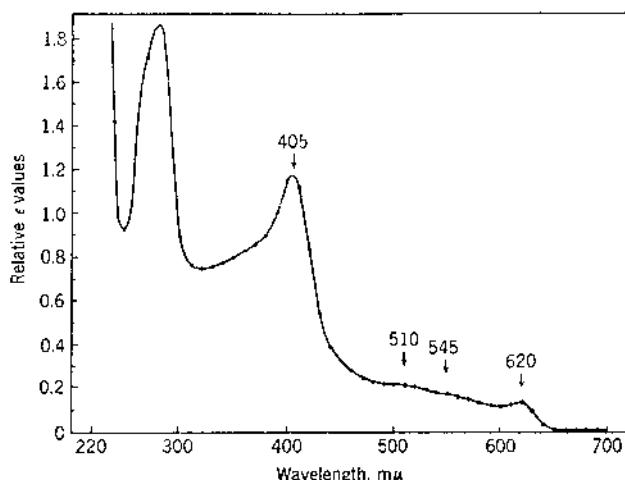

<sup>b</sup> Purity (Katalasefähigkeit) determined as Kat.f. =  $k/\text{g catalase/mL}$ . Source: Ref. 69.

0.1 M  $\text{Na}_2\text{HPO}_4$ , give a good catalase absorption spectrum (Fig. 5).

The catalase prepared by the above method contained 0.049% iron, approximately half the value for a pure 4-hematin catalase. The prosthetic group is protoporphyrin, as shown by preparation of a typical pyridine hemochromogen in the acetone-HCl supernatant of an aliquot of the enzyme.

The enzyme is inhibited by KCN and  $\text{NaN}_3$ , 50% inhibition being produced by  $5 \times 10^{-6}$  M KCN and  $2 \times 10^{-5}$   $\text{NaN}_3$ ; Na diethyldithiocarbamate does not affect activity.

The enzyme is completely inactivated in 10 min when incubated at 60°C but is indefinitely stable at 1°C between pH 5.3 and 8.9. The activity is optimal between pH 5.3 and 8.0, but decreases rapidly at more acid values and slowly at more alkaline values.

**Figure 5** Absorption spectrum of electrophoretically prepared spinach leaf catalase. Kat.f. = 23,600. Concentration of the enzyme was  $\sim 0.5 \text{ mg/mL}$ . (From Ref. 69.)

## Horseradish Peroxidase

**Zhong Yi Yuan and Tai Jiao Jiang**

*Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences, Shanghai, China*

### I. INTRODUCTION

Horseradish peroxidase (HRP; donor:hydrogen-peroxide oxidoreductase; EC 1.11.1.7) catalyzes the reaction:

The enzyme utilizes hydrogen peroxide, some organic peroxides, or peroxy acids of the general formula ROOH as hydrogen acceptors to catalyze the oxidation of a variety of organic and inorganic hydrogen donors, such as phenols, aromatic amines, and others.

Horseradish peroxidase occupies an important position in the history of enzymology. Because of its stability and availability, the purified enzyme is often used as a typical model for the family of peroxidases. Since the 1950s, research on the reaction mechanism, structure, and function of this enzyme has drawn much attention (1–6). The practical applications of HRP in clinical, food, and industrial analyses (ELISA, etc.) (7–9) and catalysis in nonaqueous media (producing pharmaceuticals, synthesizing polymers, etc.) (10, 11) have been exploited. Horseradish peroxidases are glycoproteins, containing one polypeptide chain, one protoporphyrin IX as prosthetic group, three to eight carbohydrate chains, and two  $\text{Ca}^{2+}$  (1, 12).

### II. OCCURRENCE AND PHYSIOLOGY FUNCTION

Peroxidases are widely distributed in the leaf, stem, and root of horseradish (*Armoracia rusticana*, *A.*

*lapathifolia*, *Cochlearia armracia* L., etc.); the highest activity is in the roots. The content of peroxidase not only varies with location but also with maturity and season. However, little is known about its cellular location, microenvironment, or specific participation of HRP in physiological pathways. Plant peroxidases play very important physiological roles:

1. Degrading and synthesizing lignin in cell wall damage and repair. It is also important in the elongation of plants (13).
2. Providing defense against pathogens and stress (14).
3. Catalyzing the catabolism of phyto-growth hormones, e.g., indole acetic acid (IAA) and auxin to regulate plant growth (15).
4. Controlling respiration (16).
5. Promoting formation of highly reactive species, i.e., free radicals and electronically excited states. These species may participate in cell damage or be of benefit against pathogens (17).
6. Catalyzing removal of hydrogen peroxide (18).

### III. PEROXIDASE FAMILIES AND SUPERFAMILIES

Besides being found in horseradish, peroxidases are found also in other plants, microorganisms, and animals including humans. On the basis of sequence homologies, Welinder (3) proposed classification of peroxidases by families and superfamilies as shown in Table 1.

**Table 1** Superfamilies and Families of Peroxidases

Superfamily	Family
Plant peroxidase	(a) Peroxidases of prokaryotic origin: yeast cytochrome C peroxidase, chloroplast and cytosolic ascorbate peroxidases, gene duplicated bacterial peroxidases. (b) Secreted fungal peroxidases: lignin peroxidase ( <i>Phaneraete chrysoporum</i> ), manganese peroxidase ( <i>P. chrysoporum</i> ), ink cap mushroom peroxidase ( <i>Coprinus sinereus</i> ), chloroperoxidase ( <i>Caldariomyces fumago</i> ), cytochrome C peroxidase ( <i>Pseudomonas aeruginosa</i> ). (c) Classical plant peroxidases: HRP isoenzyme C is the most intensively studied.
Animal peroxidases	Myeloperoxidase, verdoperoxidase, eosinophil peroxidase, prostaglandin H synthase, glutathione peroxidase, lactoperoxidase, thyroid peroxidase.
Catalases	They are found in plants and animals. These are tetrameric proteins.

#### IV. PROPERTIES AS PROTEINS

##### A. HRP Isoenzymes

Over 40 isoenzymes of peroxidase have been found in the horseradish plant. By cloning techniques, some of the isoenzymes come from different genes and others may be produced by posttranslational modification, especially by degree of glycosylation. There are differences in amino acid composition and sequences among the isoenzymes (19). Based on the isoelectric points, the isoenzymes can be classified as shown in Table 2 (20).

**Table 2** Horseradish Peroxidase Isoenzymes

FORM	pI	pH <sub>opt</sub>	Carbohydrate (%)
HRP-A	4	Acid	Higher
HRP-B, -C	5.75, 9.63	Neutral <sup>a</sup> , slightly alkaline	Low
HRP-D, -E	10.6, > 12	Strongly alkaline	Low

<sup>a</sup>Neutral HRP-C is the main isoenzyme in the plant.

##### B. Primary, Secondary, and Tertiary Structures of HRP

Determination of the complete amino acid sequence of HRP-C was largely contributed by Welinder (21). HRP-C consists of 308 amino acid residues, a heme group, and eight neutral carbohydrate side chains attached to asparagine residues. The amino acid sequence and carbohydrate attachment points are shown in Figure 1. The molecular weight was reported to be between 40,000 and 45,000, and the carbohydrate moiety constitutes ~ 18%. HRP-C is the most extensively investigated isoenzyme in the plant peroxidase superfamily. Within the superfamily, HRP-C belongs to Class III of the plant extracellular peroxidases (22). Peroxidases from flowering plants have considerable identity of amino acid sequences (40–64%). In particular, those sequences in the regions of the two His residues (the distal His42 and proximal His170 in HRP) and Cys residues forming disulfide bonds are conserved (12, 22).

Gajhede et al. (23) published a 2.15 Å resolution structure of HRP-C, which gave complete information on overall structure and its comparison to other peroxidases. HRP-C has the same overall fold typical of the peroxidase superfamily, with the secondary structure elements (especially the 10 prominent helices A–J), heme group, and calcium-binding sites in similar positions. The secondary and the tertiary structures of HRP-C are summarized in Figure 2.

More recently, the synthetic and native HRP-C have been cloned in various microorganisms—*E. coli*, *Baculovirus*, and *Pichia pastoris*, etc. (24–26).

#### V. PROPERTIES AS AN ENZYME

##### A. Specific Mechanism of Action

The normal peroxidase cycle is shown in Figure 3. The reaction of HRP with H<sub>2</sub>O<sub>2</sub> produces a two-electron oxidized species known as Compound I in which the ferric iron is oxidized to a ferryl (Fe<sup>IV</sup>=O) species and the porphyrin to a radical cation. Stepwise reduction of Compound I by two substrate-derived electrons produces Compound II, in which the porphyrin radical cation has been quenched, and subsequently the resting ferric state form. The second-order rate constants for the reaction HRP and H<sub>2</sub>O<sub>2</sub> are: k<sub>1</sub>, (1.58 ± 0.05) × 10<sup>7</sup> M<sup>-1</sup> s<sup>-1</sup>; k<sub>2</sub>, (9.97 ± 0.28) × 10<sup>6</sup> M<sup>-1</sup> sec<sup>-1</sup>; and k<sub>3</sub>, (3.64 ± 0.01) × 10<sup>2</sup> M<sup>-1</sup> sec<sup>-1</sup> (1, 27, 28).

Generally, k<sub>3</sub> is always 10–20 times slower than k<sub>2</sub>, and under most steady-state conditions is rate limiting.

**Figure 1** The amino acid sequence of horseradish peroxidase (carb = site of carbohydrate attachment). Disulfide bridges: 11–91, 44–49, 97–301, 177–209. (From Ref. 21.)

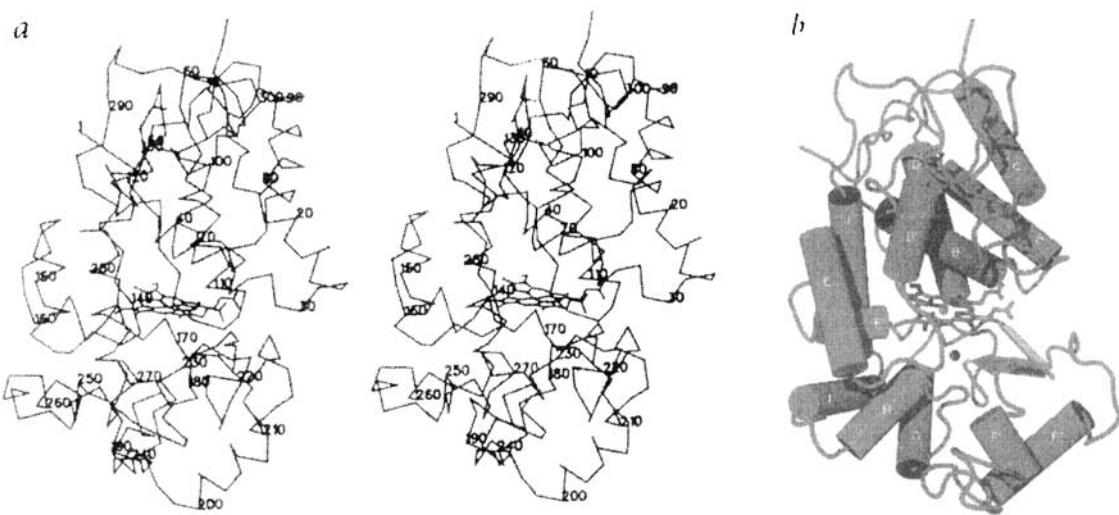

The values of  $k_2$  and  $k_3$  depend on the nature of the substrate.

Both competitive binding (1) and spectroscopic studies (29) have revealed that the peroxide- and substrate-binding sites are not the same. Specific-site mutation analyses (30, 31) and the high-resolution crystallographic structure of HRP-C (23) have provided detailed information on structural basis of HRP catalysis. Peroxide binding, activation, and Compound I formation occur in the distal heme pocket, where the key residues (His42 and Arg38)

play a role in mediating the reactions with a general acid/base mechanism. The aromatic donor molecule interacts with a substrate accessible channel contributed by Phe residues (Phe68, Phe142, and Phe179) and the heme C18 methyl group.

## B. Substrate Specificity

Peroxidase is specific to the hydrogen acceptors. Only hydrogen peroxide, methylhydroperoxide, and ethylhydroperoxide can be used as hydrogen acceptors.

**Figure 2** (a) Stereo C<sub>α</sub> trace of HRP-C with the heme C20 edge in the foreground. Every 10th residue is labeled. This figure was prepared with program SETOR. (b) The relative positions of the secondary structural elements ( $\alpha$ -helices and  $\beta$ -sheets) in HRP-C. The helices are labeled with their conventional names. (From Ref. 23.)

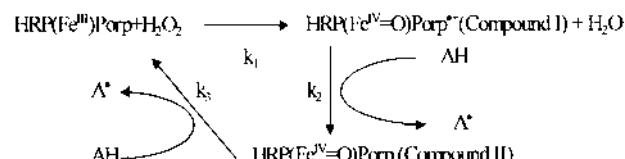

The enzyme is not specific to the hydrogen donor. A variety of phenols, aminophenols, diamines, indophenols, leucodyes, ascorbate, and several amino acids are hydrogen donors. In HRP kinetic studies and activity assays, guaiacol and 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) are the most commonly used hydrogen donors as shown in Table 3 (32, 33). The kinetic parameters of other substrates (including hydrogen acceptors) are also listed in Table 4 (34–36).

### C. Effect of Environmental Factors

#### 1. pH and Temperature Optima

pH optimum is 7.0 for the commercial HRP preparations. As seen from Table 2, each isoenzyme has a different optimal pH.

Temperature optimum is 40–52°C, depending on the type of isoenzyme and the substrates (1).

**Figure 3** The catalytic cycle of horseradish peroxidase. (From Ref. 1.)

### 2. Inhibitors

Horseradish peroxidase is inhibited reversibly by cyanide (36, 37), sulfide, and dithionite (10<sup>-4</sup>–10<sup>-6</sup> M) (36). Azide fluoride, hydroxylamine, diethyldithiocarbamate, cyclopropanone hydrate, and borohydride at ~10<sup>-3</sup> M inhibit HRP (36, 38). Vanadate and hydroxymethylhydroperoxide inhibit the enzyme irreversibly (39, 40). As HRP inhibitor, 1,10-phenanthroline is used in immunoperoxidase procedures (41).

### 3. Stability

Horseradish peroxidase is very stable. The commercial HRP, as a lyophilized powder, may be stored at 4°C for several years without apparent loss of activity. A solution of purified HRP (1 mg/mL) is stable for 1 year at 4°C.

## VI. DETERMINATION OF HRP ACTIVITY

Based on chromogenesis and chemiluminescence of products, numerous methods have been developed for determining the activity of HRP. The hydrogen donors in common use are guaiacol, pyrogallol, ABTS, 4-methoxy- $\alpha$ -naphthol, and phenol plus aminoantipyrine. Among them, guaiacol is easily available and simple to operate and is used very often, although its product is not stable. ABTS and phenol plus aminoantipyrine are widely used in microanalysis, enzyme-

**Table 3** The Steady-State Kinetic Parameters for the Peroxidation of Guaiacol and ABTS by HRP

Substrate	Enzyme (nM)	$K_m (\mu M)$	$k_{cat} (s^{-1})$	$k_{cat}/K_m (s^{-1} \mu M^{-1})$	Specific activity (units/mg)
ABTS <sup>a</sup>	0.2	$8.0 \times 10^2$	$4.1 \times 10^3$	$5.1 \pm 0.2$	$1.15 \times 10^3$
Guaiacol <sup>b</sup>	2	$5.8 \times 10^3$	$4.2 \times 10^2$	$(7.2 \pm 1.1) \times 10^{-2}$	— <sup>c</sup>

Source: Refs. 29, 30.

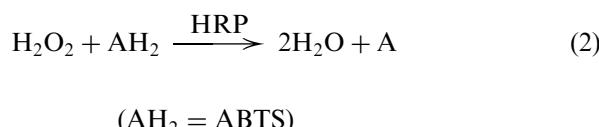

<sup>a</sup>pH 4.6, 10 mM H<sub>2</sub>O<sub>2</sub>.<sup>b</sup>pH 6.0, 1 mM H<sub>2</sub>O<sub>2</sub>.<sup>c</sup>Unverified.

linked immunosorbent assay (ELISA), and histochemical tracer techniques. Both methods are rather sensitive, and the chromogenic products are relatively stable. On the other hand, aromatic amines, such as *o*-dianisidine, *o*-phenylenediamine, and mesidine are less used now, because the oxidized products are carcinogenic.

### A. Determination of HRP Activity Using ABTS (42, 43)

#### 1. Reaction

The reaction catalyzed is shown in equation (2).

ABTS (2,2'-azinobis(3-ethylbenzthiazolin-6-sulfonate)) has an absorption maximum at 340 nm (pH 4.4) and  $\epsilon_{340} = 3.97 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ . It is oxidized by HRP to a radical cation that has an adsorption at pH 5.0 with  $\epsilon_{414} = 3.6 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ .

**Table 4** Kinetic Parameters of HRP with Different Substrates

Substrate	Rates constants (31)
(a) Hydrogen acceptors	$k_1 [\text{M}^{-1} \text{ sec}^{-1}]$
H <sub>2</sub> O <sub>2</sub>	$9 \times 10^8$
Methyl hydroperoxide	$1.5 \times 10^6$
Ethyl hydroperoxide	$3.6 \times 10^6$
(b) Hydrogen donors	$K_m (\text{mM})$ (32, 33)
KI	181.7
<i>o</i> -dianisidine	0.48
4-Aminophenazone	83.33
Pyrogallol	23.80

Source: Refs. 31–33.

#### 2. Solutions

All solutions are prepared with deionized water and kept at 4°C.

a. *ABTS*. 1.5 × 10<sup>-2</sup> M as a stock solution. Dissolve 0.077 g ABTS (diammonium salt) in 10 mL water.

b. *H<sub>2</sub>O<sub>2</sub>*. Dilute the ~ 10 M commercial solution to a stock solution of 0.01 M. Titrate the stock solution with a 0.02 M KMnO<sub>4</sub> solution. The concentration of the stock solution can be checked by its  $\epsilon_{240} = 4.36 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ .

c. *HRP*. Dissolve 1.00 g lyophilized HRP in 1 mL deionized water, and dilute to 0.01 g/mL just before use. The concentration of HRP is determined by the Soret absorbance at 403 nm using  $\epsilon_{403} = 1.02 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$ .

d. *Sodium Acetate Buffer*. 0.2 M, pH 5.0.

#### 3. Procedure

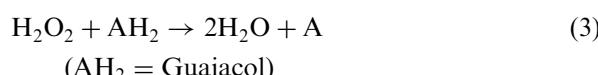

The method is according to Chailds and Bardsley (42) with some modification. Ten microliters of HRP sample with the appropriate dilution is added to a cuvette containing 50 μL of ABTS, and 0.1 M sodium acetate buffer in a final volume of 1.9 mL. After the mixture is preincubated at 20°C, 100 μL of H<sub>2</sub>O<sub>2</sub> (0.5 mM) is added to initiate the reaction and formation of the ABTS radical cation is monitored at 414 nm for the first 5 min against a blank in which the HRP sample is replaced by deionized water. One unit of enzymatic activity is defined as the amount of HRP which causes oxidation of one μmol of ABTS per min at 25°C, pH 5. Molar absorption coefficient  $\epsilon_{414} = 3.6 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ .

#### 4. Calculation

Specific activity (U/mg) =  $\Delta A_{414}/(3.6 \times 10^4 \cdot d \cdot \Delta t [E])$ , where d is light path = 1 cm, Δt is time of reaction in min, and [E] is enzyme concentration in mg/mL.

## B. Determination of HRP Activity Using Guaiacol (35, 44, 45)

### 1. Reaction

### 2. Solutions

a. *Phosphate Buffer.* 0.2 M sodium phosphate buffer, pH 7.0.

b. *Guaiacol Solution.* 18 mM (245 mg of guaiacol in 100 mL water).

c. *H<sub>2</sub>O<sub>2</sub> Solution.* 8 mM (dilute 0.1 mL of 30% H<sub>2</sub>O<sub>2</sub> solution with redistilled water to read A<sub>240</sub> = 0.400; light path = 1 cm).

### 3. Procedure

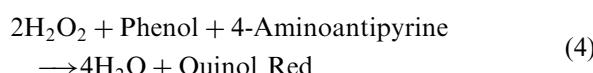

The appropriately diluted HRP sample is mixed with 0.3 mM guaiacol in 0.1 M phosphate buffer in a total volume of 3.0 mL and preincubated at 25°C. Addition of 0.03 mL 8 mM H<sub>2</sub>O<sub>2</sub> initiates the oxidation reaction; the oxidation of guaiacol is monitored at 470 nm ( $\epsilon_{470} = 2.75 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ ) for the first 5 min. One unit of HRP activity is the amount of enzyme that results in the oxidation of 1 μmol of guaiacol per min at 25°C, pH 7.0, under the above-described conditions.

### 4. Calculation

Specific activity =  $3.03 \Delta A_{470} \text{ min}^{-1} / (2.75 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1} \times d \times [E])$  where 3.03 is the total reaction volume in mL, d is the light path = 1 cm, [E] is the enzyme concentration in mg/mL, d is the light path and ΔA/min is the change of absorbance at 470 nm/min.

## C. Determination of HRP Activity Using Phenol Plus 4-Aminoantipyrine (46)

### 1. Reaction

When phenol plus 4-aminoantipyrine is used as hydrogen donor, the HRP-catalyzed reaction is monitored by measuring the increase in absorbance at 510 nm due to formation of quinol in red color with extinction coefficient  $\epsilon_{510} = 6.58 \text{ M}^{-1} \text{ cm}^{-1}$ .

## 2. Solutions

a. *Phosphate Buffer.* 0.2 M sodium phosphate buffer, pH 7.0.

b. *H<sub>2</sub>O<sub>2</sub>.* Dilute 1 mL of 30% H<sub>2</sub>O<sub>2</sub> to 100 mL with redistilled water. Further dilute 1 mL of this solution to 50 mL with 0.2 M phosphate buffer to obtain 1.7 mM H<sub>2</sub>O<sub>2</sub>. Prepare fresh daily.

c. *4-Aminoantipyrine and Phenol.* Dissolve 810 mg phenol and 25 mg 4-aminoantipyrine in 40 mL redistilled water and add more water to a final volume of 50 mL.

### 3. Procedure

Pipette 1.4 mL of phenol/4-aminoantipyrine solution and 1.5 mL of 1.7 mM H<sub>2</sub>O<sub>2</sub> into each cuvette, and preincubate at 25°C for 3–4 min. Add 0.1 mL of the diluted enzyme and measure the ΔA<sub>510</sub> for 4–5 min. One unit of the enzyme is defined as the amount which brings about 1 μmol of hydrogen peroxide to result in A<sub>510</sub> increase per min at 25°C and pH 7.0 under the specified conditions.

### 4. Calculation

Specific activity (U/mg) =  $(\Delta A_{510}/\text{min}) / (6.58 \times \text{mg enzyme/mL reaction mixture})$ .

The RZ (Reinheitzahl) number, the absorbance ratio A<sub>403</sub>/A<sub>275</sub>, is used as an evaluation of enzyme purity. As an example, partially purified HRP has an RZ of 0.8–1.0 with a specific activity of 85–200 U/mg. The chromatographically purified HRP has an RZ of 3.0 with a specific activity of 650–900 U/mg. However, the RZ values for the isozymes have been found to vary from 2.50 to 4.19 (47); RZ is also pH dependent. Therefore, both the specific activity and RZ value have been given together as the criterion of purity.

## VII. PREPARATION OF PEROXIDASE FROM HORSERADISH

Since the 1950s, a variety of isolation and purification methods have been developed. Preparation of HRP is generally composed of (a) initial extraction, (b) isolation and partial purification, and (c) refinement.

### A. Initial Extraction

Fresh roots of horseradish plant are cut, minced, extracted with water, and filtered through cheesecloth.

The extract may contain > 40 HRP isoenzymes as harvested (47, 48).

## B. Traditional Purification of HRP

In the traditional processes of HRP production pioneered by Theorell (1945) and Keilin and Hartree (1951), the common biochemical methods involved ammonium sulfate fractionation, organic solvent (acetone, ethanol, etc.) different precipitation, calcium phosphate gel adsorption, and corresponding dialysis and crystallization selected to achieve the HRP with  $RZ \sim 2.3\text{--}3.04$  (46–48).

HRP isoenzyme C was successfully separated from isoenzyme B by using a modified elution gradient from CM-cellulose column, and further purified using a preparative isoelectric focusing to achieve HRP C as a single component (49). However, this process was time-consuming and expensive with respect to ampholyte needed.

Ion-exchange column chromatography was also used in isolating five major neutral isoenzymes of HRP from a partially purified preparation ( $RZ = 0.8$ ). Three columns of SP-Sephadex C-50 combined with an improved elution system in which a step-wise increase of pH of elution buffer at a fixed low concentration was used instead of increasing the concentration of the buffer at a fixed pH (50).

In recent years, a cation-exchange column was combined with an anion-exchange column to form a simple and effective approach to purify HRP. The partially purified preparation of HRP flowed in an anion-exchange column. The acidic HRP isoenzymes and other contaminant proteins were adsorbed on the resin, whereas the neutral and basic HRP passed through. Then the effluent was applied on the second

cation-exchange column to remove all the basic isoenzymes and contaminant proteins. The effluent contained neutral HRP. After being desalted and lyophilized, a purified HRP with a specific activity  $\sim 500 \text{ U}\cdot\text{mg}^{-1}$  and  $RZ = 3.0$  was obtained (Zhong-Yu Ji, personal communication, 1995).

## C. Reverse Micellar Purification of HRP

As an alternative to the above methods, reverse micelles were recently utilized in isolation and purification of the enzyme from the root extract (51). The reverse micellar isolation involved two stages.

The horseradish root extract with a specific activity of  $1.1 \text{ U}\cdot\text{mg}^{-1}$  was diafiltrated using 10 kDA MWCO membranes against deionized water. In the first forward transfer, the anionic surfactant AOT (aerosol-OT [sodium-bis(2-ethylhexyl)sulfosuccinate]) in isoctane (110 mM) was mixed with the dialyzed extract at pH 4.15 and 0.15 M NaCl ( $V_{aq}/V_{org} = 5$ ). In this case, HRP protein solubilized in the aqueous phase, and most contaminant proteins ( $\sim 49\%$  protein) were removed into the organic phase. After centrifugation, the organic phase was separated and regenerated by backtransfer. In the second stage, the forward transfer of the HRP micelles was carried out at pH 3.5, 0.15 M NaCl by mixing with AOT in isoctane ( $V_{aq}/V_{org} = 10$ ). Finally an HRP of specific activity of  $86 \text{ guaiacol U}\cdot\text{mg}^{-1}$  was obtained with 80-fold purification and 46% yield.

Comparison between the two-stage reverse micellar extraction and traditional methods (two ammonium sulfate fractionations plus two differential ethanol precipitations with the corresponding dialysis steps) gave a good efficiency of the former (see Table 5). Other techniques, such as affinity chromatography

**Table 5** Peroxidase Purification Using the Traditional Biochemical Methods in Combination with Reverse-Micelle Extraction (Horseradish Peel only; Method C)<sup>a</sup>

Purification stage	Protein (mg) <sup>b</sup>	Activity (U) <sup>c</sup>	Specific activity (U mg <sup>-1</sup> )	Purification factor	Yield (%)
Crude extract	5500	5300	1.0	1	100
Crude preparation	100	4100	41	40	76
Two-stage reverse-micelle extraction	16	2400	150	150	45

Source: Ref. 51.

<sup>a</sup>Values are the mean of three replicates with SE within 5% of the mean.

<sup>b</sup>Total protein was measured using the BCA method (32).

<sup>c</sup>Activity measured by the guaiacol assay (30).

and hydrophobic chromatography, were also used for peroxidase purification (52, 53).

## Glutathione Peroxidase

**Jun-qiu Liu and Gui-min Luo**

*Jilin University, Changchun, China*

### I. INTRODUCTION

Glutathione peroxidase (GPX; EC 1.11.1.9) is a selenoenzyme that protects biomembranes and other cellular components against oxidative damage (1–3). Its activity was discovered by Mills in 1957 (1). In 1973, the stoichiometric amount of selenium was found in this peroxidase in the effort of searching for the prosthetic group of GPX and the essentiality of selenium as the trace element (4, 4a). The enzyme catalyzes the reduction of a variety of hydroperoxides including hydrogen peroxide, organic hydroperoxides, and lipid hydroperoxides using glutathione (GSH) as the reducing equivalent [Eq. (1)]:

where ROOH is the hydroperoxide such as  $\text{H}_2\text{O}_2$ , *tert*-butyl hydroperoxide, cumene hydroperoxides, etc. (**Table 1**), GSSG is the oxidized form of glutathione which is reverted to GSH by glutathione reductase, and ROH is the corresponding alcohol or  $\text{H}_2\text{O}$  in the case of  $\text{H}_2\text{O}_2$  acting as substrate.

Four types of GPX have been discovered: (a) the classical cellular glutathione peroxidase, cGPX (1); (b) the phospholipid hydroperoxide glutathione peroxidase, PHGPX (5); (c) the plasma glutathione peroxidase, pGPX (6–8); and (d) the gastrointestinal glutathione peroxidase, giGPX (9). Another type of enzyme that contains GPX activity but does not depend on selenium for catalysis has been previously classified as selenium-independent GPX (10). It catalyzes glutathione-dependent nucleophilic substitution

and addition reactions with endogenous and xenobiotic electrophiles as well as the reduction of organic hydroperoxides, but not hydrogen peroxide. The enzyme has subsequently been demonstrated to be glutathione S-transferase (11). Among the GPX isozymes, cGPX, pGPX, and giGPX are tetramers and have similar substrate specificity. They catalyze the reduction of  $\text{H}_2\text{O}_2$ , *tert*-butyl hydroperoxide, cumene hydroperoxide, and linoleic acid hydroperoxide with glutathione, but reduce cholesterol hydroperoxide and phospholipid hydroperoxide poorly (9–13). The giGPX displays most of the enzymatic properties of the classical cellular GPX, but shows little activity toward lipid hydroperoxides (9). Plasma glutathione peroxidase is an extracellular enzyme, which is different from other GPX enzymes in structural and enzymatic properties (7, 8). PHGPX is a membrane-bound enzyme, a monomer, and has different substrate specificity compared to cGPX, pGPX, and giGPX. It catalyzes the reduction of phospholipid hydroperoxide, linoleic acid hydroperoxide, and cholesterol hydroperoxide in biological membranes, and also shows activity on  $\text{H}_2\text{O}_2$  and organic hydroperoxides (5, 14).

### II. BIOLOGICAL DISTRIBUTION OF GPX

Glutathione peroxidase has been found in most animals but not in plants (15–17). A low level of the enzyme has been demonstrated in some insects (18), and GPX activity has been detected in yeast, *Hansenula mraki* (19). The enzyme is found chiefly in

**Table 1** Substrates and Their Structures of Glutathione Peroxidase

Substrate	Chemical structure	Examples
Glutathione Hydroperoxides	$\gamma\text{-Glu-Cys-Gly}$ $\text{R-O-O-H}$	$\text{H}_2\text{O}_2$ <b>Organic hydroperoxidase:</b> ethyl, cumene, tert-butyl, 5-phenyl-4-pentenyl, linoleic, linoleic acid hydroperoxides, and their methyl esters: 13-hydroperoxy-9, 11-octadienoic acid, cholesterol $7\beta$ -hydroperoxide; allopregnanolone $17\alpha$ -hydroperoxide; thymine hydroperoxide. <b>Lipid hydroperoxide:</b> phosphatidylethanolamine, phosphatidyl-choline, phosphatidylserine, cardiolipin and phosphatidic acid hydroperoxides: mono- and dihydroperoxydilinoleoylphosphatidyl cholines

respiratory tissues (blood vessels, lung, heart), digestive tissues (liver, kidneys), and brain tissues where oxygen is required. In rats, a high level of the enzyme is found in the liver with lower concentrations detected in red cells, heart, lung, and kidney. In hepatocytes 70% of the GPX activity is from the cytosol and 30% is localized within the mitochondrial matrix (20).

Classical GPX is present abundantly in erythrocytes, kidney, and liver (16). The lens of different animal species contain remarkably high GPX activity (21, 22). PHGPX has been identified in all tissues in which it was searched for, namely, rat kidney, heart, lung, muscle, and brain; bull spermatozoa; and fish liver (23). A high level of GPX activity has been observed in rat testis (24). pGPX is detected in plasma, milk, and lung (6, 7). giGPX has been found in the cytosol of human and rat gastrointestinal tracts (9). It was detected in human liver and colon, but not other human tissues including kidney, heart, lung, placenta, and uterus. In rodent tissues, giGPX is only detected in the gastrointestinal tract, not in other tissues. In rat, the highest activity of the enzyme is detected in stomach followed by decreasing activities in esophagus, colon, and intestine.

The study by Godin and Ganett (25) showed that the distribution of GPX in mammalian tissues is strictly functionally related to other antioxidant enzymes such as superoxide dismutase (SOD; EC 1.15.1.1) and catalase (EC 1.11.1.6). It should be kept in mind that the level of GPX is subject to numerous influences, including dietary selenium, age and sex, and estrous cycle, and other environmental factors (26–28). It has been documented that GPX activity is subject to large species differences in all organs (20).

### III. UTILITY OF GPX

The biological damage such as peroxidation of lipids and nucleic acid damage can be caused by reactive oxygen species. Antioxidant defenses consist of a number of antioxidant enzymes protecting cells and membranes against the reactive oxygen. The first line of defense seems to be governed by superoxide dismutase which acts by converting the superoxide ion  $\text{O}_2^-$  into hydrogen peroxide. Secondly, catalase, and GPX share the task of metabolizing  $\text{H}_2\text{O}_2$  to water. In the last line of defense, the GPX is the sole enzymatic system capable of preventing lipid peroxidation. The enzyme can reduce a wide variety of hydroperoxides, and acts as an important part of the antioxidant defense of biology body.

Many studies have shown that low selenium in the diet can result in low levels of GPX activity leading to oxidative damage and several medical disorders such as Keshan disease, Kashin-Beck disease, cancer, heart disease, premature aging, and diabetes. The importance of this enzyme as an oxidant defense enzyme has led to its proposed strong possibilities to be used in treatment for these diseases (29–32).

### IV. PROPERTIES AS PROTEIN

#### A. Molecular Weight and Physical Properties

cGPX, pGPX, and giGPX are tetrameric proteins of four identical subunits, with each subunit containing one atom of selenium in the form of selenocysteine residue. The average molecular weight is 19–25 kDa (33, 34, 42). PHGPX is a monomeric protein of 23

kDa containing a single selenocysteine residue (5, 13, 35). The properties of GPXs from different sources are listed in Table 2.

## B. Protein Structure

Multiple forms of GPX exist in different animal tissues. In the cGPX family, the bovine erythrocyte cGPX was well investigated. It consists of four identical subunits each of 198 amino acids. The catalytic active selenocysteine is localized at residue 45 with four other cysteine residues present at positions 74, 91, 111, and 152 (36). The primary structures of several GPXs have been determined from their cDNA sequences (Fig. 1) (9, 37–42).

Within each GPX class high-sequence homology is found. The similarity between any two cGPXs ranges from ~80% to 90% (43). The mouse pGPX protein sequence is 98% identical to rat, 89% identical to human, and 88% identical to bovine pGPX protein sequences (44); the homology between different classes is much lower. The sequence homology of human pGPX is 44% identical with the human cGPX, 34% with the human giGPX, and 25% with the human PHGPX (9, 41). The homology of mouse pGPX is <52% identical to mouse cellular cGPX (44). However, the homology is much higher in the active-site domain with the selenocysteine residue and in some regions containing residues 61–74, 93–108, 119–138, and 181–192 (41, 44).

In the GPX family, only two crystal structures have been determined—the bovine erythrocyte GPX (45) and the human plasma GPX (34). Bovine cGPX exists as a tetramer with each asymmetric unit consisting of two identical subunits. The secondary structure within each subunit contains four  $\beta$ -sheets, four  $\alpha$ -helices, 12 clearly defined  $\beta$ -turns, and three one-turn  $3_{10}$  helices. Two  $\beta$ -turns,  $\beta_1$  and  $\beta_2$ , are parallel, and close to the

N-terminus. The other two,  $\beta_3$  and  $\beta_4$ , are antiparallel. The  $\alpha$ -helices,  $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_4$ , are located on the side of the central  $\beta$ -sheets and another one,  $\alpha_3$ , is on the other side. The  $\alpha_1$  and  $\alpha_4$  are nearly parallel and their axes seem to parallel with  $\beta$ -sheets. The active selenocysteine residue 45 is located at the N-terminal end of helix  $\alpha_1$  which forms a  $\beta\alpha\beta$  substructure. The  $\beta\alpha\beta$  structure may be important for catalysis and substrate binding. The structure of the other GPX, human pGPX, was proved to be similar to that of cGPX, although they belong to different species and have 42% sequence identity. No significant deviation of secondary structure was found between the two enzymes (34). The main differences in two enzyme subunits are an extended N-terminus and possible existence of a disulfide bridge in the pGPX.

cGPX exists as a rather flat, tetrahedral quaternary structure with point symmetry 222. Each asymmetric unit consists of two identical subunits in the dimer. The contact regions are extensive along two of the perpendicular twofold symmetry axes, a local axis relating the monomer of an asymmetric unit, and a crystallographic axis producing the tetrameric structure from the dimer. The interactions at each interface contain hydrogen bonds formed across the local axis by residues Glu77, Arg86, Arg286, and Glu227; hydrophobic actions; and the main-chain hydrogen bonds (45). The active-site selenocysteine residues are located on two opposite surfaces of the tetramer. The active center of GPXs is found in a flat depression on the tetramer surface surrounded by aromatic amino acid residues, with selenocysteine located at the N-terminal ends of  $\alpha$ -helices forming  $\beta\alpha\beta$  structures together with adjacent parallel  $\beta$ -sheets. Three residues, Arg40, Glu130, and Arg167 are involved in binding of substrate glutathione (GSH). Arg167 and Arg40 form salt bridges with the carboxyl groups of GSH, and Glu130 can form a hydrogen bond with

GSH. A proposed model of glutathione binding was given by Epp et al. (45).

Compared with cGPX, the three residues for binding GSH are mutated or deleted in pGPX. The surface of pGPX is more negatively charged, especially close to the active site. These differences may affect substrate binding and lead to different enzyme activities (34, 41).

Although there are no data on the crystal structure of PHGPX, a model has been developed by molecular dynamics calculation (43). According to this model, the shape of the core of these enzyme families comprising the pleated sheets and three of the helices is largely identical to that of cGPX. However, the deletion of several amino acids in the PHGPX sequence causes a substantial short-cut of the subunit interaction loop and an elimination of a small helix. In the PHGPX model, the active site appears more freely accessible. This allows the enzyme to attack more complex hydroperoxy lipids.

### C. Isoforms

The existence of multiple forms of GPX is due to the expression of different genes (41, 46). Many mammalian cGPX genes display highly conserved sequences around the site of selenium (47). The gene for human pGPX has been found at chromosome 5q32, and contains five exons rather than two for cGPX. Rat and bovine pGPX genes have been identified similar to human pGPX (48). The gene for PHGPX has seven

exons; exons 3 and 5 show homology with exons of cGPX, indicating that this gene, although related to cGPX, is distinct from it (40, 46). Multiple isoforms of PHGPX have been detected in human, rat, pig, and bovine tissues (5, 23, 24, 49–51). Another intercellular GPX is giGPX. The gene expression was found in human liver and colon and also detected in mouse and rat gastrointestinal tract (9). giGPX has been regarded as the most closely related offspring of the cGPX family (43).

An artificial GPX mimic, selenosubtilisin, was created by converting the active serine residue of the catalytic site of subtilisin into selenocysteine. It displays GPX activity but not as efficient as cGPX (52, 53). Another artificial selenium-containing enzyme has been generated by monoclonal technique and chemical modification (54). The abzyme displays a higher GPX activity compared with rabbit liver cGPX.

All the cDNA sequences of these GPX contain a UGA codon coding for selenocysteine (9, 41, 38). The UGA codon, usually functioning as a “stop” codon, was demonstrated to encode the amino acid residue selenocysteine, which could be incorporated directly during protein synthesis (46, 38).

## V. ENZYMETIC PROPERTIES

### A. Kinetics of GPX

The steady-state kinetics of bovine erythrocyte GPX was studied by Flohé et al. (56). The enzyme system

follows *tert uni* Ping-Pong mechanism with indefinite Michaelis constants and indefinite maximum velocities (56, 57). The double-reciprocal plots of GPX reaction with hydroperoxides in various concentrations of both GPX and hydroperoxide lead to parallel lines. The rate equation was described in Eq. (2).

$$[E_0]/v = \Phi_1/[ROOH] + \Phi_2/[GSH] \quad (2)$$

In this mechanism,  $[E_0]$ ,  $[ROOH]$ , and  $[GSH]$  are the concentrations of GPX, ROOH, and GSH, respectively,  $v$  is initial rate of the enzyme reaction, and  $\Phi_1$  and  $\Phi_2$  are Dalziel coefficients, examples of which are presented in Table 3. In double-reciprocal plot of  $[E_0]/v$  vs  $1/[ROOH]$ , the slope is identical to  $\Phi_1$  and the intercepts equal  $\Phi_2/[GSH]$ . The Michaelis constant for one substrate depends on the other and is expressed as follows:

$$K_{m,ROOH} = (\Phi_1/\Phi_2)[GSH] \quad (3)$$

$$K_{m,GSH} = (\Phi_2/\Phi_1)[ROOH] \quad (4)$$

cGPX from bovine and ovine erythrocytes and hamster liver show no saturation for GSH, and true Michaelis constants for GSH cannot be measured (56, 58). However, the apparent Michaelis constant for ROOH and GSH can be calculated according to Eqs. (3) and (4).

The reaction kinetics of cGPX and PHGPX is in agreement with a *tert uni* Ping-Pong mechanism (5). The  $K_m$  values and other kinetic parameters for cGPX and PHGPX are listed in Tables 4 and 5.

The reaction mechanism of pGPX also displays Ping-Pong and is similar to those for cGPX and PHGPX. However, the pGPX shows saturation kinetics on both substrates (8, 60). The true  $K_m$  values can be obtained from kinetic plots. Some kinetic constants for human cGPX and pGPX are listed in Table 4 and Table 5. The value of  $k_{cat}/K_m$  are very close to the diffusion controlled limit for a bimolecular reac-

tion, suggesting that pGPX is a very effective hydroperoxide scavenger at low concentration of plasma GSH.

## B. Specific Mechanism of Action

In the catalytic cycle of the enzyme reaction with a *tert uni* Ping-Pong mechanism, the selenol form (E-SeH) of the enzyme is first oxidized by hydroperoxide to a selenenic acid (E-SeOH) which is reduced back by two GSH through an intermediate selenenyl sulfide form (E-SeSG) (5, 56).

A proposed catalytic cycle containing selenenic acid, selenenyl sulfide, and selenol has been suggested (Fig. 2), which is consistent with Ping-Pong kinetics (45, 56, 60). The seleninic acid (E-SeOOH) is not involved in the main catalytic cycle but may become important at high concentrations of hydroperoxide.

## C. Substrate Specificity

The enzyme has a broad substrate specificity. The relative substrate specificity of different GPXs are presented in Table 6. All GPXs have specificity toward hydroperoxides (ROOH) but not on peroxides (ROOR). GSH is the only physiological donor substrate although GPX exhibits activities for some sulphydryl compounds such as mercaptoethanol (5, 62). cGPX, PHGPX, pGPX and giGPX display substrate specificity for  $H_2O_2$  and organic hydroperoxides. Although it shows lower hydroperoxide

**Table 3** Dalziel Coefficients for cGPX and PHGPX

Substrate	cGPX		PHGPX	
	$\phi_1(10^{-8} \text{ msec})$	$\phi_2(10^{-6} \text{ msec})$	$\phi_1(10^{-6} \text{ msec})$	$\phi_2(10^{-4} \text{ msec})$

	H <sub>2</sub> O <sub>2</sub>	120		—	—
	5-phenyl-4-pentenyl hydroperoxide				
Human cGPX		12		—	—
		10		—	—

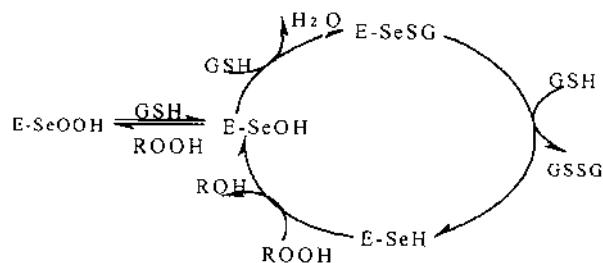

Source: Refs. 60, 61.

activities for phospholipid hydroperoxides than organic hydroperoxides, pGPX possesses the ability to reduce phospholipid hydroperoxides, whereas giGPX and cGPX have no activities for lipid hydroperoxides (Table 6).

Phospholipid hydroperoxides are the primary substrates for PHGPX, which is also active on H<sub>2</sub>O<sub>2</sub> and organic hydroperoxides such as *tert*-butyl hydroperoxide, cumene hydroperoxide and linoleic acid hydroperoxide (5). pGPX is about one-tenth less reactive against organic and hydrogen peroxides than cGPX (63, 64). giGPX displays lower activity than pGPX against organic and hydrogen peroxides.

The second-order constants for the reduction of the hydroperoxides show that H<sub>2</sub>O<sub>2</sub> is a poorer substrate for PHGPX than for cGPX, while linoleic acid hydroperoxide is reduced faster by PHGPX. PHGPX is highly active on lipid hydroperoxides (Table 7).

In cGPX, the hydrophobic effect of a bulky substrate seems important, the more hydrophobic, the faster a bulky substrate is reduced by cGPX. For

**Figure 2** The proposed catalytic mechanism of GPX for reduction of ROOH by GSH.

small and unhindered substrate such as H<sub>2</sub>O<sub>2</sub> and ethyl hydroperoxide, this effect can be negligible (63).

#### D. Effect of Environmental Factors

##### 1. pH Effects

GPX is relatively stable in the range of pH 7–10 (20). Enzymes from different sources have similar pH optimum > 8 (Table 8). The enzyme alone can form oxidized state (seleninic acid) in the air, but can be reactivated by incubation with GSH (45, 65).

cGPX is very stable at pH 7.0 at 4°C. The enzyme lost only 15–20% activity when stored at 4°C at pH 7.0 for 4 months. However, it is very unstable at low pH; At pH 4.0, the enzyme lost all its activity in 20 min (65). The GPX from rat lung was found to have very little activity at physiological pH 7.0, < 20% of the activity at the pH optimum of 8.8 (67).

**Table 5**  $K_m$  Values for Human pGPX and Human cGPX

**Table 6** Activity of GPX Toward Different Hydroperoxides

Substrate	Specific activity (U/mg enzyme)			
	cGPX <sup>a</sup>	pGPX <sup>b</sup>	PHGPX <sup>c</sup>	giGPX <sup>d</sup>
H <sub>2</sub> O <sub>2</sub>	216	31.3	135	2.1
tert-Butyl hydroperoxide	224	26.6	13.5	0.6
Cumene hydroperoxide	199	25.0	8.7	0.9
Linoleic acid hydroperoxide	—	—	187	1.2
Phosphatidyl choline hydroperoxide	0	8.41	226	0.004

The specific activities are defined as  $\mu\text{mol NADPH oxidized}/\text{min}/\text{mg protein}$ .

Data shown for GPXs: <sup>a</sup>human erythrocyte cGPX (63); <sup>b</sup>human plasma pGPX (63); <sup>c</sup>pig heart PHGPX(5); <sup>d</sup>human carcinoma MCF-7 cells giGPX (9).

## 2. Inhibitors

Divalent cations, sulfhydryl reagents, and iodoacetate inhibit the enzyme activity. The enzymes from human erythrocyte and human plasma exhibit similar inhibitory spectrum by divalent cations (8, 66). Cu<sup>2+</sup> and Hg<sup>2+</sup> completely inhibit the two enzyme activities. Zn<sup>2+</sup> completely inhibits human pGPX but partly inhibits human cGPX. Ni<sup>2+</sup>, Co<sup>2+</sup>, Ca<sup>2+</sup>, and Mg<sup>2+</sup> also inhibit the two enzymes. Most enzymes from various sources are inhibited by iodoacetate in the presence of GSH or a sulfhydryl reagent such as mercaptoethanol or dithioerthritol (5, 8, 66). The active selenocysteine residue of the reduced enzyme can be alkylated by iodoacetate, but the other alkylating reagent, iodoacetamide, has no inhibitory effect. Human erythrocyte GPX was reported to be inactivated by *N*-ethylmaleimide (66, 68). In an inhibition study for hamster liver GPX, a number of mercaptocarboxylic acids and tertiary mercaptans have been found to be strong and specific inhibitors (69).

**Table 7** Second-Order Rate Constants ( $k_1$ ) for the Reaction Between cGPX and PHGPX with Hydroperoxidic Substrates (pH 7.6)

Substrate	cGPX $k_1 \cdot 10^5$	PHGPX ( $\text{mM}^{-1}\text{min}^{-1}$ )
H <sub>2</sub> O <sub>2</sub>	2.98	1.8
tert-Butyl hydroperoxide	7.1	0.71
Cumene hydroperoxide	10.4	1.1
Linoleic acid hydroperoxide	23.6	1.8
Phosphatidyl choline hydroperoxide	0	8.6

## VI. DETERMINATION OF ACTIVITY

### A. Methods for Determining the GPX Activity

Three methods are used for determining the GPX activity. The most commonly used assay is the GSH reductase-NADPH coupled assay (33, 70, 71). The method takes advantage of the capability of glutathione reductase to regenerate GSH from GSSG. The loss of NADPH is monitored continuously by absorbance spectrophotometry. The other two methods involve measurement of the GSH removal by the formation of thionitrobenzoate from Ellman's reagent, 5,5'-dithiobis-2-nitrobenzoic acid (DTNB) (72) and by polarographic GSH analysis (20).

#### 1. Method 1: Coupled Enzymatic Assay

*a. Reagents.* 100 mM potassium phosphate buffer, pH 7.0, containing 1 mM sodium azide and 1 mM EDTA; 2.4 U/mL glutathione reductase (from yeast), prepared daily; 10 mM GSH (AR) in distilled water; 2.5 mM NADPH in 0.1% NaHCO<sub>3</sub>, prepared daily; 12 mM hydroperoxide (AR) in water.

**Table 8** Optimum pH of GPXs

Enzyme	Optimum pH	Ref.
Bovine erythrocyte cGPX	8.8	56
Human erythrocyte cGPX	8.5	66
Hamster liver cGPX	8.0	58
Rat lung cGPX	8.8	57
Human pGPX	8.9	64

*b. Procedure.* 500  $\mu$ L of 100 mM phosphate buffer (pH 7.0), 100  $\mu$ L of enzyme sample, 100  $\mu$ L of glutathione reductase (0.24 U), 100  $\mu$ L of 10 mM GSH, and 100  $\mu$ L of 2.5 mM NADPH are added into a 1-mL cuvette. The reaction mixture is preincubated for 10 min at 37°C. The reaction is started by adding 100  $\mu$ L of hydroperoxide solution. The linear decrease of NADPH absorption is monitored at 340 (or 366) nm for about 5 min. The control is assessed by replacing the enzyme with phosphate buffer.

## 2. Method 2: Assay of GSH Removal by DTNB

*a. Reagents.* 50 mM potassium phosphate buffer, pH 7.0; 10 mM GSH (AR) in distilled water; 1.5 mM DTNB in potassium phosphate buffer, pH 7.0; 12 mM hydroperoxide (AR) in water.

*b. Procedure.* 700  $\mu$ L of potassium phosphate buffer, 100  $\mu$ L of 10 mM GSH, 100  $\mu$ L of enzyme solution are added into a 1-mL cuvette and preincubated for 10 min at 37°C. The reaction is started by adding 100  $\mu$ L of hydroperoxide solution. Over 10 min 50  $\mu$ L of the reaction mixture is taken at 1-min intervals. The solution is transferred into a cuvette containing 1.5 mM DTNB. The amount of GSH remaining in the reaction is determined by measuring the absorbance at 412 nm with an extinction of coefficient 13.0  $\text{mM}^{-1} \text{cm}^{-1}$ .

## 3. Method 3: Assay of GSH Removal by Polarography

*a. Reagents.* 100 mM potassium phosphate buffer, pH 7.0, containing 1 mM sodium azide and 2 mM EDTA; 4 mM GSH (AR) in distilled water; 5 mM H<sub>2</sub>O<sub>2</sub> in distilled water prepared from a commercial solution (30%); 0.7 M HClO<sub>4</sub>.

*b. Procedure.* 1 mL of 100 mM phosphate buffer is incubated with 0.5 mL GSH solution for 10 min at 37°C. The reaction is started by addition of 0.5 mL of 5 mM H<sub>2</sub>O<sub>2</sub> and stopped after various times by addition of 2 mL of 0.7 M HClO<sub>4</sub>. The acidified assay mixture is cooled to room temperature and bubbled with nitrogen for 3 min. Polarogram is recorded between 0 and -0.5 V with 5  $\mu$ A full scale, versus a mercuric sulfate reference electrode. The calibration curve is prepared by adding HClO<sub>4</sub> to a series of different GSH concentrations. The control is measured without enzyme addition.

## 4. Definition of Units

In the above three methods, 1 unit of the enzyme activity is defined as the amount of enzyme oxidizing 1  $\mu$ mol of NADPH per min at 37°C. The specific activity expresses units/mg of protein or units/ $\mu$ mol of protein. Some GPX specific activities with different peroxide substrates are listed in Table 6.

## B. Factors Affecting Activity Determination

The coupled enzyme method is suitable for activity determination of both purified and crude enzymes. In working with crude biological materials (e.g., liver and kidney), it is necessary to use H<sub>2</sub>O<sub>2</sub> as the substrate in order to differentiate GPX from glutathione S-transferase which has similar activity on organic hydroperoxides but is unreactive toward H<sub>2</sub>O<sub>2</sub>. In this case, sodium azide should also be added to inhibit catalase. For blood red cells, the conversion of hemoglobin into cyanomethemoglobin prior to assay is necessary because of the interference of methemoglobin (20). PHGPX activity is measured by this method with the phospholipid hydroperoxide substrate dispersed in mixed micellar form using Triton X-100 (5).

The method for assay of GSH removal is suitable for determining only purified enzymes. Inorganic halides interfere with polarographic determination. Other sulphydryl compounds such as mercaptoethanol and cysteine will interfere with both polarography and DTNB methods.

In all assay systems, the assay mixture should be preincubated with GSH. The inactive state of the enzyme (E-SeOOH) can be activated by GSH to the active E-Se-SG form. High concentrations of polyvalent cations (e.g., Hg<sup>2+</sup>, Cu<sup>2+</sup>, and Zn<sup>2+</sup>) can inhibit GPX activity.

## VII. PURIFICATION

Several GPXs have been purified from various sources (1, 5–14, 21, 63, 66, 67). A currently used procedure for cGPX isolation has been described by Wendel (20). This strategy includes dialysis of the hemolysate, organic solvent precipitation, ion-exchange chromatography on DEAE-Sephadex, hydrophobic chromatography on phenyl-Sepharose, gel filtration on Biogel P-100, or hydroxyapatite chromatography.

Step 1. Hemolysate. Eight liters of bovine blood is centrifuged. The erythrocytes are washed twice with 0.9% NaCl and are hemolyzed by adding water to

form 8 L of hemolysate. Six liters of 0.6 M potassium phosphate at pH 6.6 is added and the mixture is stored in the cold for 2–12 h.

Step 2. Organic solvent precipitation. A mixture of chloroform/ethanol (3:5, v/v), 4 L, cooled to –20°C, are added dropwise to the vigorously stirred hemolysate. The dark-brown precipitate is removed by centrifugation at 2000 g for 30 min at 0°C. The yellowish supernatant liquid is filtered and immediately concentrated to ~1 L with a membrane with exclusion limits of 50 kDa.

Step 3. Phosphate precipitation. One liter of concentrated enzyme solution is mixed with 2 L of 3.65 M potassium phosphate at pH 7.0. The floating precipitate is collected by filtration and dissolved in 0.7 M potassium phosphate at pH 8.0.

Step 4. Phenyl-Sepharose. The enzyme is adsorbed in a batch step to phenyl-Sepharose equilibrated with 0.7 M potassium phosphate at pH 8.0. The adsorbed gel is added to a column (2×30 cm) previously prepared with 5 mL of fresh equilibrated gel. The column is washed with 300 mL of 0.7 M phosphate buffer and then with 300 mL of 0.5 M phosphate buffer with the same pH. A linear, 300-mL gradient, from 100 to 10 mM potassium phosphate, pH 8.0, is used to elute the enzyme at a flow rate of 6 mL/h.

Step 5. DEAE-Sephadex. The pooled fraction is diluted to a final buffer concentration of 5 mM phosphate, pH 8.0, and applied to a column of DEAE-Sephadex equilibrated by the same buffer. After washing with 1 L of starting buffer, the enzyme is eluted with a linear gradient of 5–80 mM potassium phosphate containing 1 mM GSH at pH 8.0.

Step 6. S-300 Sephadryl. The active fractions are concentrated by a Diaflo cell to 15 mL and charged onto a S-300 Sephadryl column (2.0×180 cm), equilibrated with 20 mM potassium phosphate, pH 8.0, containing 0.5 M NaCl, with a rate of 12 mL/h. The enzyme is eluted as a single protein that has an apparent molecular weight of ~100 kDa.

Step 7. The enzyme is dialyzed against 5 mM potassium phosphate at pH 7.4, adsorbed onto a hydroxyapatite column (1×100 cm), equilibrated with the same buffer, and eluted with a gradient up to 80 mM phosphate.

Purification of PHGPX from pig heart has been described by Ursinbi et al. (49). This procedure can also be used for other tissues.

Step 1. A total of 500 g of ventricular muscle is prepared from pig heart and is minced and thoroughly homogenized in a Polytron mixer, set at

maximum power, for 5 min in 3 volumes of ice-cold 0.1 M Tris-HCl (pH 7.4), 5 mM mercaptoethanol. The soluble fraction is prepared by two centrifugations of the homogenate: 30 min at 10,000 g and 45 min at 100,000 g. Before the second centrifugation, the supernatant is filtered through cheesecloth to eliminate fluffy material. The supernatant is dialyzed exhaustively against 10 mM potassium phosphate buffer (pH 7), 5 mM mercaptoethanol. During dialysis some proteins precipitate and are eliminated by centrifugation.

Step 2. The supernatant is applied to a DEAE-Sepharose 6B column (13×5.5 cm) equilibrated with 10 mM potassium phosphate buffer (pH 7), 5 mM mercaptoethanol. The column is washed with 2 L of the equilibration buffer and then eluted with 0.5 L of 0.2 M potassium phosphate buffer (pH 7), 5 mM mercaptoethanol. The active fractions are collected and pooled, and 10% (v/v) (final concentration) glycerol is added.

Step 3. The above fraction is loaded onto a Sepharose-bromosulfophthalein glutathione (BSP) affinity column. The column is equilibrated with 25 mM Tris-HCl (pH 7.2), 5 mM mercaptoethanol, and 10% (v/v) glycerol. After the sample is loaded, the column is washed with 300 mL of 25 mM Tris-HCl (pH 7.2), 100 mM KSCN, 5 mM mercaptoethanol, and 10% (v/v) glycerol. The elution is carried out with 25 mM Tris-HCl (pH 7.6), 300 mM KSCN, 5 mM mercaptoethanol, and 10% (v/v) glycerol. The active fractions are pooled and concentrated to 5–10 mL using an Amicon ultrafiltration apparatus with a YM10 membrane.

Step 4. The above fractions are applied onto a Sephadex G-50 column (140×5.5 cm) equilibrated with 25 mM Tris-HCl (pH 7.4), 5 mM mercaptoethanol, and 10% (v/v) glycerol. The active fractions are pooled and concentrated with the same ultrafiltration apparatus as before. This fraction is dialyzed against potassium phosphate buffer (pH 6.5), 0.1 M KCl, and 5 mM mercaptoethanol.

Step 5. The final purification step is carried out by HPLC using a weak cation-exchange column, TSK CM. The chromatographic conditions are as follows: Buffer A: 10 mM potassium phosphate buffer, 100 mM KCl, 5 mM mercaptoethanol (pH 6.5); buffer B: 10 mM potassium phosphate buffer, 300 mM KCl, 5 mM mercaptoethanol (pH 6.5). The gradient from 0–100% buffer B is developed in 25 min after 3 min in isocratic conditions. Injection volume is < 0.2 mL. Peaks isolated from several runs are pooled, and 10% glycerol is added.

## Glucose Oxidase

**A. J. Vroemen**

*DSM Food Specialties, Delft, The Netherlands*

### I. INTRODUCTION

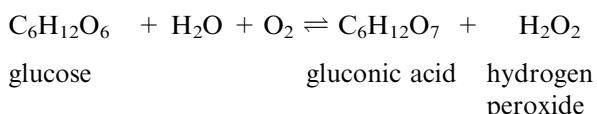

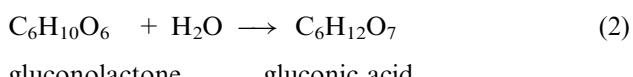

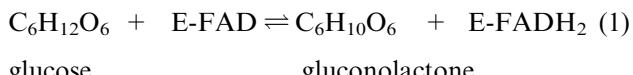

Glucose oxidase (GOX) is produced predominantly by fungi as part of an enzyme complex also containing catalase. The best-studied microorganisms are species of *Aspergillus* (1–3) and *Penicillium* (4, 5). In *Aspergillus* the enzymatic complex is located in cell compartments called peroxisomes (6), which results in the need to open the fungal cell walls before the enzyme can be released and purified. The enzyme complex of *Penicillium* is secreted into the extracellular environment (7). Almost all GOX preparations available on the market are produced by *Aspergillus niger*. These preparations are either highly or somewhat or completely exempt of catalase (see Sec. II.A.1). This chapter will focus mainly on GOX of *Aspergillus niger*.

The question can be raised why fungi like *Aspergillus niger* invest a high amount of nutrients and energy in the synthesis of the enzymatic complex. As we will see later, the catalyzed reaction of glucose to gluconic acid does not yield energy for the microorganism. Most probably the enzymatic complex gives the microorganism an ecological advantage in the soil. In nature, GOX is produced by the fungus only when glucose is present: It is an inducible enzyme. When glucose is liberated from, for instance, starch or cellulose, the synthesis of the enzymatic complex starts and in the presence of air, glucose is oxidized to gluconic

acid with simultaneous production of hydrogen peroxide. The decrease of the pH caused by the gluconic acid as well as the antibacterial effect of the hydrogen peroxide produced, are favorable for the fungus. In addition, *A. niger* is able to consume the gluconic acid produced, which is not the case for most of the competing microorganisms. Bacteria like *Gluconobacter* are also capable of converting glucose into gluconic acid, but these bacteria use a different mechanism. *Gluconobacter oxidans* contains two types of glucose dehydrogenases, one PQQ and one NADP dependent, which convert glucose to gluconic acid without formation of hydrogen peroxide. The PQQ-dependent enzyme seems to be the most important (8). This oxidation process yields energy for the bacteria concerned. It is notable that these bacteria are rather acid tolerant.

### II. REACTION CATALYZED

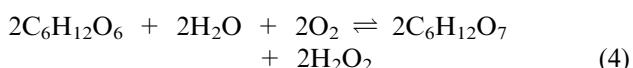

As substrates GOX uses  $\beta$ (D)-glucose and oxygen. Two hydrogen atoms are first transferred from glucose to the coenzyme FAD during formation of  $\delta$ -gluconolactone (9). Subsequently the enzyme transfers the two hydrogen atoms directly to molecular oxygen during formation of hydrogen peroxide. The  $\delta$ -gluconolactone is hydrolyzed to gluconic acid spontaneously or by the enzyme gluconolactonase.

The fact that GOX uses only  $\beta$ -glucose as substrate does not mean that glucose can be only partially oxidized; during the process  $\alpha$ -glucose spontaneously mutarotates to  $\alpha$ , $\beta$ -glucose, making all the glucose available as substrate. GOX is rather specific for glucose. There is < 1% activity on related sugars like xylose and galactose. Also, the activity on other natural mono- and disaccharides is very low. In a systematic study Whitaker showed that in the deoxyglucoses, replacement of the hydroxyl group by a hydrogen atom at successively the 6, 4, 2, 3 and 5 position resulted in respectively 10%, 4%, 3%, 1% and 0% remaining activity (10).

The hydrogen peroxide formed causes the reaction to stop since it inactivates the GOX rapidly and irreversibly. In principle, hydrogen peroxide can be hydrolyzed by the enzyme catalase, or the active oxygen can be transferred spontaneously or enzymatically to another molecule.

As mentioned before, the fungi concerned also produce catalase, which oxidizes/reduces the hydrogen peroxide produced into water and oxygen. The overall reaction of the enzyme complex becomes:

### Overall reaction:

### III. ENZYME CHARACTERISTICS

### A. Michaelis-Menten Constants

The enzyme has two substrates: glucose and molecular oxygen. Simple Michaelis-Menten kinetics results in

$$v = k_{\text{cat}} \cdot [E] \cdot \frac{c_{\text{glu}}}{K_{m_{\text{glu}}} + c_{\text{glu}}} \cdot \frac{c_{O_2}}{K_{m_{O_2}} + c_{O_2}}$$

The  $K_m$  values as determined by Gibson et al. (11)

$$K_{m_{\text{ch}}}=110 \text{ } \mu M; \quad K_{m_{\text{O}_2}}=0.48 \text{ } \mu M$$

(both determined at 27°C.)

Here the molarity of glucose is defined as total glucose, not as  $\beta$ -glucose.

The value of 110 mM mentioned by Gibson seems rather high. Other values mentioned in the literature are 37 mM (12), which is more in agreement with GOX from other microorganisms. The *Penicillium amagasakiense* enzyme has a higher affinity for glucose: a  $K_m$  value of 5.2 mM is reported (13). The problem in the determination of the Michaelis-Menten constant for glucose is that precautions must be taken to ensure that the concentration of dissolved oxygen, which is consumed during the reaction, remains constant. Technically it seems possible to maintain the dissolved oxygen concentration constant during the reaction in for instance a fermenter, enabling the determination of correct velocity values at different glucose concentrations. However, to the author's best knowledge such an approach has never been published so far. Initial velocity,  $v_0$ , can also be used to obtain correct data.

These  $K_m$  values mentioned above show that the affinities of GOX for the two substrates are rather poor. This is especially true for the substrate oxygen when we compare the  $K_m$  for oxygen with the solubility of oxygen in water. At 1 bar, 25°C, and in the presence of air, the maximum solubility of oxygen is  $\sim 6$  mg/L or 0.2 mM, equaling < 50% of the  $K_m$ . Even with pure oxygen the maximum solubility of  $\sim 30$  mg/L is only twice the  $K_m$ . With glucose concentrations far below the  $K_m$  value, which is between 7 to 20 g/L for the *Aspergillus* enzyme, the velocity of the reaction will be low. As a consequence it can be concluded that for the elimination of low quantities of glucose or oxygen from certain foods, high quantities of enzyme and/or long incubation times are necessary even under optimal conditions. The affinity of the enzyme catalase for its substrate hydrogen peroxide is extremely low:  $K_m = 1.1 M$  or 37.4 g/L. This aspect is very important in certain applications.

## B. Determination of GOX Activity

From a theoretical point of view, the analysis of GOX is rather complicated. The enzyme has two substrates: glucose and oxygen. In principle high glucose concentrations can be chosen, far above the  $K_m$ , so that the

velocity of the reaction is no longer dependent on the glucose concentration. This is more difficult for the second substrate oxygen. To obtain oxygen concentrations in solution far above the  $K_m$ , very high oxygen pressures have to be chosen, which is not practical. The concentration of oxygen is below the  $K_m$  if the reaction is performed under normal conditions, and as a result the velocity of the reaction is below the maximum velocity.

An extra complication is that the reaction consumes oxygen. When there is insufficient supply to maintain the oxygen concentration at a saturation level, there will not be a linear production of gluconic acid in time at a fixed enzyme concentration or a linear relationship between the amount of gluconic acid produced within a fixed time and amount of enzyme. Such linear relationships are desirable for an analytical method. Therefore, an analytical method for GOX is preferably based on a system in which only very small quantities of oxygen are consumed. A sensitive method is not realized when it is based on the consumption of glucose or the formation of gluconic acid. If the analysis is based on the consumption of oxygen, the result is influenced by the presence of catalase. In this type of method high quantities of GOX-free catalase have to be added. This is the principle underlying a method described in 1953 by Scott (14) and in 1957 by Underkofler (15). In a Warburg equipment the amount of oxygen consumed under optimal conditions was determined. The unit most frequently used is the Sarrett unit, which is defined as the amount of enzyme which catalyzes the uptake of  $10\mu\text{L}$  oxygen/ min at  $30^\circ\text{C}$ , pH 5.9, and a glucose concentration of 3%. Working with a Warburg is rather laborious, and therefore Underkofler also describes a method using a sodium hydroxide solution neutralizing the gluconic acid produced.

A very sensitive and accurate method is based on the production of hydrogen peroxide. The amount of hydrogen peroxide is determined indirectly by the oxidation of a chromogen catalyzed by a peroxidase. Owing to the very high affinity of this peroxidase for hydrogen peroxide compared to catalase, the presence of this last enzyme in GOX preparations does not influence the analytical result. As chromogen, *o*-dianisidine, *o*-toluidine, and others are used, the developed color is measured in a spectrophotometer, and by using internal standards the amount of oxidized glucose can be determined. The activity is often expressed as IU (international units), defined as micromolar glucose oxidized per min under optimal conditions. For the *Aspergillus niger* enzyme the rela-

tionship between IU and Sarrett units is determined as  $1 \text{ IU} = 1.12 \text{ SU}$  (16, 18) or  $1.1 \text{ SU}$  (17). (See Annex 1 for a detailed description of a method with *o*-dianisidine.) Methods based on the oxidation of a chromogen by hydrogen peroxide are now generally used. The relationship between IU and Sarrett units can be different for glucose oxidation from different organisms. Finally, it should be mentioned that comparison of units in literature is extremely difficult owing to different incubation conditions, including saturation levels of oxygen, and different unit definitions. The best thing to do is to work with an internal standard of GOX of known activity.

### C. Specific Activity

By measuring the oxygen consumption of a pure, catalase-free GOX preparation of *A. niger*, Tsuge et al. (21) found a specific activity of 172 IU/mg protein at  $30^\circ\text{C}$  and pH 5.6. About the same value has been reported by Hayashi and Nakamura (22). Several research groups have purified the *A. niger* enzyme by ion-exchange chromatography and obtained pure preparations with activities from 200 to 250 Sarrett units/mg protein, equaling 180–225 IU/mg protein. Pure catalase-free preparations can be obtained from compa-

### Annex 1 Analysis of Glucose Oxidase

The method used by Whittington (26) is mentioned here:  
Glucose solution A: 2 g/L in 0.2 M Tris phosphate buffer,  
pH 7.0.

*o*-Dianisidine solution B: 2 g/L in 0.2 M Tris phosphate  
buffer pH 7.0.

Horseradish peroxidase solution C: 60 units/mL in 0.2 M  
Tris phosphate buffer pH 7.0.

Glycerol.

Enzyme solution standard D: 10 IU glucose oxidase/mL.  
Hydrochloric acid solution E: 5 M.

All reagents Sigma quality.

Preincubate all solutions at least 10 min at  $30^\circ\text{C}$ .

Add to 1 mL A, 0.1 mL B, 0.1 mL C, and 0.8 mL glycerol.  
Mix carefully.

Add 10–20  $\mu\text{L}$  of an enzyme sample containing 0–10 IU/  
mL.

Incubate 30 min at  $30^\circ\text{C}$ .

Stop reaction by adding 2 mL of 5 M hydrochloric acid  
solution. Mix carefully.

Oxidized *o*-dianisidine is measured in a spectrophotometer  
at 525 nm.

Compare with internal standard of 0–10 IU/mL enzyme.

nies selling research chemicals, or by growing a transgenic yeast harboring a GOX gene.

The specific activity of the purified *Penicillium amagasakiense* enzyme is ~60% higher than that of the *A. niger* enzyme (22).

#### D. Turnover Number

Gibson et al. (11) found a turnover number of 16,200/min. Whittington et al. (27) cloned the *A. niger* enzyme in yeast and found a value of 17,000–20,000 for the yeast-derived enzyme.  $V_{max}$  values of 235/sec for the wild-type enzyme and 500 for the yeast-derived enzyme are found, but it remains unclear whether these differences are really significant.

#### E. pH Activity Profile

The pH activity curves for both the *Penicillium* and *Aspergillus* enzymes show a horizontal profile between pH 4.5 and 7.5, with a sharp decline on both sides (10, 20). There is almost no activity at < pH 3.0 or > pH 8.5. GOX is stabilized by its substrate glucose (32), explaining why in certain applications with a pH between 2.5 and 3.0 and with a high concentration of glucose the enzyme is still active. Also at > pH 8.0 the stability of the enzyme is improved by adding the substrate.

#### F. Temperature Activity Profile

In determination of the temperature activity profile of GOX, some specific complications are encountered. GOX is sensitive to the hydrogen peroxide formed especially at higher temperatures. This means that when a method is applied in which the hydrogen peroxide is not removed immediately and completely, the optimum temperature and the maximum temperature will be low as compared to a method where this is done properly (10). Moreover, long incubation times give a lower optimum. In the analytical method using peroxidase and a chromogen, the hydrogen peroxide reacts immediately with the chromogen. This method gives an activity profile which is rather constant with time between 30°C and 60°C. Above 60°C activity goes down slowly with still 10% activity at 70°C but no activity at 80°C.

#### G. Protein Properties

The molecular weights of the enzymes from both *Aspergillus* and *Penicillium* have been determined at between 140 and 160 kDa (19–21). The enzyme consists

of two identical subunits with 1 molecule FAD per subunit as coenzyme. Because of this, the color of the oxidized protein is yellow with absorption maxima at 377 and 455 nm. Under anaerobic conditions in the presence of glucose, the enzyme molecule is reduced and the color disappears. When oxygen is admitted to the system the color reappears. The FAD is not covalently linked and can easily be removed by acid, urea, or guanidine. But without these reagents, the FAD is bound to the enzyme. The apoenzyme is not active but activity is restored upon incubation with FAD (15).

GOX is a glycoprotein. The amount of carbohydrate in different preparations from *A. niger* can vary from 10% to 18% (22, 23). Mannose is by far the most important sugar with amounts of 70–80%. Galactose contributes ~5% and glucosamine ~15% to the total carbohydrate content. In the *Penicillium* enzyme Kalisz (13) found 95 residues of mannose, 12 residues of glucosamine, and five residues of galactose per molecule of enzyme, and a total carbohydrate content of 13%.

In the *A. niger* enzyme the sugar molecules are N and O linked. By selective elimination of the O-linked sugars Takegawa (12) showed that predominantly mannose monomers are linked to serine and threonine, but the exact place in the molecule is not yet known. The N-linked sugar moiety can be selectively removed by an enzyme from *Flavobacterium*, resulting in the liberation of 30% of the total carbohydrates. The partly deglycosylated enzyme has the same kinetic and biochemical properties and resistance to proteases as the native enzyme except that the native enzyme precipitates at higher concentrations of ammonium sulfate or TCA, and the deglycosylated enzyme is less stable in relation to pH and temperature. The same results were obtained with the *Penicillium* enzyme by Kalisz et al. (13). In this case 95% of the carbohydrate was split off by the enzymatic treatment. Losses in pH and temperature stability were observed as well.

The enzyme from *Phanerochaete chrysosporium* (24) was found to be a flavoprotein with a molecular weight of ~160 kDa and containing 2 mol FAD per mol protein, but it does not seem to contain any carbohydrate and its specificity is lower. Although glucose is the main substrate, considerable activity is still found on sorbose, xylose, and maltose.

The gene of the *A. niger* enzyme has been isolated and the sequence analyzed by various research groups with identical results (25–27). This sequence is now available in data bases. The gene codes for a signal peptide of 22 amino acids (1–22), followed by the 583 amino acid subunit itself (–23–605). The molecular weight of the subunit plus signal peptide is calculated

to be 65,638, and without signal peptide it is 63,250. With ~16% sugars and two molecules of FAD the total molecular weight can be calculated to be ~152 kDa. When the gene is expressed in yeast, an enzyme is obtained with a higher glycolysation level and an improved thermostability. This is in line with the observed lower thermostability the deglycosylated enzymes. The kinetic parameters of the yeast-derived enzyme and the original one are not significantly different. The yeast expression system can be used to obtain GOX completely free of catalase. The transgenic yeast must not been grown on glucose since the hydrogen peroxide formed will inactivate the enzyme and stop growth. Instead it can be grown on saccharose, since this sugar is hydrolyzed by membrane-bound invertase in the cell to fructose and glucose, which are immediately metabolized without formation of gluconic acid and hydrogen peroxide.

## H. Genetic Aspects

A comparison of the mature GOX sequence with sequences present in data bases shows 26% homology with the alcohol oxidase from *Hansenula polymorpha*. The GOX's from *Aspergillus* and *Penicillium* show 66% identity and 79% similarity. The *Penicillium* enzyme consists of 587 amino acids. The two enzymes are highly conserved in the FAD-binding and substrate-binding domain, in their secondary structures and in regions at the subunit interface. The highest similarity with other oxidoreductases is observed in the FAD-binding domain. Aryloxidase, a FAD-dependent enzyme involved in lignin degradation, has been cloned from *Pleurotus eryngii*. The enzyme is composed of 593 amino acids, 27 of which form a signal peptide. It shows 33% sequence identity with GOX from *Aspergillus niger*. The predicted secondary structures of the two enzymes are very similar (28).

## I. Three-Dimensional Structure

The three-dimensional structures of the two enzymes of *Aspergillus* and *Penicillium* have been determined by x-ray crystallography at 2.3 Angstrom resolution (29) and later improved to 1.9 Å resolution (30). The FAD-binding domain is very similar to other FAD-binding proteins, and 11 amino acid residues from different parts of the molecule are involved in this binding. The same is true for substrate binding. The substrate enters a deep pocket and is stabilized by 12 hydrogen bonds and hydrophobic contacts to three aromatic residues and to FAD. A detailed analysis of this sub-

strate-binding site explains the high specificity of GOX described above. Part of the entrance to the pocket is at the interface to the second subunit and is formed by a 20-residue lid. The carbohydrate moiety attached to Asn89 at the top of this lid forms a link between the subunits of the dimer. In total, there are four N-glycosylation sites, with an extended carbohydrate moiety at Asn89. Starting from the 3D structure of the *Penicillium amagasakiense* enzyme, it could be shown by mutation of key conserved active-site residues that Arg516 is involved in the binding to the 3-OH group of the glucose molecule (31). Replacement of this arginine by another amino acid lowers the affinity for the substrate. Aromatic residues on other locations like 73, 418, and 430 are important for the correct orientation and maximum velocity of glucose oxidation.

## IV. APPLICATIONS OF GOX IN FOOD

Looking at the reaction catalyzed by the enzyme, the applications are linked to four different aspects:

1. Removal of glucose
2. Removal of oxygen
3. Production of gluconic acid
4. Production of hydrogen peroxide

A separate subject is the application of glucose oxidase as an analytical agent.

### A. Removal of glucose (10)

Glucose is a reducing sugar that can react with amino groups in, for instance, proteins, to form colored Maillard components that are often undesirable in food products. Additions of GOX to the food system in the presence of air or an oxygen donor like hydrogen peroxide will result in the conversion of glucose to the non-amine-reactive gluconic acid and thus prevent the formation of these Maillard components. The best known application is the prevention of nonenzymatic browning in egg white powder. A detailed description of this application is given by Scott (10). Treatment can be done up to 50°C and in the pH range from 4 to 7. Egg white is neutral at the time of laying, but the pH rises quickly as carbon dioxide is lost, such that it is generally close to 9 when the egg white is processed. The pH is brought below 7 by adding citric acid; addition of hydrogen peroxide as oxygen donor is advantageous. Owing to the low affinity of GOX for glucose, high quantities of enzyme and/or long incubation times are necessary to remove the glucose almost completely,

making this application less competitive than other systems like addition of active yeast. Canadian researchers have shown that GOX is also efficient in the reduction of nonenzymatic browning in potato products like chips and French fries (33, 34). However, complete removal of glucose is also not realized in this process. It is clear that in this type of application only glucose is converted to a nonreducing component; other sugars, such as maltose and lactose, maintain their reducing characteristics. A solution can be the application of an oxidase active on a broad range of reducing sugars. Some enzyme candidates are under investigation now.

## B. Removal of Oxygen

During storage of food, oxygen can have a detrimental effect on quality. As an example, oxidation of unsaturated fatty acids can lead to rancidity of vegetable oils. Oxidation of colored components will change the color of beverages or wine. In addition, oxygen influences the taste of beer in a negative way during storage. The majority of foods contain certain quantities of glucose. In closed systems, the quantity of oxygen to be removed, in order to prevent oxidation, is generally rather low. Therefore GOX can be used to remove oxygen. If necessary a small quantity of glucose is added. An important aspect is the stability of the enzyme under application conditions. Fruit juices and wine have a very low pH of 2.5–3, conditions in which the enzyme is neither active nor stable. However, the high glucose concentrations in fruit juices appear to have a stabilizing effect on the enzyme.

A large number of publications describe the positive effect on quality of adding GOX to food. A good review is given by Scott (10). Other publications concern: prevention of rancidity in oils, fats and fish (35–37); and prevention of off-flavors and color changes in fruit juices, fruit concentrates, white wine, and beer (10, 38, 39). Despite all these positive results, no applications of adding GOX to food has been realized on an industrial scale until now. The main reason seems to be the existence of competing technologies to prevent oxidation; for example, flushing out of oxygen by carbon dioxide or nitrogen in beverages, addition of antioxidants as BHA, ascorbic acid, sulfite, etc.

## C. Production of Gluconic Acid

Milk can be directly acidified by adding glucose, GOX, and hydrogen peroxide as oxygen donor. A variant is combining lactase, which hydrolyzes the milk sugar

into glucose and galactose, with GOX and hydrogen peroxide (40). Owing to the pH drop, the milk coagulates. In principle, the same can be done in cheese manufacture, where direct acidification is fairly common. However, in industrial practice, the addition of an acid or gluconolactone, which under the conditions of cheese manufacturing slowly hydrolyzes into gluconic acid, is preferred.

Until now production of gluconic acid on an industrial scale is done by fermentation with selected strains of *Aspergillus niger* and *Gluconobacter oxydans*. Several attempts have been made toward production of gluconic acid using an enzymatic system. Until recently complete bioconversion was only obtained with glucose solutions of 10% and lower, which is not interesting from an economical point of view. Beverini and Vroemen (41) have now shown that glucose concentrations as high as 40–50% can be completely converted in a fermenter at pH 5–6 and up to 30°C, using low quantities of GOX rich in catalase in a relatively short time. The high catalase content needed is necessary owing to the low affinity of this enzyme for hydrogen peroxide. Under the conditions mentioned, the concentration of hydrogen peroxide remains low such that the two enzymes GOX and catalase are not completely inactivated before the end of the bioconversion. The advantages of this enzymatic process are that no fermentation is necessary (sterilization, nutrients, time), the yield is up to 100%, and the purification of the final product is much easier.

## D. Production of Hydrogen Peroxide

Hydrogen peroxide is a potent oxidant, which can be used as an active antimicrobial agent. Based on this property of hydrogen peroxide, several applications of GOX have been developed of which some are applied on a large scale. For these applications the GOX preparations have to be exempt or poor in catalase. Unfortunately, the GOX itself risks also being inactivated by the hydrogen peroxide formed.

### 1. Toothpaste

In the Netherlands, toothpaste containing enzymes has been developed (42). If sufficient glucose is present, the GOX generates hydrogen peroxide, which kills plaque-forming bacteria in the mouth. To obtain sufficient glucose, amyloglucosidase can be added, which together with the amylase present in saliva, hydrolyzes starch into glucose. In addition, it is claimed that GOX stimulates the lactoperoxidase system in the mouth.

## 2. Milk and Milk Products

GOX can generate hydrogen peroxide for the lactoperoxidase (LPO) system naturally present in milk. This combined GOX-LPO system has been studied extensively by a number of research groups to solve severe contamination problems in milk and cheese production (43, 44). Especially in cheese made from raw non-pasteurized milk, there is an urgent need for a natural antibacterial system. Although a strong effect could be shown on a high number of pathogens, introduction of the GOX-LPO system has not yet taken place. One of the reasons is that it has not given an absolute guarantee against all pathogens.

## 3. Baking

An important aspect of baking is the strength or weakness of the dough. Flours with a low protein content are characterized as weak, and the gluten is very extensible under stress but does not return to its original dimensions when the stress is released. Bakers generally prefer strong doughs because of their better rheological and handling properties, which result in a better form and texture of the final bread. Bakers have used dough conditioners to strengthen the dough. These conditioners are mostly nonspecific oxidants like bromates, iodates, and ascorbic acid. In North America and Western Europe, public opinion and legislation are more and more opposed to the use of chemicals in bread. Moreover, these nonspecific oxidants can have a negative influence on the bread aroma. In the United Kingdom bromates are no longer allowed since 1990, and in France no addition of chemicals is permitted in the production of traditional bread (*pain à tradition française*). Therefore, a need exists to replace the nonspecific oxidants by a natural alternative. Enzymes are judged as natural and in agreement with "clean label." Already in 1957, a patent appeared (45) which describes the addition of GOX to flour to improve the dough quality and the baking properties. As a particular advantage, the combination with ascorbic acid is mentioned. This is already an indication that GOX added gives a better result than ascorbic acid or other nonspecific oxidants alone, which has been confirmed in many tests. This, together with the fact that in that era the acceptance of chemicals was still high, resulted in a low market penetration of the addition of GOX to flour.

The big breakthrough came in the beginning of the 1990s, when researchers of the Finnish company Cultor discovered the synergistic effect of combining several enzymes. The first patent (46) concerns the

combination of GOX and sulfhydryl oxidase. The latter enzyme catalyzes the selective oxidation of sulfhydryl groups to disulfides by oxygen.

This leads to interprotein disulfide bonds. The role of GOX is not yet completely understood. It clearly participates in the formation of disulfide bonds between gluten proteins, but most probably it also participates in the formation of other bonds like oxidative gelation. This is the coupling of two ferulic acid residues of neighboring arabinoxylan chains by the hydrogen-peroxide formed by glucose oxidase.

The second patent (47) concerns the synergistic effect of GOX and hemicellulases, like xylanases. It is believed that GOX makes stronger doughs, permitting the addition of higher amounts of hemicellulases. Addition of such amounts of hemicellulases alone often results in softer and sometimes sticky doughs. Especially, the latter combination of GOX and hemicellulases has obtained a high market acceptance. This "Hemilox" preparation, produced and commercialized by DSM Baking Ingredients under license of Cultor, permits production of clean-label breads of high quality without addition of nonspecific oxidants or emulsifiers (48).

## 4. Glucose Oxidase as an Analytical Agent

GOX is the most widely employed enzyme as an analytical agent, particularly for the determination of glucose in clinical laboratories, fermentation media, food, feed, etc. Different systems have been developed using glucose oxidase in soluble form, but also in immobilized form as glucose electrodes or sticks for the determination of glucose in urine, as practiced by every physician. For a good detailed review see Raba and Mottola (49).

## ACKNOWLEDGMENTS

The author wants to thank his son Casper W. Vroemen of Wageningen University for valuable comments on the manuscript.

# Lactate Dehydrogenase

Hayao Taguchi

*Tokyo University of Science, Noda, Chiba, Japan*

## I. INTRODUCTION

This chapter will focus on the NAD-dependent lactate dehydrogenases (LDHs), although there are NAD-independent LDHs that are usually linked to flavoproteins. There are two forms of NAD-dependent LDHs with distinct stereospecificities for lactate: L-LDHs (*L*-lactate:NAD oxidoreductases, EC 1.1.1.27) and D-LDHs (*D*-lactate:NAD oxidoreductases, EC 1.1.1.28). This chapter will mainly concern L-LDHs, D-LDHs being concomitantly mentioned. L-LDHs catalyze the following overall reaction:

D-LDHs catalyze virtually the same reaction as L-LDH beside the distinct chirality of the lactic acid substrates (products). The physiological reaction of both types of LDHs generally comprises pyruvate reduction (NAD oxidation), the reverse reaction, in which the equilibrium is much more favorable than that of the forward reaction under physiological (neutral) pH conditions (see Sec. IV). Therefore, LDHs act in the last step of the glycolytic pathway, converting pyruvate and NADH into lactate and NAD<sup>+</sup>. It should, however, be noted that LDHs are highly diverged enzymes during evolution, and exhibit a multiplicity in their

catalytic properties in different species and tissues. The structures, properties, and relationships of various LDHs have been described in great detail by some other reviews (1-4). This chapter outlines these aspects of LDHs, with a few recent advances.

## **II. IMPORTANCE TO QUALITY OF FOOD**

LDHs play key roles in the production of lactic acid, which gives food a sour taste, by stimulating glycolysis through the consumption of pyruvate and the recycling of NAD<sup>+</sup> under anaerobic conditions. It is known that muscles of exhausted animals are acidic and taste sour because of the lactic acid produced. Glycolysis from glycogen also proceeds in the meat after the death of the animal, producing ATP and lactic acid. While the ATP produced is mostly consumed, lactic acid is accumulated and reduces the pH of the meat, usually to ~5.5 (ultimate pH). The pH decrease in the meat mostly results from the lactic acid produced, and the rate differs with animal species and storage conditions. The rapid pH decrease, before cooling of the meat, tends to occur particularly in the case of pork, and causes the denaturation of some proteins in the meat, leading to the decline of meat quality. Since the isoelectric points of many meat proteins are around pH 5, the pH decrease also releases water molecules from hydrated proteins of meat and thus makes the meat watery.

In processed foods such as dairy products, lactic acid is produced through lactic acid fermentation by some bacteria, in particular, lactic bacteria.

Homofermentative lactic bacteria usually produces > 85% lactate as an end product, and heterofermentative bacteria form mixed end products containing acetic acid or ethanol besides lactic acid. Lactic bacteria ferment D- or L-lactic acid, or both, depending on the growth conditions, such as the oxygen concentration, temperature, pH, and sugars or other catabolites supplied, and also on the nature of the LDHs contained in bacterial strains. D- and L-LDHs play key roles in the fermentation of D- and L-lactic acids in lactic bacteria, respectively, and the amount and properties of each LDH greatly affect the fermentation patterns of lactic bacteria. Bacteria that possess L-LDHs activated by fructose-1,6-bisphosphate (Fru-1,6-P<sub>2</sub>) (see below) produce mainly L-lactic acid when Fru-1,6-P<sub>2</sub> is accumulated in the cells, but under other growth conditions the bacteria may ferment a large amount of D-lactic acid, or some other end products, rather than L-lactic acid (3).

### III. LOCATION OF LDH

L-LDHs are widely distributed in animals, plants, and bacteria. Vertebrates have L-LDH in isoforms, depending on the tissues and organs, such as the A (or M), B (or H), and X types of the enzymes, which are mainly located in skeletal and heart muscles, and testes, respectively. These isozyme subunits can also be hybridized, and form heterotetramers such as A<sub>4</sub>, A<sub>3</sub>B, A<sub>2</sub>B<sub>2</sub>, AB<sub>3</sub>, and B<sub>4</sub>. On the other hand, D-LDHs are widely found in invertebrates, fungi, and bacteria, and the tissue-specific isozymes of D-LDHs are found in invertebrates. It has been reported that invertebrates possess either L- or D-LDH, depending on the species (5). For example, only D-LDHs are found in horseshoe crab, arachnids, and gastropods, but insects or crustaceans only possess L-LDHs. On the other hand, some lactic bacteria contain D- or L-LDHs, or both, and therefore ferment D-, or L-, or both lactic acids (3, 6).

Activity staining with a tetrazolium salt (see below) is often used for the histological analysis of the isozymes, or phylogenetic or taxonomic analysis of LDHs in lactic bacteria. LDHs are usually separated by electrophoresis of a native protein sample, and distinct bands on the electrophoresis gel are visualized by staining with D- or L-lactate, or both.

### IV. UTILIZATION OF LDH IN FOODS

LDHs are used for the quantitative or qualitative determination of pyruvate, lactate, and related com-

pounds (7). In particular, the pyruvate content can be simply determined through measurement of the reduction of NADH by the direct LDH reaction. The decrease in NADH, which can be monitored as the change in absorbance at ~340 nm, is equal to the reduction in the pyruvate content. The equilibrium constant ( $K_{eq}$ ) of this reaction is shown in the following equation:

$$K_{eq} = \frac{[\text{pyruvate}] \times [\text{NADH}]}{[\text{lactate}] \times [\text{NAD}^+]} \\ = 2.76 \times 10^{-6} (\text{pH } 7.0, 25^\circ\text{C})$$

The favorable equilibrium allows pyruvate to be quantitatively converted into lactate under conventional LDH assay conditions. The contents of some other catabolites in glycolysis, such as phosphoenolpyruvate and D-glycerate 2-phosphate, can also be quantitatively determined by means of the LDH reaction, coupling with enzyme(s), such as pyruvate kinase (EC 2.7.1.40) and/or enolase (EC 4.2.1.11). Therefore, LDHs are also useful as coupling enzymes for the determination of enolase and pyruvate kinase activities. In addition, some common LDHs exhibit low but sufficient catalytic activity on certain pyruvate analog such as hydroxypyruvate, and these substrates can also be assayed using the enzyme.

On the other hand, the L- and D-lactate contents in food can be individually determined by the use of L- and D-LDHs, respectively. To remove the pyruvate produced, appropriate coupling reagents are required for quantitative determination because of the unfavorable equilibrium. For example, L-alanine aminotransferase (EC 2.6.1.2) is used to convert pyruvate into L-alanine in the presence of L-glutamate. Assay kits for D- or L-lactate including LDHs and aminotransferase are available commercially (such as F-kits for L- and D/L-lactate from Boehringer Mannheim).

L-LDHs from many sources can be purchased from commercial source, such as the muscle, heart, and liver isozymes from rabbit, cow, and pig, and the enzymes of lobster and some bacteria. The D-LDHs of lactic bacteria, for example, *Lactobacillus leichmannii* and *Leuconostoc mesenteroides* enzymes, are also available from commercial sources.

### V. STRUCTURES AND STRUCTURE-FUNCTION RELATIONSHIP

The three-dimensional structures of LDHs were first determined for vertebrate L-LDHs in apo and ligand complex forms (2, 4), and then extensively analyzed for

the bacterial L- (8–10) and D- (11) LDHs. Most L-LDHs are tetrameric enzymes composed of identical polypeptides (subunits) with three twofold symmetric axes, P-, Q-, and R-axes, although some L-LDHs, such as the *Alcaligenes eutrophus* enzyme (12), are homodimers. Vertebrate L-LDHs can form heterotetramers through association among the different subunits of the isozymes both in vivo and in vitro, and some bacterial enzymes may also associate in vitro, if they are closely related to each other (13). Subunits of L-LDHs, as well as those of D-LDHs, are usually composed of 310–350 amino acids (molecular weights 34,000–40,000).

The subunits of L-LDHs comprise two similar sized domains: NAD-binding and catalytic domains. The NAD-binding domain is located in the N-terminal half of the L-LDH primary structure and is folded into a typical open  $\alpha/\beta$  structure (Rossmann fold), which is a highly conserved domain structure among NAD-dependent dehydrogenases. The structure of the catalytic domain in the C-terminal half appears unique in L-LDHs among these dehydrogenases, except for L-malate dehydrogenases (MDH), the catalytic domain of which quite resembles that of L-LDHs as well as the NAD-binding domain. Although MDHs are usually dimeric enzymes with a symmetric axis, their quaternary structures are quite homologous to that of the Q-axis dimer of L-LDHs. The homology of the tertiary and quaternary structures indicates that MDHs and L-LDHs appear to have recently diverged during enzyme evolution, although there is little similarity in their primary structures. It is known that only one amino acid substitution in L-LDH (Arg102 to Gln) sufficiently alters the substrate specificity of L-LDHs to that of MDHs (14).

In the case of L-LDHs, the amino acid sequences have been systematically aligned with a standard alignment system (N-system) based on the primary structure of a vertebrate isozyme (15). Although all known L-LDHs have essentially the same overall protein structures, however, the primary structures of L-LDHs are highly divergent in different species and tissues. The vertebrate isozymes usually exhibit more than 70% amino acid identity with one another, but bacterial L-LDHs share considerably less common amino acids with one another, depending on the species, and with the vertebrate enzymes up to < 40%. Evolutionary trees have been proposed for L-LDHs on the basis of the divergence of their primary structures (16, 17).

There are, in particular, marked differences in the N-terminal region between vertebrate and bacterial

L-LDHs. The N-terminus of vertebrate L-LDHs is usually acetylated, while bacterial L-LDHs have a free amino group at the N-terminus. In addition, vertebrate L-LDHs possess a long additional amino acid sequence (R-arm) at the N-terminus, which is followed by the  $\beta$ -sheet strand of the NAD-binding domain. The R-arm (~20 amino acids) extends from the NAD-binding domain to another subunit across the R-axis subunit interface, and is responsible for inter-subunit interactions on the R-axis subunit interface in vertebrate L-LDHs. On the other hand, bacterial L-LDHs, in general, exhibit no or much weaker interactions on the R-axis subunit interface, since they largely or completely lack the R-arm sequence and are thought to form tetramers mostly through P- and Q-axis interactions (9). The lack of an R-arm may be important in allosteric types of L-LDHs, which are widely distributed in bacterial cells and are usually activated by fructose 1,6-bisphosphate (see below). The 3D structures of the active and inactive forms of the *Bifidobacterium longum* enzyme indicate that the quaternary structure markedly changes through alteration of the intersubunit interactions in the allosteric transition (9). The lack of an R-arm possibly provides the enzyme sufficient flexibility for the structural change in the allosteric transition.

Unlike L-LDHs, many D-LDHs have dimeric structures comprising identical subunits and only one two-fold symmetric axis in the quaternary structure, which is not homologous to the P-, Q-, or R-axis dimer of L-LDHs. But some D-LDHs, such as the *Haemophilus influenzae* enzyme, the molecular weight of which was estimated to be 35,000 and 135,000 by SDS-PAGE and gel filtration, respectively (18), are possible tetrameric forms. D-LDHs have been distantly separated from L-LDHs in the enzyme evolution (19) in spite of the quite homologous catalytic functions, which possibly resulted from convergent evolution. D-LDHs exhibit little sequence similarity with L-LDHs except for only a small locus such as a Gly-X-Gly-X-X-Gly motif (X is unconserved amino acid) in the NAD-binding domain, and the 3D structure of the enzymes is very distinct from that of L-LDHs. It is known that D-LDHs constitute a dehydrogenase family distinct from that of L-LDH, together with other NAD-dependent 2-D-hydroxyacid dehydrogenases such as 2-D-glycerate dehydrogenase, 3-D-phosphoglycerate dehydrogenase, 2-D-hydroxyisocaproate dehydrogenase, and interestingly, also some NAD-dependent formate dehydrogenases, since these enzymes exhibit homologous primary and 3D structures (20–23). Recently, furthermore, it has been shown that L-alanine dehydrogenases also

resemble D-LDH in 3D structure, in spite of their poor amino acid sequence identity with D-LDH (24). The primary structure of D-LDHs appear to be also divergent among species, since even the enzymes from *Lactobacillus pentosus* and *L. bulgaricus* strains of the same genus have < 50% identical amino acids (25).

The subunits of most D-LDHs are composed essentially of two domains: NAD-binding and catalytic domains, which are connected by a hinge containing two peptides (11). The NAD-binding domain of the enzyme is folded into a typical Rossmann fold, which is quite homologous to the NAD-binding domain of the L-LDH, but is located at a different position in the primary structure from that of L-LDH, i.e., in the middle of the primary structure near the C-terminus (residues 101 to 299 in *Lactobacillus pentosus* D-LDH [total 332 amino acids]) (11).

On the other hand, the structure of the catalytic domain is composed of a large N-terminal and a small C-terminal part (residues 1–100 and 300–332, respectively, in *Lactobacillus pentosus* D-LDH), and is folded into an  $\alpha/\beta$  structure, which resembles the NAD-binding domain structure but greatly differs from the L-LDH catalytic domain structure. Two of the NAD-binding domains are tightly bound to each other with no covalent bond, and are responsible for not only the main interactions for the subunit assembly but also the rigid base that allows the catalytic domains to flexibly move during catalysis through the hinge motion of the two connecting peptides. This motion of D-LDH in catalysis is also different from the loop motion of L-LDH (see below).

## VI. CATALYTIC PROPERTIES AND MECHANISMS

The kinetics of L-LDH are explained by an ordered bi-bi mechanism, in which coenzyme NADH (or  $\text{NAD}^+$ ) is bound first, and subsequently the substrate, pyruvate (or L-lactate), is bound to the enzyme active site. In the L-LDH catalysis, the imidazole group of the His195 (the numbering is based on the vertebrate enzyme according to Eventof et al. [15]) residue acts as an essential acid/base catalyst, which mediates proton transfer between the substrate and the solvent. The catalytic reaction occurs through the concerted attack by the nicotinamide ring of NAD and the His195 imidazole toward the 2-carbonyl (or hydroxymethyl) group of pyruvate (or lactate). In the case of pyruvate reduction, hydride and proton hydrogens are transferred from NADH (4-H of the nicotinamide ring)

and the protonated imidazole of His195 onto the 2-carbon and the carbonyl oxygen of the substrate, respectively, while  $\text{NAD}^+$  and the unprotonated His195 act as acceptors for hydride and proton hydrogens from lactate on lactate oxidation. The carboxyl group of Asp168, which is located close to the imidazole of His195, is thought to promote the catalytic function of the imidazole, through stabilizing the protonated form of the imidazole (26). Two guanidino groups of the enzyme are known to play an essential role in promoting enzyme catalysis. The guanidino group of Arg171 undergoes strong interactions with the substrate carboxyl group, and allows the substrate to be correctly orientated in the catalytic site of the enzyme (27). The other guanidino group of Arg109 is located on a loop polypeptide (residues 98–110) over the active site of the enzyme. The substrate binding induces marked structural rearrangement in the L-LDH active site, in which the loop closes over the active site. Arg109 moves toward the active site and comes near the carbonyl oxygen of pyruvate through the rearrangement, and promotes the hydrogen transfer reaction by polarizing the substrate carbonyl group (28). The structural rearrangement, like the hydrogen transfer, is one of the slow steps in the L-LDH catalytic process. It has been indicated that the rearrangement step is fully rate-determining in the pyruvate of *Bacillus stearothermophilus* L-LDH, which exhibits a  $k_{\text{cat}}$  value of  $250 \text{ sec}^{-1}$  for pyruvate reduction, due to the primary isotope effect of an NADH deuterium derivative on the enzyme transition state kinetics, while the hydrogen transfer step is rate limiting in lactate oxidation (4).

In the case of D-LDHs, the catalytic site of the enzyme exists in a cleft between the NAD-binding and catalytic domains, and the substrate binding allows the cleft to be closed through the hinge motion of the catalytic domain. In the active site of D-LDH, the His296–Glu264 pair plays essentially the same role as the His195–Asp168 pair does, and Arg235 possibly fulfills the roles of both Arg102 and Arg171 (11, 29, 30). In spite of their distinct substrate stereospecificities, L- and D-LDHs exhibit common stereospecificity for the NADH hydrogen, which is located on the A-side (*re*-side) at the C-4 position (*pro-R* hydrogen) of the nicotinamide ring (31).

Both L- and D-LDHs are sensitive to chemical modification reagents for His imidazole and Arg guanidino groups, such as diethylpyrocarbonate and 2,3-butandione, respectively, and are protected from inactivation by coenzymes and substrates (analogues), because the enzymes possess essential His and Arg residues in their catalytic sites. Sulphydryl reagents,

such as *p*-hydroxymercuribenzoate and N-ethylmaleimide, also inactivate vertebrate L-LDHs by the modification of Cys165, which is highly conserved in vertebrate L-LDHs, but not in other L-LDHs. Although the D-LDHs of invertebrates (31) and *Haemophilus influenzae* (18) are also inactivated by sulphydryl reagents, some bacterial D-LDHs have no cysteine residue in their primary structures (19).

The pH profile of LDH activity differs markedly in the forward (from lactate to pyruvate) and reverse (from pyruvate to lactate) reactions, depending on the *pK* of the catalytic His residue, which is ~7.0 in most LDHs (6.7 in apo and binary complex L-LDHs of mammals) (2, 26), since the unprotonated and protonated forms of imidazole are required for the lactate and pyruvate binding, respectively. Therefore, the pyruvate  $K_m$  is virtually constant at < pH 6.0, and increases to > pH 8.0 in a reverse proportion to the H<sup>+</sup> concentration in the solvent, in usual cases, while the lactate  $K_m$  is constant at > pH 8.0, and increases to < pH 6.0. In contrast, the  $k_{cat}$  values and dissociation constants of NAD are usually much less sensitive to pH conditions. In the LDH reaction, thus, the optimal pH of the pyruvate reduction is usually lower than that of the lactate reduction.

The A- and B-types of the bovine and chicken L-LDH isozymes exhibit pyruvate  $K_m$ s of 10<sup>-5</sup>–10<sup>-4</sup> M, and L-lactate  $K_m$ s of 10<sup>-3</sup>–10<sup>-2</sup> M, and the B-type of L-LDH isozymes shows several-fold lower substrate  $K_m$  values than the A-type isozymes (32). Most L-LDHs, including all known vertebrate L-LDHs, are significantly inhibited by a high concentration of the substrate, pyruvate (32), although the B-type isozyme generally shows more marked substrate inhibition than the A-type isozymes. It has been indicated that the substrate inhibition mostly results from the formation of an abortive enzyme–NAD<sup>+</sup>–pyruvate ternary complex (1). Everse and Kaplan (1) and Holbrook et al. (2) reviewed the steady-state and transition kinetics of vertebrate L-LDHs in detail.

Vertebrate L-LDHs exhibit no apparent cooperative effects on substrate binding, and require no particular factors for their enzyme activity. On the other hand, bacterial L-LDHs show great variety in their catalytic properties, and often allosteric regulation by certain factors, as reviewed by Garvie (3) in detail. Some bacterial L-LDHs, such as the enzymes of *Lactobacillus casei* (33–35), *Thermus* spp. (36, 37), and *Bifidobacterium longum* (38), show positive cooperative effects on substrate binding. It was, in addition, particularly noted that many bacterial L-LDHs require

Fru-1,6-P<sub>2</sub> as a specific activator for their catalytic activities. The regulations of these enzymes greatly differ, depending on the bacterial species (3,39). Some of the bacterial enzymes absolutely require Fru-1,6-P<sub>2</sub> and exhibit virtually no catalytic activity unless Fru-1,6-P<sub>2</sub> is present. On the other hand, some of the enzymes exhibit significant activity even without Fru-1,6-P<sub>2</sub>, but much more enhanced activity in the presence of Fru-1,6-P<sub>2</sub>, which usually improves the substrate binding. In the case of the *B. stearothermophilus* L-LDH, for example, the pyruvate  $K_m$  is reduced from 2 mM to 0.04 mM by 5 mM Fru-1,6-P<sub>2</sub> at pH 6.0 (28). On the other hand, the L-LDHs of *L. casei*, *Thermus* sp., and *Bifidobacterium longum* have positive cooperative effects on pyruvate binding, in the absence of Fru-1,6-P<sub>2</sub>, shown by the sigmoidal pyruvate saturation curve, which changes into a hyperbolic one in the presence of Fru-1,6-P<sub>2</sub>. Besides Fru-1,6-P<sub>2</sub>, the L-LDHs of *L. casei* and *curvatus* (35) and *Enterococcus faecalis* (40), previously called *Streptococcus faecalis*, require certain divalent metal ions such as Mn<sup>2+</sup> under physiological pH conditions, and thus constitute a subclass of divalent metal ion-dependent allosteric L-LDHs (35). The metal ions improve the activation function of Fru-1,6-P<sub>2</sub> by increasing its affinity to these enzymes. In the case of the *L. casei* enzyme, 10 mM Mn<sup>2+</sup> reduces the dissociation constant for the enzyme and Fru-1,6-P<sub>2</sub> from 15 mM to 0.2 mM at pH 7.0 (41).

It has been demonstrated that the Arg173 and His188 residues, which are located on the P-axis subunit interface of L-LDHs, are directly involved in the Fru-1,6-P<sub>2</sub>-binding in common allosteric L-LDHs, such as the enzymes of *L. casei* (42), *B. stearothermophilus* (8, 43), *Thermus caldophilus* (44, 45), and *B. longum* (9, 46). The side chains of these amino acids face each other across the P-axis subunit interface, and constitute the Fru-1,6-P<sub>2</sub>-binding site with a highly positive charge. The Fru-1,6-P<sub>2</sub> molecule neutralizes the positive charges and thereby reduces the static repulsions, which stabilizes the inactive form of the enzyme in the absence of Fru-1,6-P<sub>2</sub>. Thus, Fru-1,6-P<sub>2</sub> binding is one of the triggers for the change in the quaternary structure of the enzyme, which is closely coordinated with the structural change of the substrate-binding site (9) and the coenzyme in the enzyme (47). The *T. caldophilus* enzyme is converted into the fully active form that is independent of Fru-1,6-P<sub>2</sub> through chemical modifications of the Arg residues, mainly Arg173 (44) and/or Arg216 (48), which are also located on the P-axis interface of the enzyme, with protection of the catalytic site by NADH and

oxamate (49, 50). Reduction of positive charge, through the replacement of Arg173 or Arg216 by site-directed mutagenesis, also leads to partial activation of the enzyme (44, 48).

The x-ray structures revealed that one Fru-1,6-P<sub>2</sub> molecule, which possesses a pseudosymmetric structure, is bound per one P-axis dimer in the *B. stearothermophilus* (8) and *B. longum* (9) L-LDHs (two Fru-1,6-P<sub>2</sub> molecules per tetramer), although equilibrium dialysis of the *L. casei* L-LDH indicates that one Fru-1,6-P<sub>2</sub> molecule is bound per one of the subunits (four Fru-1,6-P<sub>2</sub> molecules per tetramer) (41). The pH conditions greatly influence the regulation by Fru-1,6-P<sub>2</sub>, in the cases of usual allosteric L-LDHs, since enzyme activation highly depends on the interaction between the protonated His188 (the numbering is based on the vertebrate enzyme according to Eventof et al. [15]) and the phosphate moiety of Fru-1,6-P<sub>2</sub> (both pKs are ~ 6). For example, the *L. casei* enzyme shows a dissociation constant of 1 μM with Fru-1,6-P<sub>2</sub> at pH 5.4, but one of 15 mM at pH 7.0 (41). Usually allosteric L-LDHs are markedly stabilized, or protected from the dissociations of subunits, in the presence of allosteric ligands such as Fru-1,6-P<sub>2</sub>, or divalent cations in some cases, as well as coenzymes, although the *E. faecalis* enzyme is unique in that it is rather labile in the presence of these ligands (51).

Nonallosteric L-LDHs of vertebrates possess a corresponding binding site at the same locus of the Fru-1,6-P<sub>2</sub>-binding site, called the anion-binding site, where citrate ions were found to be bound on x-ray crystallographic analysis (2). In vertebrate enzymes, the active forms are sufficiently stabilized in the absence of Fru-1,6-P<sub>2</sub>, through some intrinsic interactions, such as the R-axis interaction that is missing in bacterial enzymes. It is nevertheless thought that the anion-binding site is not involved in the regulation of the enzyme activity, but in the stabilization of the enzyme structure through binding certain organic or inorganic anions. Both Arg173 and His188 are also highly conserved in most known nonallosteric L-LDHs including vertebrate enzymes, except for the enzymes of *L. pentosus* (19, 52), *L. plantarum* (53), and *Pediococcus acidilactici* (54), in which His188 is substituted by Asp. The mutant *L. pentosus* enzyme, in which Asp188 is replaced with His by site-directed mutagenesis, is not significantly regulated, but markedly stabilized by Fru-1,6-P<sub>2</sub> (52).

D-LDHs of invertebrates and bacteria generally display hyperbolic saturation curves for substrates, and exhibit high activities independent of certain allosteric factors. Unlike L-LDHs, no D-LDH has been found

that is regulated by Fru-1,6-P<sub>2</sub>. Nevertheless, some D-LDHs, such as the enzymes of *Butyribacterium rettgeri* (55) and *Escherichia coli* B (56), show positive cooperativity in the substrate binding, as shown by the sigmoidal pyruvate saturation curves. The enzyme from *Pythium devaryanum*, a homolactate-fermenting fungus, is unique in that it also shows cooperativity in the NADH and D-lactate binding, but not in NAD<sup>+</sup> or pyruvate binding (57). In addition, GTP has an allosteric inhibition effect on the enzyme by increasing the cooperative effects on the NADH and D-lactate binding, while ATP inhibits the enzyme reaction by only competing with coenzyme NAD<sup>+</sup>.

Adenine nucleotides such as AMP, ADP, and ATP generally inhibit the catalytic reactions of LDHs through competition with coenzymes at the NAD-binding site of the enzymes, and exhibit *K*<sub>1</sub> values of ~ 10<sup>-3</sup> M in human L-LDH A- and B-type isozymes. On the other hand, oxamate and oxalate, the structures of which are analogous to those of pyruvate and lactate, respectively, are representative substrate-relative inhibitors that inhibit LDH reactions by competing with substrates, and exhibit particularly strong inhibitory effects on pyruvate reduction and lactate oxidation, respectively. In the case of the bovine A-type isozyme, for example, oxamate and oxalate show dissociation constants of 1.1 × 10<sup>-5</sup> and 5.5 × 10<sup>-3</sup> M with the enzyme-NADH binary complex, and 1.7 × 10<sup>-4</sup> and 2.1 × 10<sup>-6</sup> M with the enzyme-NAD<sup>+</sup> complex, respectively (58, 59). Nevertheless, oxamate also sometimes exhibits an apparent activation effect on the LDH reaction. In the case of LDHs that show positive cooperativity in the substrate binding, a low concentration of oxamate usually stimulates the enzyme reaction when the substrate concentration is sufficiently low through reduction of the cooperativity of substrate binding.

In the case of Fru-1,6-P<sub>2</sub>-activated L-LDHs, inorganic phosphate usually competes with Fru-1,6-P<sub>2</sub> at the Fru-1,6-P<sub>2</sub>-binding site, and has a strong inhibitory effect on the enzyme reaction, besides the coenzyme- and substrate-related inhibitors. It is nevertheless known that the *Enterococcus faecalis* L-LDH is not markedly sensitive to inorganic phosphate (40).

## VII. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

The enzyme activity is usually assayed based on pyruvate reduction, in which the catalytic efficiency of most LDHs together with the equilibrium are much

more favorable than those of lactate oxidation. The rate of decrease of the NADH is quantitatively determined by monitoring absorbance at 340 nm ( $\epsilon$  of NADH =  $6,220 \text{ M}^{-1}\text{cm}^{-1}$  at 338 nm, pH 7.5). Pyruvate concentrations of  $\sim 2$  and 0.3 mM are usually appropriate for the A<sub>4</sub> and B<sub>4</sub> isozymes of mammals, respectively, at pH 7.2 and 25°C. In general, however, the pyruvate concentrations must be chosen or searched for carefully, together with pH and temperature conditions, in particular for new or unknown LDHs, because the pyruvate  $K_m$  and inhibitory concentrations of pyruvate change greatly depending on the pH and temperature. It should be noted that the suitable concentrations of pyruvate markedly differ with individual enzymes, depending on the species and tissues containing the enzymes, in particular in bacterial L-LDHs, which often exhibit sigmoidal saturation curves for pyruvate or require Fru-1,6-P<sub>2</sub> for enzyme activities. The concentration of NADH which is more favorable for the reaction than NADPH in LDHs in general, and does not critically affect the enzyme activity in the usual LDH assay compared with the pyruvate concentration, because the dissociation constants between LDH and NADH are sufficiently small ( $10^{-7} - 10^{-6}$  M for vertebrate A and B L-LDH isozymes) under usual assay conditions, in which the NADH concentration is  $\sim 0.1$  mM (A<sub>340</sub> is 0.62). In addition, the NADH binding is usually less sensitive to the pH condition, and the excess concentration of NADH inhibits the enzyme reaction less than in the case of pyruvate.

The concentration of Fru-1,6-P<sub>2</sub> must also be carefully chosen for the assay of Fru-1,6-P<sub>2</sub>-activated L-LDHs, since it highly depends on the bacterial strain and pH. Phosphate buffer is usually unsuitable, since inorganic phosphate reduces the activation effects of Fru-1,6-P<sub>2</sub> on the enzymes.

Lactate oxidation is also useful for the assay of LDHs in some cases, and can also be determined by following the rate of the change in the absorbance at 340 nm. However, it is recommended that this enzyme reaction be performed in the presence of much higher coenzyme and substrate concentrations and/or under a more alkaline pH (pH > 9) than those in the pyruvate reduction, since the equilibrium is unfavorable at neutral pH, and LDHs generally show higher optimal pHs for lactate oxidation than pyruvate reduction. The NADH resulting from lactate oxidation can also be detected using a tetrazolium salt with a coupling reagent, phenazine methosulfate (PMS). Since the reduced tetrazolium salt displays a blue color as lactate oxidation proceeds, this assay is also useful for the

semiquantitative or qualitative determination of the enzyme activity, and can be applied to histological staining or phylogenetic or taxonomic differentiation of distinct LDHs or isozymes. For example, LDHs are separated on a native electrophoresis gel and give distinct colored bands on staining of the gel with lactate, NADH, PMS, and tetrazolium salt (35). If an enzyme hardly catalyzes the lactate oxidation, the reverse reaction (pyruvate reduction) is also available for the assay (negative staining). In the case of the reverse reaction, the sample gel is primarily treated with NADH and pyruvate (and Fru-1,6-P<sub>2</sub> if necessary) for the LDH reaction to proceed in the gel, and subsequently with PMS and a tetrazolium salt. Since LDHs consume NADH during the pretreatment, the tetrazolium gives clear bands for the LDHs in a blue-colored background.

### VIII. PURIFICATION

Since LDHs are usually localized in the cytoplasmic fraction of cells, the first step of purification is the preparation of cell-free extract through disruption of the cells with a homogenizer, or through osmotic shock or sonication. The conventional methods for protein purification, such as ammonium sulfate precipitation, and ion exchange, or gel filtration chromatography, are generally available for both L- and D-LDH purification. The excess dilution or repeated freezing and thawing of an enzyme sample is usually undesirable during the purification or storage of the enzyme, since these promote the dissociation of the enzyme subunits. Purification of LDHs is usually performed in conventional buffers such as phosphate and Tris-HCl buffers, around neutral pH (between 6.0 and 7.5), where the enzymes are relatively stable. However, acetate buffers of pH 5.5 are often used in the case of *Lactobacillus* LDHs. The *L. casei* and *L. curvatus* allosteric L-LDHs tend to dissociate into dimers or monomers under neutral or slightly alkaline conditions (60).

Heat-treatment is sometimes used for the purification of certain bacterial L-LDHs, although the thermostability of the enzymes greatly differs with the original source of the enzyme (3). The *L. casei* and *L. curvatus* allosteric enzymes have been three to fivefold purified from cell-free extract by heat treatment at 60°C and pH 5.5, at which the enzymes are stable in the presence of Mn<sup>2+</sup> as compared with other cell proteins (35). In the case of *L. plantarum* cells, which contain both L- and D-LDHs, the former is much more thermostable

than the latter, and it alone can retain activity after heat treatment at 50° or 60°C (61). The L-LDHs from thermophilic bacteria are usually thermostable. The enzyme of *B. stearothermophilus* retains 50% of its activity after heat treatment at 90°C for 7 min (28). The *T. caldophilus* enzyme is not markedly inactivated by heating at 95°C for 1 h, and 50% of its activity remains at 100°C after 20 min (36). Heat treatment is not effective for purification of the enzymes from the original bacterial cells, in which other proteins are also thermostable, but effective when the recombinant proteins are produced in other host cells such as *E. coli* cells (44).

The conventional approaches alone may lead to sufficient purity if an enzyme is an abundant protein in the cell-free extract, but affinity chromatographies based on the affinity of LDH to NAD<sup>+</sup> and the substrate often allow very efficient and specific purification of LDHs. Columns of 5'-AMP, NAD<sup>+</sup>, and dye-immobilized gels, such as 5'-AMP and Blue Sepharose, are promising for both L- and D-LDH purification, as in the case of general nucleotide binding proteins. After the enzymes have been adsorbed to the gel, they are usually eluted with buffers containing NADH or a high salt concentration.

Another resin for affinity chromatography, which is also specific for L-LDH, is prepared by the immobilization of oxamate on gels such as Sepharose-4B through a spacer such as diaminohexane (62). With the use of the oxamate gel, L-LDH is adsorbed to the gel in the presence of NADH, and eluted by removing NADH from the elution buffer. This purification protocol is based on the fact that the binding of a substrate (oxamate in this case) to the enzyme absolutely depends on NADH. This elution, however, sometimes gives a broad peak of the eluted enzyme. If a sharper peak of the enzyme is required, oxamate (or pyruvate) may be added to the NADH-free elution buffer. The oxamate gel gives efficient purification of usual L-LDHs, but appears to be unsuitable for D-LDH purification (63).

These affinity chromatographies are promising approaches for general LDH purification, in particular, when the enzyme is not abundant in the enzyme source. To obtain a successful result, it is recommended that one or two conventional purification steps be carried out before the affinity chromatography step, since cell-free extracts usually contain certain compounds that inhibit the adsorption of the enzyme on to the gel, such as some nucleotides and 2-keto-acids, which compete with the affinity resin in the enzyme binding.

## Alcohol Dehydrogenase

Sabato D'Auria

*Institute of Protein Biochemistry and Enzymology, Naples, Italy, and University of Maryland, Baltimore, Maryland, U.S.A.*

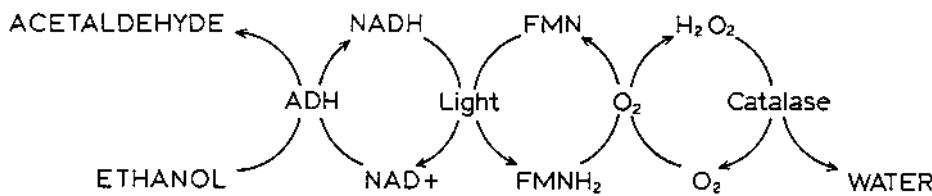

### I. INTRODUCTION

Of the estimated 25,000 enzymes present in nature, ~2800 have been classified and ~400 have been commercialized. On a larger industrial scale, in particular for detergent and food processing, only ~50 enzymes are used. The main impetus for the use of enzymes is the continuous growth in the demand for enantiomerically pure compounds. This trend plays an important role in the use of chiral drugs, but is also essential in the flavor industry where, besides microbial fermentation, enzyme technology is an alternative for the biotechnological production of flavor compounds (1). For example, acetaldehyde is an important low-molecular-weight flavor compound that plays a significant role in the flavor of yogurt and certain fruits, such as orange. **Figure 1** shows the conversion of ethanol to acetaldehyde using alcohol dehydrogenase. This process suffers from the same drawbacks as all enzymatic oxidation reactions that rely on cofactor regeneration. Specifically, the process involves the use of alcohol dehydrogenase and its cofactor NAD<sup>+</sup>, which during the reaction is reduced and subsequently regenerated by light-catalyzed oxidation with flavin mononucleotide (FMN). The reduced flavin mononucleotide (FMNH<sub>2</sub>) is reconverted to FMN by oxidation with molecular oxygen. The byproduct of this reaction is hydrogen peroxide, which is in turn decomposed by the action of the enzyme catalase to oxygen and

water. Conversion rates in the range of 10–20% are typically obtained, and in a continuous batch reactor system the concentration of acetaldehyde is ~2.5 g/L after a period of 9 h (2).

Recently it has been shown that genetic manipulation of alcohol dehydrogenase levels in ripening tomato fruit affected the balance of some flavor aldehydes and alcohols. In particular, modified alcohol dehydrogenase levels in the ripening fruit influenced the balance between some of the aldehydes and the corresponding alcohols associated with flavor production. Hexanol and Z-3-hexenol levels were increased in fruit with increased alcohol dehydrogenase activity and reduced in fruit with low alcohol dehydrogenase activity. In some taste trials, fruits with elevated alcohol dehydrogenase activity and higher levels of alcohols were identified as having a more intense “ripe fruit” flavor (3). Moreover, the involvement of alcohol dehydrogenases in the biosynthesis of six carbon alcohol constituents of the aroma of olive oil has been recently discussed (4). In yeast, ethanol is produced from acetaldehyde during anaerobic fermentation of sugar and this could represent an important process in the production of alcohol-containing beverages.

A survey of the actual use of enzymes in synthetic organic chemistry shows that 65% of all reported applications fall into the classes of hydrolytic and dehydrogenase reactions (1).

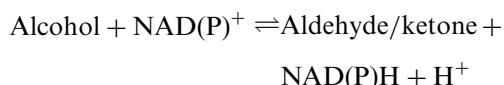

**Figure 1** Enzymatic oxidation of ethanol to acetaldehyde. (From Ref. 2.)

## II. PROPERTIES AS PROTEIN

Alcohol dehydrogenase (ADH) (EC 1.1.1.1) is an oxidoreductase enzyme that catalyzes the oxidation of alcohols and the reduction of carbonyl compound such as aldehydes and ketones. The enzyme displays a broad substrate specificity, being active on a variety of primary, secondary, branched, and cyclic alcohols. Alcohol dehydrogenases are widely distributed enzymes and have been found in many microorganisms, fungi, and animal cells (5). Most bacterial ADHs are so-called soluble enzymes and are located in the cytoplasmic, but some have been shown to be membrane bound. The intracellular compartmentation of eukaryotes gives rise to greater possibilities of variation in location. Thus, *Saccharomyces cerevisiae* contains three ADHs of which two are cytoplasmic and the third is mitochondrial (6). Some of these enzymes (e.g., ADHs from horse liver and yeast) have been extensively studied, because they can provide new data on the relationship between structure and function, being oligomeric, coenzyme dependent, and containing structural and functional metal atoms (5).

ADH requires a nicotinamide cofactor for the catalytic activity, and it is capable of distinguishing the diastereotopic methylene hydrogens at the dihydropyridine C-4 position of NADH or NADPH, transferring the hydride to the substrate stereospecifically (7). This interesting enzymatic feature suggests a potential use of ADHs for the production of alcohols with a 100% optical yield (7).

ADHs catalyze the interconversion of alcohols to aldehydes/ketones:

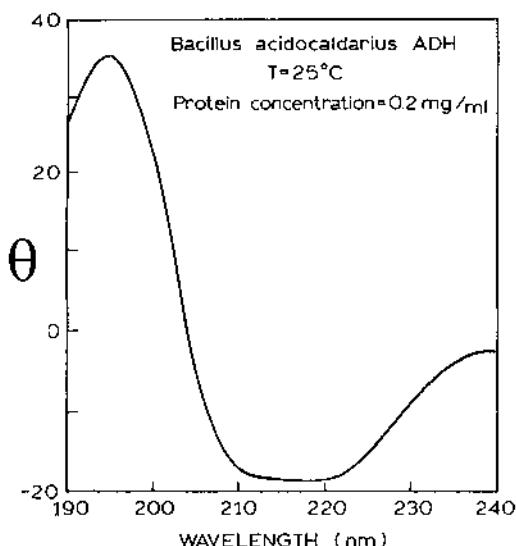

This reaction is highly reversible and the direction of the reaction is influenced by pH of the reaction medium. At pH 9 the equilibrium of this reaction is directed toward aldehyde formation, while at pH 7

alcohol formation is favored. ADHs can be very effective for the conversion of the readily available aldehydes citronellal and citral for the production of (−)-citronellol and geraniol, compounds with a much higher flavor impact than the corresponding aldehydes or ketones (8). Thus, the potential applications of ADHs in industry are numerous. With mesophilic enzymes, however, limitations due to narrow specificity, instability to heat and organic solvents, and loss of activity on immobilization have been incurred. The use of these enzymes from thermophilic sources in immobilized and continuous reactor systems has also been proposed for the regeneration of NAD(P)H needed for such reactors, the lifetime of which would be extended with stable enzymes. The ADH from *Thermoanaerobium brockii* has been shown to reduce aliphatic acyclic ketones asymmetrically with an optimal purity. Furthermore, this enzyme has been used to obtain optically pure cyclic ethers, which are constituents of civet used as a fixative in the perfume industry (9).

ADHs have been subdivided into different families according to the polypeptide chain lengths: the short-chain family consisting of non-metalloenzymes with subunits of ~250 residues (10); the medium-chain family with subunits of 350–375 residues, often containing zinc (11); and the long-chain family with subunits of >700 residues (12). Moreover, ADHs lacking zinc as well as alcohol dehydrogenases requiring iron for activation have been described (13). A monomeric ADH was also isolated from *Saccharomyces cerevisiae*, but its metal content is yet unknown (14).

ADHs have been classified as  $\alpha/\beta$  proteins with high amounts of  $\alpha$ -helices and  $\beta$ -structures. Figure 2 shows the far-UV circular dichroism spectrum of *B. acidocaldarius* ADH. The deconvolution of the spectrum resulted in ~22%  $\alpha$ -helix and 45%  $\beta$ -structure, suggesting that ADHs from thermophilic microorganisms could also have a secondary structural organization similar to that described for mesophilic ADHs (15).

**Figure 2** Far-UV circular dichroism spectrum of *Bacillus acidocaldarius* ADH. Protein concentration 0.2 mg/mL. Temperature 25°C.

Moreover, conformational variations have been reported in many ADHs on binding to coenzyme or substrate. One of the many techniques utilized to detect conformational changes in protein structure is fluorescence spectroscopy. Horse liver ADH (HLADH) contains two tryptophan residues: Trp15 located at an outer edge of the catalytic domain and accessible to solvent, and Trp314 located in the apolar intersubunit region of the catalytic domain, inaccessible to the solvent. In a detailed fluorescence study Lakowicz and coworkers showed that these two tryptophan residues displayed different emission spectra and time decay by using one- or two-photon excitation. The results suggest that the intrinsic fluorescence of HLADH can be used to probe small changes in the active site of the enzyme (16).

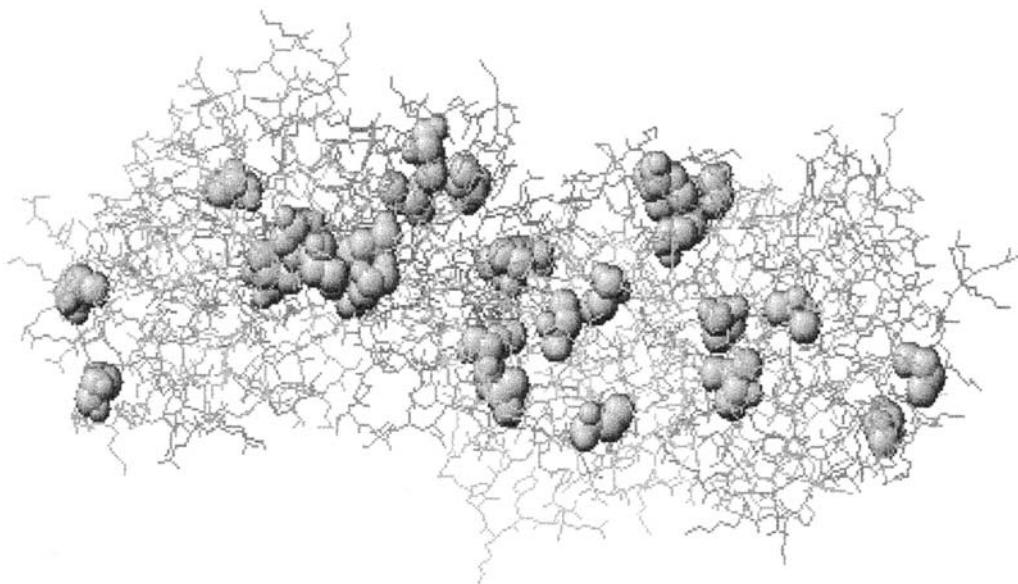

Zinc-dependent alcohol dehydrogenases have a dimeric or tetrameric structure. Dimeric enzymes are the ADHs from mammals (11) and from higher plants (17). Tetrameric enzymes are the ADHs from yeasts and bacteria. Recently, a detailed characterization of the ADH from *S. solfataricus* has ascertained the presence of both dimeric and tetrameric forms, with the dimeric conformation showing a lower level of catalytic efficiency than the tetrameric one (18). Moreover, mammalian ADHs have been divided into three major classes (I, II, and III) based on their electrophoretic mobility and kinetic properties (19).

Multiple sequence alignment of > 60 ADHs from different sources with that of HLADH has shown

that in almost all the zinc containing ADHs studied to date, three zinc-binding amino acids (Cys46, His67, and Cys174) are highly conserved (20). However, in ADH from *Thermoanaerobacter brockii* only Cys37 and His59, which align with Cys46 and His67 of HLADH, are conserved. Although the residue corresponding to Cys174 of HLADH is absent in *Thermoanaerobacter brockii* ADH, it has been suggested that Asp150 could serve as the third Cys residue in the latter enzyme. Moreover, the absence in *Thermoanaerobacter brockii* ADH of all four amino acid residues found in HLADH to coordinate the structural zinc ions (Cys97, Cys100, Cys103, Cys111) suggests that the Cys37 is involved in the catalytic activity of *T. brockii* enzyme (21). The ADHs isolated from *Bacillus acidocaldarius* and *Sulfolobus solfataricus* have two zinc atoms per enzyme subunit, one with a catalytic role and the other with a structural role (15, 22).

The thiol groups of cysteines are important for protein structure and folding (23). As in other proteins, chemical modification of reactive cysteine residues has been used extensively to investigate the importance of cysteine residues in the structure and function of the ADHs. [Figure 3](#) shows the structure of the E-subunit of HLADH resolved at 2.2 Å. In the same figure the cysteine residues are shown as “spacefill.”

In zinc-containing ADHs, cysteine serves as binding site for the catalytic zinc atom (24). In most eukaryotic and prokaryotic ADHs, cysteine serves as binding site for a structural zinc atom as well (25). The role of other cysteine residues present in the ADHs has not been determined. Of the three catalytic zinc atoms that have been identified in the 3D structure of HLADH, the only enzyme for which a detailed 3D structure of an ADH with its coenzyme is available (24), two residues, Cys46 and Cys174, can be selectively alkylated by  $\alpha$ -halo acids in an affinity-labeling type of reaction (28). Whereas carboxymethylation of Cys46 and Cys174 of HLADH, or the putative active site zinc ligand cysteines of human ADH, sheep liver sorbitol dehydrogenase, and human liver aldehyde dehydrogenase, abrogates enzymatic activity (27), similar modification of the ADH from *S. solfataricus* significantly increases the oxidation rate of alcohols (28). Recently it has been shown that Cys283 and Cys295 of the ADH from *Thermoanaerobacter brockii*, although they are buried within the protein core and are not accessible for chemical modification, are oxidized to cystine when the enzyme is heated at 75°C, forming a disulfide bridge that was not present in the native enzyme, without affecting either enzymatic activity or thermal stability (21).

**Figure 3** Structure of E-subunit of horse liver ADH solved at 2.4 Å. The cysteine residues are shown as spacefill.

**Figure 4** shows the 22 amino acid residues strictly conserved in 16 ADHs from different sources (11). It is worth noting that His → Arg substitution at the position 47 (HLADH numbering) has been reported to affect both the affinity for the coenzyme and pH optimum for the activity in human ADH isoenzymes, the native enzyme displaying a lower optimum and higher  $K_m$  and  $V_{max}$  values than the mutant (18, 25).

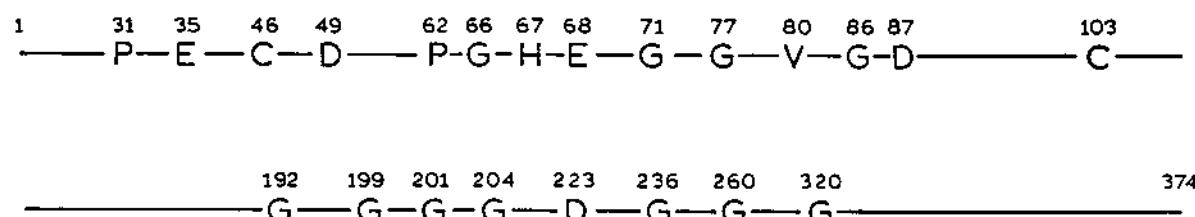

Table 1 shows some biochemical features for some ADHs with His or Arg at position 47.

### III. PROPERTIES AS ENZYMES

According to their source ADHs differ in substrate and coenzyme specificity (5). It is commonly believed that ADHs from eukaryotes are mainly NAD<sup>+</sup> dependent, while those from prokaryotic organisms are either NAD<sup>+</sup> or NADP<sup>+</sup> dependent. However, two ADHs

isolated recently from thermophilic bacteria utilize NADP<sup>+</sup> as coenzyme (29, 30), while the ADHs from the eubacteria *Bacillus acidocaldarius* and *Bacillus stearothermophilus* require NAD<sup>+</sup> as coenzyme (15, 31). Moreover, ADHs containing pyrroloquinolin quinone (**Fig. 5**) as a cofactor have been isolated from various Gram-negative bacteria. Based on the cofactor requirement two classes of ADHs can be distinguished: quinoprotein alcohol dehydrogenase (containing PQR and Ca<sup>2+</sup>) and quinohemoprotein alcohol dehydrogenase (containing PQQ, Ca<sup>2+</sup>, and heme c). The first class includes the methanol dehydrogenases from methyotropic bacteria and alcohol dehydrogenases occurring in *Pseudomonas* (32).

HLADH is a well-characterized zinc-containing ADH. Each subunit of the dimeric enzyme contains one catalytic and one structural zinc atom (5) and binds one ligand of NAD(P)H.

**Figure 4** The 22 amino acid residues strictly conserved in several ADHs (11). The amino acids are numbered according to HLADH sequence.

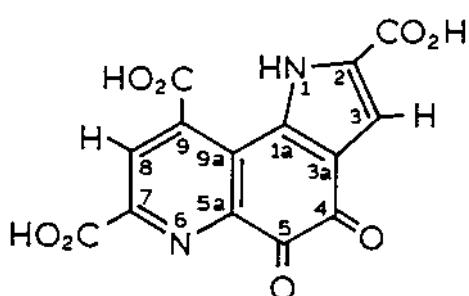

**Table 1** Optimal pH and  $K_m$  Values Related to Amino Acid 47 of Horse Liver (HL), Yeast (Y),  $\beta_1\beta_1$  Human ( $\beta_1\beta_1$ h),  $\beta_2\beta_2$  Human ( $\beta_2\beta_2$ h), and *Bacillus acidocaldarius* (Ba) ADHs

	HL ADH	Y ADH	$\beta_1\beta_1$ h ADH	$\beta_2\beta_2$ h ADH	Ba ADH
Amino acid residue 47	Arginine	Histidine	Arginine	Histidine	Not determined
Optimal pH activity	10	8.6	10	8.5	10
$K_m$ ( $\mu M$ ) ( $NAD^+$ )	53	160	7.4	180	1600

The most widely accepted reaction mechanism for alcohol dehydrogenase is indicated in Figure 6 (33) and includes: binding of  $NAD^+$ ; binding of alcohol substrate by replacing a zinc-bound water molecule; deprotonation of the alcohol; hydride transfer from the alkoxide ion to  $NAD^+$ , yielding NADH and a zinc-bound aldehyde; dissociation of NADH. In applicable steps (7–9), the zinc-bound water molecule equilibrates with a zinc-bound hydroxyl ion, which gives rise to a dead-end complex. The catalytic zinc in HLADH is bound to Cys46, His67, and Cys174. The fourth ligand is a water molecule that is linked to a hydrogen-bonding network involving Ser48 and His51 (34). The four cysteine residues coordinating the noncatalytic zinc (Cys97, 100, 103, and 111) and the binding amino acids of the catalytic zinc are arranged in a distorted tetrahedral geometry (35).

The nicotinamide ring system is redox active, accepting a hydride of two electrons and a proton to form 1,4-dihydronicotinamide derivatives of NADH or NADPH. The reversible hydride transfer from a reduced substrate to  $NAD^+$ , and that from NADH to an oxidized substrate, is stereoselective and characteristic of individual enzyme. Each enzyme is able to transfer stereoselectively one of the diastereotopic methylene hydrogens at C-4 of NADH to a substrate carbonyl group or an equivalent  $sp^2$  center with high enantiofacial or diastereofacial selectivity.

The stereospecificity of the ADH isolated from the thermoacidophilic archaeon *Sulfolobus solfataricus* (36) toward an asymmetric ketone was examined by using 3-methyl-butan-2-one as a model compound. The hydride attack, using the enzyme immobilized on Eupergit C was on *re-face* of the ketone, producing the corresponding (*s*)-3-methyl-butan-2-ol with a 100% optical yield. Moreover, the potentiality of the use of this enzyme for the preparation of chiral compounds was also pointed out by the use of resting cells of *S. solfataricus* to reduce a series of acyclic, cyclic, and aromatic ketones (37). Another interesting aspect of stereospecificity of ADH from *S. solfataricus* was discovered by studying the oxidation of secondary alcohol enantiomers (38): (*s*)-enantiomers are far better substrates than (*r*)-enantiomers. For example, (*s*)-2-butanol is oxidized about 60 times more efficiently than (*r*)-2-butanol, and (*r*)-sec-phenethyl alcohol is not oxidized at all. In a detailed study Keinan and coworkers showed that the ADH isolated from *Thermoanaerobium brockii* exhibited a high stereospecificity depending on the enzyme assay temperature (39). However, the nicotinamide cofactors are too expensive to be used as stoichiometric reagents in large-scale synthesis. Thus, recycling of the cofactors is needed if enzymes requiring nicotinamide cofactors are to be used in a preparative scale. In spite of the use of HLADH with its broad substrate acceptance, narrow stereoselectivity and bidirectional functionality, there is continuing research for novel reductases, in particular for alcohol dehydrogenases purified from thermophilic microorganisms, that are stable and active at high temperature and in the presence of organic solvents. Enzymes isolated from thermophilic sources display high levels of enzyme activity at high temperatures, being barely active at room temperature. Figure 7 shows the thermophilic behavior of two ADHs: *B. acidocaldarius* ADH (moderate thermophilic microorganism), and *S. solfataricus* ADH (hyperthermophilic microorganism). Several research groups have related these functional features to a high struc-

**Figure 5** Structure of pyrroloquinolin quinone.

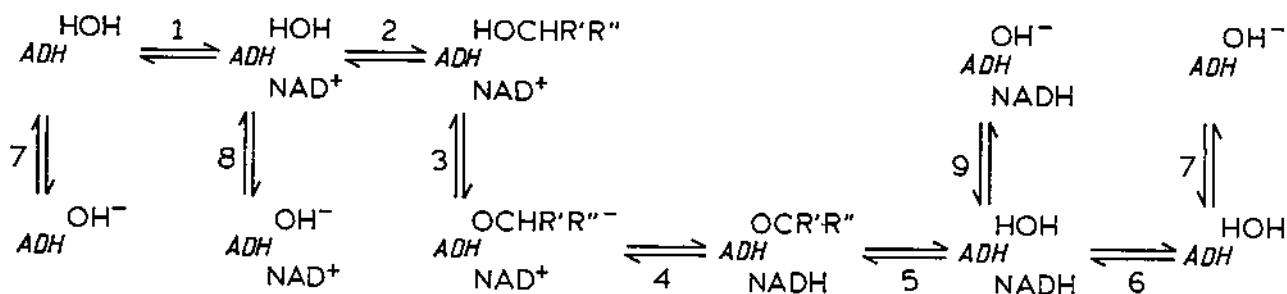

Figure 6 Reaction mechanism of ADH according to Petterson (33).

tural rigidity at room temperature (40) that could prevent the utilization of these enzymes in biotechnological applications.

#### IV. ENZYMATIC ASSAY

Usually alcohol dehydrogenase activity is assayed by following the increase in absorbance at 340 nm owing to the reduction of the  $\text{NAD}^+$ ( $\text{NADP}^+$ ) molecules. On the contrary, it is also possible to assay alcohol

dehydrogenase activity by monitoring the decrease in absorbance at 340 nm, as a consequence of the oxidation of the NADH (NADPH) molecules.

The alcohol dehydrogenase from yeast exhibits the maximal enzymatic activity in the range of pH 8.6–9.0 at 25°C. The typical assay for measuring it is the following: 50 mM Tris-HCl (pH 8.6), 10 mM ethanol, 1.0 mM  $\text{NAD}^+$ , and 1.0  $\mu\text{g}$  enzyme/mL final volume, at 20°C. The ADH activity is determined by monitoring the increase of absorbance at 340 nm. One unit of enzyme activity is defined as the amount of the enzyme that catalyzes the reduction of 1.0  $\mu\text{M}$  of  $\text{NAD}^+$  at 25°C.

For assaying enzymatic activity of thermophilic alcohol dehydrogenases it is of fundamental importance to use a sealed cuvette, in order to avoid the evaporation of the assay mixture. The alcohol dehydrogenase from the thermophilic microorganism *Bacillus acidocaldarius* shows the maximal enzyme activity at 80°C. However, *Bacillus acidocaldarius* ADH activity is usually assayed spectrophotometrically at 65°C by measuring the increase in the absorbance at 340 nm in a sealed quartz cuvette. The reaction mixture contains 50 mM glycine-NaOH (pH 10.0) and 1.0  $\mu\text{g}$  protein/1.0 mL final volume. The concentrations of cofactors and substrate are 5.0 mM  $\text{NAD}^+$  and 3.0 mM ethanol for alcohol oxidation, and 0.12 mM NADH and 3.0 mM *p*-anisaldehyde for aldehyde reduction, respectively. One unit of enzyme activity is defined as the amount of the enzyme that catalyzes the reduction of 1.0  $\mu\text{M}$  of  $\text{NAD}^+$  at 65°C, using ethanol as substrate.

It is also possible to monitor ADH activity by fluorescence spectroscopy. In this case, we follow the increase of the fluorescence emission at 450 nm (upon excitation at 340 nm) due to NADH formation. The fluorescence assay is more sensitive than the spectrophotometer one, and it is utilized when it needs the detection of low ADH activity levels.

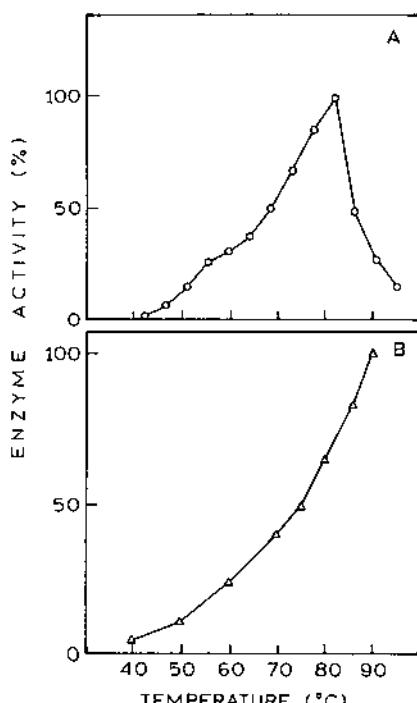

Figure 7 Thermophilic behavior of *Bacillus acidocaldarius* ADH(A) and *Sulfolobus solfataricus* ADH (B).

## V. PURIFICATION

Several purification strategies have been described to isolate ADHs from different sources. However, the utilization of an affinity column has been reported as the main purification step in almost all described purification procedures. Specifically, an affinity chromatography based on the interaction of ADH coenzyme-site-blue dye molecule was used for large-scale purification of horse liver ADH. Moreover, it has recently been shown that the affinity chromatography on Matrex Gel Red A was the essential purification step for the isolation of the ADH from a novel strain of *Bacillus steroetheromphilus* (31).

Here we report the typical procedure of purification of the ADH from *Bacillus acidocaldarius* (15). However, it is worth noting that a similar method can be also used for the purification of alcohol dehydrogenases from different sources.

1. *Preparation of cell extract.* One hundred and twenty grams of wet cell pellet was suspended in 360 mL of 10 mM Tris/HCl, 0.5 mM dithiothreitol, pH 9.0 (Buffer A), and broken by five 1-min cycles of sonication at regular intervals, utilizing an MSE Soniprep 150. Cell debris was removed by centrifugation at 160,000 g for 90 min (at 4°C). The supernatant represented the crude extract.

2. *Column chromatography steps.* The crude extract was applied to a DEAE-Sepharose Fast Flow column, previously equilibrated in Buffer A. The column was washed with 1000 mL of Buffer A, and eluted with a linear gradient from 0.0 to 0.3 M NaCl in Buffer A, at a flow rate of 60 mL/h. The alcohol dehydrogenase activity was eluted at 0.1 M NaCl. The fractions containing the enzymatic activity were pooled and loaded on a Phenyl-Superose column, at a flow rate of 30 mL/h, after addition of 1.0 M ammonium sulfate. After washing with 100 mL of Buffer A, the enzymatic activity was eluted with a gradient of ammonium sulfate from 1.0 M to 0.0 M in Buffer A. Fractions containing the ADH activity were eluted at 0.3 M ammonium sulfate, pooled, and dialyzed overnight against 10 L of Buffer A, at 4°C. The active pool was loaded at a flow rate of 30 mL/h on a Mono Q FPLC column previously equilibrated with the same buffer. The column was washed with a linear gradient from 0.0 M to 0.5 M NaCl in Buffer A, at a flow rate of 60 mL/h. The enzymatic activity, eluted at ~ 100 mM NaCl, was dialyzed overnight against 5 L of 10 mM Tris/HCl, pH 7.4 (Buffer B), and applied onto a Blue A affinity column, previously equilibrated with the same

buffer, at a flow rate of 20 mL/h. The column was washed with 150 mL of Buffer B, and the homogeneous enzyme was eluted with a step of 2 mM NAD<sup>+</sup> in the same buffer. The results of the purification are summarized in Table 2.

*Bacillus acidocaldarius* ADH was purified to homogeneity by five steps. The crucial step in the purification procedure was the specific elution of the enzyme by NAD<sup>+</sup> at pH 7.4 from the affinity Blue A column. The presence of DTT in the buffers used in *Bacillus acidocaldarius* ADH purification was necessary in order to avoid the complete inactivation of the enzyme. On the other hand, no significant enzyme stabilization was observed utilizing buffers containing divalent ions (Zn<sup>2+</sup>, etc.).

However, it is worth stating that the expression of thermophilic ADHs in mesophilic hosts (e.g., *E. coli*) makes the enzyme purification procedure very easy; in fact, it needs a thermoprecipitation step in order to separate the thermostable recombinant enzyme from the native proteins of the host. Moreover, the cloning and expression of thermostable ADHs in organisms generally recognized as safe (GRAS) from the U.S. Food and Drug Administration (e.g., *Saccharomyces cerevisiae*) give the opportunity to obtain large amounts of stable ADHs to use in the food industry.

In conclusion, ADHs have been isolated from different organisms and they differ according to their sources, in substrate and coenzyme specificity, as well as in their protein structural organization. Their wide substrate specificity makes this class of enzymes good biocatalysts in biotechnological applications, as well as interesting proteins in the study of evolution.

**Table 2** Purification of Alcohol Dehydrogenase from *Bacillus acidocaldarius*

Purification step	Protein (mg/mL)	Specific activity	Fold purification	Yield (%)
Cell extract (homogenate)	12,200	0.3	1.0	100
DEAE-Sepharose FF	1,100	3.3	11	99
Phenyl-Superose	500	6.1	20	83
Mono-Q Sepharose	150	16	53	65
Blue Sepharose CL-6B	15	150	500	61

Source: Ref. 15.

The alcohol dehydrogenase activity was assayed spectrophotometrically by measuring the change in absorbance at 340 nm. The reaction mixture contained 50 mM glycine-NaOH, pH 10, 5.0 mM NAD<sup>+</sup>, and 3.0 mM ethanol.

## ACKNOWLEDGMENTS

I thank Professor Joseph R Lakowicz (University of Maryland), Professor Mosé Rossi (University of Naples), and Professor Carlo Fini (University of Perugia) for their stimulating scientific discussions; and Mr. Carlo Vaccaro (Italian National Research Council) for his technical assistance. Skillful assistance in the preparation of the figures by Ms. Krystyna Gryczynska is gratefully acknowledged. This work was supported by a grant from the Ministry for University and for Technological and Scientific Research (M.U.R.S.T.) 60%, and EU contract "Extremophiles," and the National Center for Research Resources, NIH RR-08119.

This chapter is dedicated to Cristina, Leandro Maria, and Gerard Joseph.

### I. INTRODUCTION

$\text{NAD}^+$ -dependent alcohol dehydrogenases (ADHs) (alcohol: $\text{NAD}^+$ ) oxidoreductase E.C.1.1.1.1) are enzymes that occur widely in living organisms where they are important for the detoxification and metabolism of ethanol and other alcohols (1). ADHs catalyze the reversible oxidation of various alcohols to the corresponding aldehydes and ketones, with the concomitant reduction of  $\text{NAD}^+$  (2). Depending on the biological source, ADHs show different substrate specificity (short-long-chain alcohols, aliphatic/aromatic alcohols, and branched alcohols).

Even though ADHs show some divergence in amino acid sequences, isoenzymes, and substrate specificity, they have certain structural and functional similarities. Three structurally and catalytically different types of ADHs are currently known (3). The medium-chain ADHs (containing  $\sim 350$  residues per subunit) are named type I. They are zinc dependent and are characterized by a preference for primary alcohol. The short-chain ADHs (containing  $\sim 250$  residues per subunit), named type II, are zinc independent and they display a better affinity toward secondary alcohols. Iron-activated long-chain ADHs, named type III, have an average subunit size of  $\sim 385$  residues. Among these  $\text{NAD}^+$ -dependent ADHs, type I ADHs are the most studied with respect to structure and kinetic mechanism (4, 5). Originally, the ADHs of type I had been termed as the long-chain ADHs but

were renamed as the medium-chain family after the still longer ADHs were discovered (3).

Many different type I ADHs have been characterized as subclasses based on their dimeric and tetrameric forms such as horse liver alcohol dehydrogenase (HLADH) and yeast *Saccharomyces cerevisiae* alcohol dehydrogenase (SADH or YADH), respectively. Primary structures of most ADHs are known but only the tertiary structure of HLADH is known at present (6,7). Crystallization of HLADH with or without  $\text{NAD}^+$  has been achieved in order to understand the binding mechanism of different substrates and the kinetic mechanism (8, 9). The three-dimensional modeling of other medium chain ADHs is based on the structure of HLADH. Comparison of structure between HLADH and the other ADHs has shown that the three-dimensional structures of these enzymes must be very similar in the catalytic domains. Although the general overall sequence homology is  $< 40\%$ , all the structurally important residues are either homologous or conservatively substituted (Fig. 1) (4). Since HLADH and YADH are the most studied ADHs, we will present below only the state of the science concerning these two enzymes.

### II. SOME UTILIZATION OF ADH IN FOOD TECHNOLOGY

The applications of ADHs as industrial catalysts are limited by the expense of the cofactors  $\text{NAD(H)}$ . Many

complex methodologies have been studied for recycling the redox coenzyme, as for instance the coupling of ADH with another enzyme together with a coupled substrate in order to regenerate the coenzyme (12). An alternative approach consists in using a coenzyme mimic, bearing functional similarity to NAD<sup>+</sup> (13). Independently of the cofactor recycling, ADHs obviously have been used for the production of alcohols during the alcoholic fermentation or the production of aldehydes which represent a major source of numerous flavors.

In the case of alcoholic beverage production, it is not the enzyme that is used but the cell. The production of beverages by alcoholic fermentation is one of the oldest fermentations known. Beer and wine were probably the two earliest alcoholic drinks produced. A brief history of the knowledge in alcoholic fermentation could be summarized as follows. Until Pasteur's work in the late 19th century, little was known of the actual processes and mechanism of alcohol produc-

tion. Pasteur showed that living yeast cells caused fermentation in the absence of air, converting sugar into ethanol and carbon dioxide. Research later in the 19th century showed that fermentation resulted from the action of substances contained within the yeast cells. Later, one of the major discoveries of fermentation microbiology was made by Hansen at the Carlsberg center in Copenhagen while working on "wild" yeast. These wild yeast were known to give problems during beer fermentation and, by isolating pure cultures of yeast, which he then used in the brewing process, Hansen initiated the use of pure cultures in beer production. Alcoholic beverages are produced by the alcoholic fermentation of the sugar-containing material to ethanol and carbon dioxide (see Chapter 2 for other details).

Fermentation is carried out by species of the yeast *Saccharomyces*. In some cases, sugar is present naturally, such as in grapes used in wine making; in others, sugars are produced from starches in cereals, as in beer

production. Free sugar is essential for alcoholic fermentation by *Saccharomyces* as the species is not able to hydrolyze polysaccharide material. Production of ethanol from glucose occurs via the Embden-Meyerhof-Parnas pathway. In the last reaction of this alcoholic fermentation, yeast ADHs catalyze the reduction of acetaldehyde to ethanol (14).

The yeast used in the manufacture of alcoholic beverages are strains of *Saccharomyces cerevisiae* or *S. carlsbergensis*. The definitive difference between these yeasts is that *S. carlsbergensis* ferments raffinose completely, whereas *S. cerevisiae* does not (14).

### III. PROPERTIES AS PROTEIN

#### A. Horse Liver Alcohol Dehydrogenase

Horse liver alcohol dehydrogenase (HLADH) is generally considered to be a symmetrical dimer, composed of two identical chains of 40 kDa but with difference in amino acid sequence at six positions. One cannot ignore the different forms observed in several experiments owing to dissociation-reassociation or in other studies of the purified isoenzymes. It is known that three main isoenzymes are formed by the dimeric combination of the two different types of subunit chains, which are based on the difference in substrate specificity. There is a subunit called E for its ethanol activity and another subunit S for its steroid activity, therefore, the main isoenzymes are EE, ES, and SS. The three isoenzymes differ in that SS also has ethanol activity but lower than ES and still lower than EE and that EE has some activity toward certain steroid side chain hydroxyl groups (4).

##### 1. Primary, Secondary, Tertiary, and Quaternary Structures

Studies of primary structure of E- and S-subunits have shown that each subunit is composed of 374 residues plus two zinc atoms. The crystal structure analysis of the apoenzyme helped to determine the position of each residue in the polypeptide chains and showed that the principal difference between these subunits is a 6 amino acid difference at positions Glu17, Thr94, Arg101, Phe110, Asp115, and Glu366 (residues listed for E-subunit). Three of the six amino acid differences observed between the E- and S-chains may be responsible for the difference in substrate specificity. These are Phe110, Asp115, and Thr94 in the E-subunit, and Leu110, Ser115, or a gap and Ile94, respectively, in the S-chain. The other three residues (Gln17, Ser101, and

Lys366) that are different are all located in different regions from the catalytic domain (4).

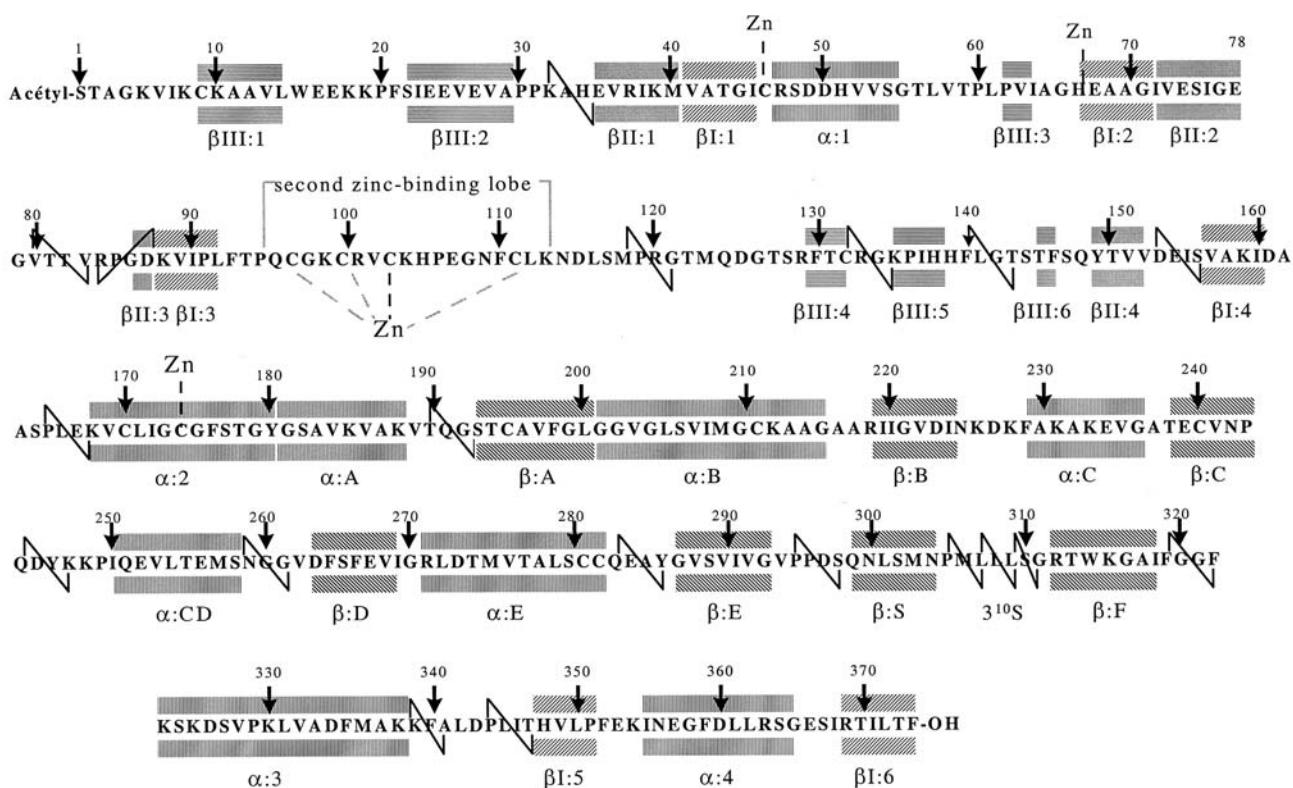

Each subunit is divided into two domains separated by a crevice that contains a wide and deep hydrophobic pocket (active site). One of these domains, called the coenzyme-binding domain, binds the coenzyme. The two zinc atoms are bound within the second domain, called the catalytic domain. The two domains are unequal in size. The catalytic domain is larger and comprises 231 residues, whereas the coenzyme-binding domain contains 143 residues. The primary and secondary structures in the subunit of HLADH are illustrated in Figure 2 (6).

The two subunits of the dimeric enzyme are joined together mainly through noncovalent interactions within the coenzyme-binding domains. These domains thus form a core in the middle of the molecule by homologous interactions within corresponding regions of the coenzyme binding to enzyme. The catalytic domains are located on the exterior of the molecule, and the catalytic sites are found in the junction between the two domains and the core. The whole molecule has an approximate helical content of 29% of the residues while 34% are in pleated-sheet regions.

#### 2. Coenzyme-Binding Domain

The coenzyme-binding domain of the subunit comprises residues 176–318. The amount of secondary structure in this domain is considerable; 45% of the residues are helical (mainly  $\alpha$ -helices), 32% are in pleated-sheet structure, and 13% in reverse bends. Thus only ~10% of the residues have no regular secondary structure. The domain is built of six parallel strands of pleated sheet ( $\beta$ A– $\beta$ F) flanked by five helices ( $\alpha$ A– $\alpha$ E) in a regular pattern. There are three hydrophobic regions in this domain. One is involved in subunit interactions; the  $\beta$ F strands of each subunit run in opposite directions perpendicular to the twofold axis and are joined together by hydrogen bonds forming two strands of antiparallel  $\beta$  structure. The other two hydrophobic regions are implicated in the folding of the domain and form hydrophobic cores between helices and the parallel pleated sheet. The unique fold of the coenzyme-binding domain creates a large cleft region between the two domains of HLADH for binding of a coenzyme molecule (4, 6, 15).

Two coenzyme molecules are bound per enzyme molecule independently of each other. The coenzyme binds to the enzyme in the central region of the carboxyl end of the parallel pleated sheet. The coenzyme binding induces different conformational changes: the active site is more shielded from the solution; the active

**Figure 2** Primary structure and schematic diagram of the regions of secondary structure in the subunit of HLADH. Helices are called  $\alpha$  with a numeral for those that appear in the catalytic domain and a letter for those that are in the coenzyme-binding domain. Strands of pleated sheet are called  $\beta$  with a similar nomenclature as for the helices. Reverse turns are denoted by the following symbol ( $\nwarrow$ ). ■: indication of length of helix or strand. (From Ref. 6.)

site is then in a more hydrophobic environment in the holoenzyme than in the apoenzyme. All water molecules that are located in the active site in the apoenzyme are displaced in the ternary complex, and the catalytic reaction of the enzyme takes place in a completely water-free environment (15). The increase of hydrophobicity around the nicotinamide group in the ternary enzyme-NAD<sup>+</sup>-alcohol complex facilitates the reaction (8).

### 3. Catalytic Domain

The catalytic domain comprises residues 1–175 and 319–374 plus two zinc atoms. Both ends of the polypeptide chain are within this region. The two zinc atoms of the subunit are bound to ligands from the domain; these bindings are illustrated in Fig. 2. Only the zinc atom participates in the catalytic activity; the second zinc atom is remote from the active site and may help in stabilizing protein folding (a structural zinc). Only 19% of the residues are helical ( $\alpha$ 1;  $\alpha$ 2;

$\alpha$ 3, and  $\alpha$ 4); 35% are in pleated-sheet regions ( $\beta$ I,  $\beta$ II,  $\beta$ III), and 14% are in reverse bends. Thus, a large number of residues, 32%, have no regular secondary structure. An important region in the domain, necessary for the structural stability of the enzyme, is the lobe comprising residues 95–113 that binds the structural zinc atom by four sulfur atoms from cysteine residues 97, 100, 103, and 111. Although it is bound near the surface of the molecule, this zinc atom is completely surrounded by the protein and is not accessible in the native conformation of the enzyme (6).

### 4. Substrate-Binding Site

The substrate-binding site, lined almost exclusively by hydrophobic residues, is located in a cleft between the coenzyme-binding core and the catalytic domain. This cleft is open in the apoenzyme form, which is well suited for the initial coenzyme binding and does not hinder its entrance.

The catalytic zinc atom is situated at the bottom of this deep pocket, with a distance of  $\sim$  20–25 Å from the exterior surface of the protein. The active-site zinc performs several functions associated with the catalytic reaction. Three of the four coordination ligands to the catalytic zinc belong to the protein; two sulfur atoms from Cys46 and Cys174 and one nitrogen atom from His67. In the apoenzyme, the fourth ligand is an ionizable water molecule that is hydrogen-bonded to the hydroxyl group of Ser48. Following the binding of the coenzyme, the water is displaced by the substrate. This is facilitated by a coenzyme-induced shift in equilibrium from an open/closed conformation of the enzyme.

## B. Alcohol Dehydrogenase from Yeast (YADH)

YADH has a molecular weight of 150 kDa and contains four identical subunits of  $\sim$  36–37 kDa. Just like in HLADH, each subunit contains two zinc atoms. They have structural and catalytic roles and are bound tetrahedrally to four sulfur atoms all close to one another in the primary sequence (structural zinc atom) or to three protein ligands (two sulfur atoms and one nitrogen atom) and a water molecule or hydroxyl ion, depending on the pH (catalytic zinc atom) (16). The primary structure of YADH has been compared to the known tertiary structure of the corresponding HLADH after proper alignment of the two proteins (17). The results show that YADH and HLADH are distantly homologous with many insertions/deletions and with only 25% of all residues conserved, but all functionally essential residues are similar or identical. Moreover, the difference in the tertiary structures of YADH and HLADH are less than the large differences in the primary structure of these proteins (Fig. 1) (17). This comparison shows that the general subunit conformations and enzymatic mechanisms of both enzymes are probably similar (Table 1). The residues in HLADH that participate in coenzyme binding, substrate binding and the catalysis are listed in Table 1, together with the equivalent residues in YADH.

Quaternary structure of YADH and residues involved in subunit contacts are not yet well known. But, in 1995, De Bolle et al. (18) suggested that a part of the subunit contacts observed in HLADH are located at homologous positions in YADH. The main difference in quaternary structure is likely to be due to surface changes of the subunits.

Four alcohol dehydrogenase isoenzymes are found in the yeast *Saccharomyces cerevisiae*. These enzymes have different substrate specificities and are differen-

tially expressed, at least partly related to the requirement for fermentation or for oxidation of alcohols. The three chromosomally encoded isoenzymes are differentially expressed. Although YADH I and YADH II perform separate metabolic roles, they do not differ greatly in their  $V_{max}$  values for both forward and reverse reactions, but they do differ in their affinity for ethanol as a substrate. YADH I is the fermentative cytoplasmic enzyme that, when the yeasts are grown on glucose under anaerobic conditions, can account for up to 1% of cell protein. An opposite physiological role of ethanol oxidation is carried out by YADH II which converts ethanol accumulated in anaerobic growth to acetaldehyde and is expressed when ethanol is used as a carbon source. These two isoenzymes have

94% sequence homology (11). YADH III is mitochondrially located and has 79% and 78% amino acid identity with YADH I and YADH II, respectively (11). The function of YADH III has not been identified, although its mitochondrial location would indicate that it may have had a role in respiration. Cells lacking YADH III isoenzyme can survive aerobically or anaerobically (11). The fourth ADH is an iron activated enzyme.

#### IV. PROPERTIES AS ENZYMES

##### A. Substrate Specificity and Activity

Alcohol dehydrogenases catalyze the reversible interconversion of a wide variety of aldehyde/alcohol substrates. The specificity of ADHs for their substrates is not the same for all enzymes. In fact, yeast alcohol

dehydrogenase has more restricted specificity than horse liver alcohol dehydrogenase. The activity of YADH decreases as the chain length of the primary alcohols increases (19). YADH and HLADH also have quite different activities and stereospecificities on secondary and branched alcohols. The difference in substrate specificity between HLADH and YADH could be due to a difference in the size of the substrate binding pocket. The main differences in the substrate binding pocket are the changes from Phe93 and Ser48 in HLADH to Trp and Thr, respectively, in YADH. As a consequence YADH has a smaller substrate binding pocket (20).

The activities of HLADH and YADH on primary, secondary, and branched alcohols and the kinetic constants ( $k_{cat}$  [turnover number],  $K_M$ , and  $k_{cat}/K_M$  [catalytic efficiency]) characteristic for HLADH and YADH are listed in Section V (see Tables 2–4).

<sup>a</sup> NA, no measurable activity.

## B. Effects of Environmental Factors

ADHs, like most enzymes, may be affected structurally and catalytically by environmental factors such as pH, temperature, and pressure.

### 1. pH

Alcohol dehydrogenases catalyze a reversible reaction, and forward and backward reactions occur simultaneously. The reaction of NAD<sup>+</sup> acidifies an unbuffered reaction medium by producing a proton while the oxidation of NADH consumes a proton (21). For YADH and HLADH, a double pH dependence for the forward and the backward directions has been established. For YADH, the optimal pH in the forward reaction (oxidation of alcohol) is 8.3 and in the backward direction 6.0 (reduction of aldehyde). These pH optima have been obtained under standard conditions (absence of buffer at high substrate concentration (100 mM), 5 mM NAD<sup>+</sup> or 0.5 mM NADH and zero initial product concentration). The distance between the two optimal pH values (the pH optimal distance) corresponds to two pH units. Other substrates (2-propanol/propanal) shift the optimal pH of the forward and the backward directions by about two pH units toward higher values. Moreover, whatever the substrates, the forward and the backward directions have different maximum rates, even at their corresponding optimal pH (20). In the case of HLADH,

the optimal pH is 9 in the forward direction and 6 in the backward direction. The kinetic constants obtained versus pH are listed in Table 5. The  $K_{eq}$  (equilibrium constant of enzyme-coenzyme complex with substrates) decreases when pH increases. The approximate values are of 2, 1, and 0.1 nM at pH 7, 8, and 9, respectively (22).

### 2. Effect of Temperature on Activities of YADH and HLADH

The optimal temperature for YADH is 25°C. The optimal temperature for HLADH is 53°C. The behavior of YADH and HLADH versus temperature is opposite in direction. Whereas YADH activity decreases when temperature increases above 25°C, HLADH activity increases when temperature increases up to 53°C.

The half-life of YADH is 3.5 h when a solution of YADH at 0.1 mg/mL is stored at 25°C in 50 mM Tris-HCl buffer, pH 8.5 (23). Concerning HLADH, the half-life at 53°C is 8.5 h and it is 14.3 h at 25°C. These studies have been performed in a solution of HLADH at 0.045 mg/mL, in 50 mM Tris-HCl buffer, pH 8 (24).

### 3. Effect of Pressure on Activities of YADH and HLADH

In studying the effect of pressure on YADH activity at 25°C, it has been shown that pressurization of YADH

<sup>a</sup> The values have been determined in the following conditions: T = 23.5°C, in 100 mM sodium phosphate buffers (for experiments at pH 5.35–8) or in 36 mM glycine-NaOH buffer, pH 9, with 1.8–500  $\mu$ M NAD<sup>+</sup>/0.1–8.1 mM ethanol or 0.98–19.6  $\mu$ M NADH/0.027–1.0 mM acetaldehyde.

<sup>b</sup>  $K_M$  for substrate.

resulted in a decrease of catalytic efficiencies. This phenomenon became more pronounced for pressure > 50 MPa. This loss in catalytic efficiency is mainly due to a decrease of  $k_{\text{cat}}$  (70% loss from 0.1 to 175 MPa). On the contrary,  $K_M$  for ethanol seems to be less sensitive to pressure (20% less in the same range of pressure) (25). YADH activity inhibition is therefore not due to a dissociation of the tetrameric enzyme because only the tetrameric form binds ethanol.

In contrast to YADH, HLADH activity increases with pressure up to 225 MPa at 53°C. From atmospheric pressure to 225 MPa  $k_{\text{cat}}$  increases by a factor of 13. But pressure affects the affinity of HLADH for its substrates. At the same conditions  $K_M$  for NAD<sup>+</sup> increases by a factor of 50 and  $K_M$  for ethanol increases by a factor of 45, but the inhibition by ethanol observed at atmospheric pressure is not observed above 150 MPa (24).

#### 4. Some Inhibitors of ADH

There are two general classes of ADH inhibitors. One class includes analogs of alcohols and aldehydes. These compounds bind in the substrate pocket to the catalytic zinc atom displacing the zinc-bound water molecule (ex: pyrazole;  $K_i = 0.22 \mu\text{M}$  [4]). Amides and formamides are analogs of aldehydes and potent inhibitors of HLADH. These inhibitors bind preferentially to the enzyme · NADH complex. The amides inhibit alcohol metabolism and might be useful therapeutic agents—for example, to prevent oxidation of methanol or ethylene glycol to their toxic acids. The amides are uncompetitive inhibitors of ethanol and competitive of acetaldehyde (N-cyclohexylformamide;  $K_i = 8.7 \mu\text{M}$  [26]). The amides may bind to free enzyme or the enzyme · NAD<sup>+</sup> complex (26). The chelating agents such as 2,2-bipyridine ( $K_i = 400 \mu\text{M}$  [4]) or salicylate ( $K_i = 1.25 \mu\text{M}$  [4]) are competitive inhibitors with NAD<sup>+</sup> and NADH and partially competitive with alcohol. These inhibitors bind to the catalytic zinc and displace the zinc-bound water molecule at the presumed substrate binding site. Heterocyclic nitrogen bases such as imidazole form both binary and ternary complexes with HLADH. Imidazole binds to the catalytic zinc in the same way as chelating agents (4).

The second type of ADH inhibitors consists of analogs of the coenzymes NAD<sup>+</sup> and NADH, as well as structurally related compounds. These inhibitors bind in the coenzyme-binding cleft generally mimicking the binding of the adenosine portion of the cofactor. For instance, 5-β-D-ribofuranosylnicotinamide adenosine dinucleotide (CNAD<sup>+</sup>) is an isosteric and isomeric

analog to NAD<sup>+</sup> in which the nicotinamide ring is linked to the sugar via a C-glycosyl (C5–C1') bond and 5-β-D-ribofuranosylnicotinamide adenosine dinucleotide (CPAD<sup>+</sup>) is another one. The inhibition constant of CNAD<sup>+</sup> with respect to NAD<sup>+</sup> is 4 nM; this is significantly smaller than the  $K_i$  for NADH ( $0.4 \mu\text{M}$ ). Further, CNAD<sup>+</sup> competes with both cofactor and substrate binding ( $K_i = 2 \text{ nM}$ ). The other isosteric analog of NAD<sup>+</sup>, CPAD, shows competitive inhibition of NADH with respect to NAD<sup>+</sup> and does not compete with substrate binding (27).

#### 5. Some Inhibitors for YADH (4)

Some coenzyme competitive inhibitors include N-alkyl nicotinamide derivatives (the inhibitory ability increases with increase in length of the alkyl chain), N-alkyl substituted ammonium chlorides and fluorescent dyes, and drugs such as chloroquine and propanol. Other inhibitors include chelating agents such as 1,10-phenanthroline (inhibition is considerably smaller with YADH than with HLADH), and nonchelating analogs such as 1,5-phenanthroline and 2,9-dimethyl-1,10-phenanthroline. With pyrazole, the inhibition is competitive with ethanol and uncompetitive with coenzyme and acetaldehyde and with 4-substituted pyrazole amide derivatives (weaker inhibitors than pyrazole). Thiocyanate is an inhibitor that is competitive with ethanol and noncompetitive with NAD<sup>+</sup>. It is reversible or irreversible depending on the concentration. Urea at low concentrations inhibits the enzyme noncompetitively with respect to NAD<sup>+</sup>, NADH, alcohol, and aldehyde, and at higher concentrations inhibits the enzyme irreversibly. Thiourea, guanidium salts, phenylisopropyl hydrazine, and canavanine are also inhibitors.

#### C. Reaction Mechanism of HLADH

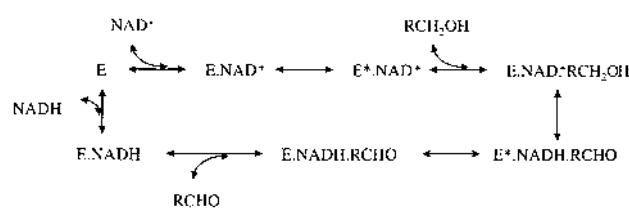

The enzyme binds coenzyme and substrate to form a ternary complex which, in general, can be assumed to be ordered with coenzyme binding preceding substrate binding and product release preceding coenzyme release.

Aldehyde formation during the catalytic action of the enzyme requires a net removal of two hydrogen atoms from an alcohol substrate. This dehydrogenation process is known to proceed by a mechanism of combined proton and hydride ion transfer. It is well established that transfer of the hydride ion occurs directly between substrate and coenzyme in the productive ternary complex formed. The first step is an

initial binding of NAD<sup>+</sup>. The E · NAD<sup>+</sup> complex isomerizes (i.e., changes conformation) with a forward rate constant of 620 sec<sup>-1</sup> at pH 8 and 1100 sec<sup>-1</sup> at pH 7.6 (28). By isomerization of the enzyme · NAD<sup>+</sup> complex, the *pK<sub>a</sub>* of the zinc bound water molecule is shifted from ~ 9.6 to ~ 7.6 (29). This isomerization is facilitated in the presence of alcohol in which case the *pK<sub>a</sub>* drops to < 4.5. As a result of this isomerization, a hydroxide ion remains bound to the zinc atom, and a proton is released. It has been suggested that this proton is released through the system of hydrogen bonds involving Ser48 and His51 (28). The electric field created by the protein framework facilitates this proton tunneling along the hydrogen bonds. The presence of NAD<sup>+</sup> and zinc with a small positive charge further enhances this effect. It is similar to a proton pump which pumps protons from the interior hydrophobic pocket to the surface of the molecule. The transfer of the proton from the alcohol to the enzyme active site occurs simultaneously with the hydride transfer from the substrate to the coenzyme. Figure 3 presents the ordered ternary complex mechanism during HLADH catalysis.

The rate of the conformational change (isomerization) could limit the transient rate of oxidation of alcohol. The isomerization of the E · NAD<sup>+</sup> complex is partially, but not fully, rate limiting for the oxidation of longer-chain alcohols. The rate of interconversion of ternary complexes can be limited by the rate of transfer of hydride ion from alcohol to NAD<sup>+</sup>, the release of a proton to solvent, or other unimolecular steps depending on the substrate (28).

When NAD<sup>+</sup> concentrations are approximately stoichiometric with enzyme, HLADH catalyzes the dismutation of different aldehydes to equimolar quantities of the corresponding alcohol and acid (30). This

**Figure 3** The ordered ternary complex mechanism usually considered for evaluation of the kinetics of HLADH catalysis. E, E · NADH, E\* · NAD<sup>+</sup>, E · NAD<sup>+</sup> · RCH<sub>2</sub>OH, and E\* · NAD<sup>+</sup> · RCH<sub>2</sub>OH denote enzyme, coenzyme-enzyme complex, coenzyme-enzyme complex isomerized, enzyme-coenzyme-alcohol complex, and enzyme-coenzyme-alcohol complex isomerized, respectively. (From Ref. 28.)

reaction is spectrophotometrically silent because there is no net synthesis of NADH. The *V<sub>max</sub>* for dismutation is higher than that for oxidation of the corresponding alcohol. At high concentrations of NAD<sup>+</sup>, the enzyme catalyzes oxidation of aldehydes to acids with net NADH production with a *V<sub>max</sub>* much less than that for alcohol oxidation (30).

## D. Reaction Mechanism for YADH

The main features of the reaction mechanisms for YADH are in all probability essentially the same as in HLADH (because of structural similarities of the catalytic domain of the two enzymes). Finer details of the reaction mechanism, however, are different between the two enzymes. There are differences in substrate specificity, in the rate of catalysis, and in the requirements for ordered events during the catalytic mechanism which may be random or ordered depending on substrate (31). The step of dissociation of NADH from the enzyme could be the rate-limiting step in the oxidation of alcohol.

## V. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

### A. Specific Activity with Assay Conditions

ADH activity assays for alcohol oxidation or aldehyde reduction were followed by an increase or a decrease of NADH absorption at 340 nm, respectively. As the molar absorptivity of NADH at 340 nm is dependent on the conditions of pH, ionic strength, buffer, temperature, and pressure, it must be determined for each kinetics condition (25, 32). However, some characteristics of HLADH must be known before using this enzyme. Its isoelectric point is 6.8, its optimal pH is ~ 9, its optimal temperature is 53°C. In Tables 2 and 3 some kinetic parameters obtained for oxidation of alcohol or reduction of aldehydes catalyzed by HLADH under different assay conditions are presented.

As for HLADH, some characteristics of YADH must be known before using this enzyme. Its isoelectric point is 5.4, its optimum pH is ~ 8.6 (for the alcohol oxidation), its optimal temperature is 25°C. The specific substrates and the corresponding kinetic constants are listed in Table 4.

## B. Enzyme Stability

Lyophilized preparations of YADH stored at  $-20^{\circ}\text{C}$  are stable for 6–12 months. Crystalline suspensions in ammonium sulfate are stable for 6 months at  $2\text{--}8^{\circ}\text{C}$ . However, preserving an active enzyme solution remains a problem. A solution of enzyme (0.1 mg/mL in 50 mM Tris-HCl buffer, pH 8.5) stored at  $4^{\circ}\text{C}$  is not stable; its half-life ( $t_{1/2}$ ) is 4.5 h. When stored at  $-20^{\circ}\text{C}$ , its half-life is 56 h. In order to increase the stability of the enzyme solution, it has been shown that storing the enzyme with NAD<sup>+</sup> (1.5 mM) or with NAD<sup>+</sup>/sorbitol (1.5 mM/1 M), enhances the stability. The  $t_{1/2}$  ( $25^{\circ}\text{C}$ ) was 28 h with NAD<sup>+</sup> and 16 h for NAD<sup>+</sup>/sorbitol. The  $t_{1/2}$  ( $4^{\circ}\text{C}$ ) increases to 82 and 68 h in the presence of NAD<sup>+</sup> and NAD<sup>+</sup>/sorbitol, respectively (23).

Both lyophilized and crystalline suspensions in buffer preparations are stable for 3–6 months when HLADH is stored at  $-20^{\circ}\text{C}$ . In solution, HLADH was more stable than YADH; at the same storage conditions of buffer and temperature, the  $t_{1/2}$  ( $25^{\circ}\text{C}$ ) is 680 h and the  $t_{1/2}$  ( $4^{\circ}\text{C}$ ) is 755 h (24). See above for stability of YADH under these conditions. To stabilize the enzymes, it is possible to add bovine serum albumin at 1 g/L.

## VI. PURIFICATION OF ADH

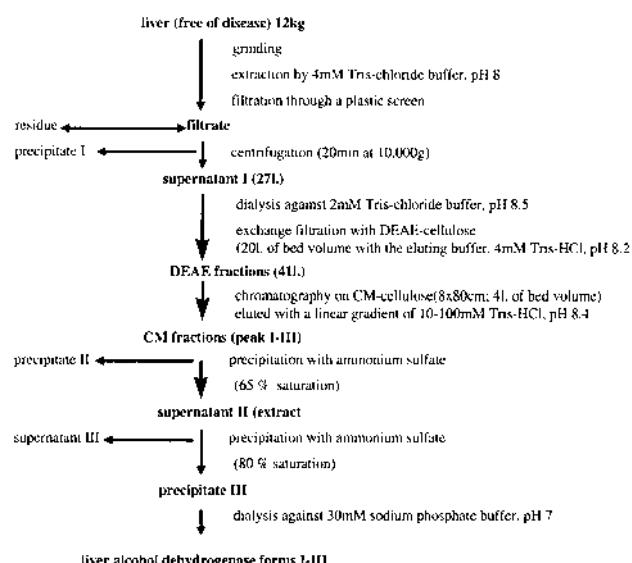

The enzyme has been purified, and the EE and SS isoenzymes separated by affinity chromatography on an immobilized AMP analog. Commercially available preparations contain the EE isoenzyme and small amounts of the ES isoenzyme (4). The more studied YADH is a cytoplasmic protein, commercially available and usually obtained from baker's yeast. Several purification methods have been reported including toluene plasmolysis; DEAE-cellulose chromatography; fractionation with protamine sulfate and calcium phosphate gel; and purification without autolysis, heat denaturation, or use of solvents. Separation of YADH from enzyme mixtures by affinity chromatography on immobilized NAD<sup>+</sup> or AMP analogs has also been reported (4). It is now not necessary to purify HLADH and YADH in one's laboratory because of their commercial availability at low price and high purity. Table 6 presents the characteristics of commercially available HLADH and YADH.

**Table 6** Characterization of Commercially Available Alcohol Dehydrogenase

	Yeast ADH	Horse liver ADH
Classification	medium-chain dehydrogenase	medium-chain dehydrogenase
Required coenzyme	NAD(H)	NAD(H)
Specific activity (U/mg)	300 <sup>a</sup>	1–2 <sup>a</sup>
Enzyme costs (\$/500 units)	2	330
Stability Limitations	sensitive to O <sub>2</sub> low stability	stable

<sup>a</sup> oxidation of 1  $\mu\text{mol}$  ethanol/min.

Figure 4 shows an example of purification of human liver alcohol dehydrogenase (which is very similar to HLADH except in regard to specificity) (37). Human liver alcohol dehydrogenase has been purified by a procedure designed to process 10- to 20-kg quantities of liver. The results are summarized in Table 7.

**Figure 4** Example of purification: human liver alcohol dehydrogenase (which is very similar to HLADH except in regard to specificity). (From Ref. 37.)

**Table 7** Large-Scale Purification of Human Liver Alcohol Dehydrogenase

Fraction	Vol (L)	Act. ( $\Delta A_{340}$ nm/min)	Protein (mg)	Specific act. ( $\Delta A_{340}$ nm/min/mg)
Crude extract	27	24,000	760	0.03
Dialyzed extract	32	23,300	770	0.03
DEAE-cellulose-treated extract	41	19,200	36	0.53
Concentrated CM-cellulose eluates				
Peak I	0.16	1,000	0.78	1.1
Peak II	0.19	2,700	2.6	1.0
Peak III	0.21	1,920	2.4	0.8

Source: Ref. 37.

The total activity recovered from CM-cellulose column chromatography, which represents 60–70% of that present in the DEAE-cellulose-treated extract, exceeds that exhibited by the selected fractions from peaks I–III which were combined and concentrated.

## Amine Oxidase

**Akio Ito and Jichun Ma**

*Kyushu University, Fukuoka, Japan*

### I. INTRODUCTION

Amine oxidase catalyzes the reaction  $\text{RCH}_2\text{NH}_2 + \text{O}_2 + \text{H}_2\text{O} \rightarrow \text{RCHO} + \text{H}_2\text{O}_2 + \text{NH}_3$  with mono-, di-, or polyamine as substrate. Amine-oxidizing enzymes are classified by their prosthetic group(s), FAD or copper plus topaquinone, or by their sensitivity to inhibitors, 2-chlorocyclopropylamine or semicarbazide. The FAD-containing amine oxidases have monoamine-oxidizing activity, and most of the copper-containing enzymes belong to the diamine-oxidase type.

### II. MONOAMINE OXIDASE (FAD-CONTAINING)

Monoamine oxidase (EC 1.4.3.4; MAO) is a flavin-containing enzyme. It catalyzes the oxidation of aliphatic and aromatic primary, secondary, and tertiary amines.

Two forms of MAO, MAOA and MAOB, are defined by their substrate and inhibitor affinities. MAOA has a higher affinity for catecholamines and 5-hydroxytryptamine (5-HT or serotonin) and is more sensitive to inhibition by clorgyline, whereas MAOB has a higher affinity for dietary amines such as phenylethylamine and is selectively inhibited by deprenyl (1, 2).

In human and animals, the enzyme plays an important role for the metabolism of biogenic monoamines in the central nervous system and peripheral tissues. MAO oxidizes neurotransmitters such as serotonin

and dopamine, and the synthetic tertiary amine 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) has been found to be oxidized by both forms of MAO, which suggests that MAO may oxidize MPTP analogs and generate toxic effects on the central nervous system. These features make MAO an extremely important enzyme related to neuronal dysfunction in schizophrenia, Parkinson's disease, Down's syndrome, and some other neurodegenerative diseases and psychological disorders in human, and vast numbers of its inhibitor have been developed as medicines.

#### A. Properties as Protein

The study of MAO has a long history. However, it was at the end of 1980s that the cDNA cloning of MAOA and MAOB ended the notion that MAOA and MAOB were the same protein with different catalyzing sites or that they had different functions at different environments, and proved that they were different proteins. Essentially, all higher eukaryotic organisms express MAO (3). Both forms of MAO are localized in the outer mitochondrial membrane. They are expressed at different levels in different cell types. For example, the highest expressions of both forms are found in the liver for most species. Placenta expresses predominantly MAOA whereas platelet contains primarily MAOB. Most of the other tissue cells express both forms of MAO.

MAOA and MAOB are encoded by two very similar but different genes. In human and probably in

other mammals, the two genes are closely linked on the X-chromosome (Xp11.23–11.4) (4), suggesting that the two genes may have arisen from duplication of a common ancestral gene. Amino acid sequences of MOAO and MOAB are deduced from cDNAs for human, bovine, and rat enzymes (5–8). MAOA and MAOB contain 527 and 520 amino acid residues (rat MAOA lacks one amino acid residue at the carboxy-terminus), respectively. Molecular mass of human MAOA and MAOB are 59.7 and 58.8 kDa, respectively. Approximately 90% of the amino acid residues are identical among the same forms of MAO from different species, while there is only 70% homology between MAOA and MAOB from the same species. One highly conserved region, residues 389–460 for MAOA and 380–451 for MAOB, contains the cysteine (residue 406 for MAOA and residue 397 for MAOB) to which the FAD covalently binds as 8- $\alpha$ -S-cysteinyl-FAD. The N-terminus shows significant similarity to several flavoproteins. This region fulfills the criteria for a predictive fingerprint for a flavin-binding domain and contains the FAD- and ADP-binding  $\beta\alpha\beta$  fold. This structure has been suggested to act as a “nucleation center.” That is, during biosynthesis this domain will form first, and the rest of the protein structure forms around it. The C-termini of both forms of MAO are responsible for anchoring the enzyme to the outer membrane of mitochondria (9).

## B. Properties as Enzyme

Since the crystal structures of both forms of MAO have not been established, the actual mechanism of catalysis has yet to be elucidated. A conserved region in the central parts of the proteins (residues 187–230 for MAOA and 178–221 for MAOB) is postulated as part of the active site. Chimeric and site-directed mutation studies suggest that the region between about residues 120–220 for MAOA and 111–211 for MAOB are responsible for substrate specificity (10, 11) and the phenylalanine of residue 208 for MAOA and isoleucine of residue 199 for MAOB are found to be the key amino acids responsible for substrate selectivity. Exchange of these two residues by site-directed mutation leads to an exchange of the enzyme properties; that is, F208I-MAOA shows properties of MAOB, and I199F-MAOB shows properties of MAOA (12).

MAO catalyzes many compounds. The typical substrate is 5-HT for MAOA and phenylethylamine (PEA) and benzylamine for MAOB. MPTP is found to be a substrate of MAOB, although it is oxidized by MAOA at a lower rate. The kinetic parameters for

substrate specificity and inhibition from different laboratories' publications show divergence. Since the  $K_m$  value is a ratio of rate constants, it is easily varied with the purity and the lipid content of the preparation. Lipophilic substrates may be concentrated around the mitochondrial membrane to which the MAO is located, leading to a lower apparent  $K_m$  when using mitochondria than when using purified MAO for the assay (13). The same is true in the assay for reversible inhibition. **Table 1** summarizes some results on the specificity of MAOA and MAOB for a number of substrates. Some are from assays using purified MAO, others from that using mitochondria or whole cell extract.

Since the discovery that MAO inhibitors are antidepressants, large numbers of inhibitors of MAOA and MAOB have been synthesized. The early MAO inhibitors were hydrazine or cyclopropylamine derivatives that showed little selectivity to the two forms of MAO. The acetylenic MAO inhibitors, clorgiline and (–)-deprenyl, however, exhibit a high degree of selectivity to MAOA and MAOB, respectively. They have been found to act as mechanism-based irreversible inhibitors of MAO. These compounds first form a noncovalent complex with the active site of the enzyme, followed by the normal catalytic process to generate a reactive species, which reacts with the enzyme to form an irreversibly inhibited species. Another type of inhibitor is a selectively reversible inhibitor, which can sometimes be derived from the substitution of the hydrogen at  $\alpha$ -carbon of MAO substrate by a methyl group. The affinity of MAO to these inhibitors is often higher than it is for its substrates, with a  $K_i$  value of  $10^{-5}$  to  $10^{-9}$  M vs a  $K_m$  value of  $10^{-4}$  to  $10^{-5}$  M. This may be a reflection of the fact that  $K_m$  is not a simple dissociation constant for the initial noncovalent complex but includes steps that may orient the  $\alpha$ -C-H so as to optimize orbital overlap for both the electron transfer and proton abstraction processes (14).  $IC_{50}$ s of some inhibitors are summarized in **Table 2**.

## C. Determination of Activity

The widely used methods for determination of activity of MAO are the kynuramine oxidation method and radiochemical method.

### 1. Kynuramine Oxidation Method

Kynuramine can be oxidized by both MAOA and MAOB to produce 4-hydroxylquinoline, which has

**Table 1** Kinetic Parameters of MAOs for Some Substrates

Substrate	Turnover number (sec <sup>-1</sup> )		<i>k</i> <sub>cat</sub> (sec <sup>-1</sup> )		<i>K</i> <sub>m</sub> (μM)		Note	Ref.
	MAOA	MAOB	MAOA	MAOB	MAOA	MOAB		
Kynuramine	146				170		purified human MAO	17
			11.63		121.5		human MAO expressed in HEK293 cell	11

the highest absorption at 315 nm and fluorescences at 380 nm. According to the absorbance or the intensity of fluorescence, the concentration of the product can be quantitatively determined. The following protocol is a modification of Krajl's method (15). In a test tube, mix 0.25 mL of 200 mM potassium phosphate buffer, pH 7.5, and suitable volume of the enzyme sample. Add distilled water to a final volume of 0.90 mL. Incubate the test tube at 30°C for 5 min, then add 0.10 mL 1 mM kynuramine preincubated at 30°C, mix immediately, and incubate at 30°C with shaking for 20 min. Terminate the reaction by adding 0.4 mL of 20% TCA. Precipitate the protein by centrifugation at 10,000 g for 10 min. Take 0.5 mL of the supernatant and add 1.5 mL of 1 N NaOH, and measure the intensity of fluorescence at a wave-

length of 380 nm with an excitation wavelength of 315 nm.

## 2. Radiochemical Method

This method provides more sensitive determination but needs special devices and laboratory for using radioisotopes. Many <sup>14</sup>C-labeled substrates for MAO are commercially available. For example, DuPont NEN(r) provides hydroxytryptamine binoxalate, 5-[2-<sup>14</sup>C]tryptamine bisuccinate, [side chain-2-<sup>14</sup>C]tyramine hydrochloride, [1-<sup>14</sup>C]phenylethylamine hydrochloride, etc. MAO can oxidize these compounds and produce radioactive products. The enzyme activity can be estimated by measuring the radioactivity of the products.

**Table 2** *IC*<sub>50</sub> of Some Inhibitors for MAOs

Hot and cold substrates are mixed to a final concentration of 5 mM (usually, the hot accounts for 1/50 by concentration when using ~1.5 GBq/mmol hot substrate) to make an application solution of substrate. In each Eppendorf tube, add 10  $\mu$ L of 300 mM potassium phosphate buffer, pH 7.5, and certain volume of sample (e.g., 50  $\mu$ g of rat liver mitochondrial protein), and add sample buffer to make a final volume of 54  $\mu$ L. Incubate the tube at 30°C for 1 min, and start the reaction by adding 6  $\mu$ L of application substrate. Incubate at 30°C for 20 min and stop the reaction by adding 40  $\mu$ L of 2 M HCl. Add 300  $\mu$ L water-saturated ethyl acetate-toluene (1 : 1 v/v) and vortex to extract the product. Centrifuge at 10,000 g for 1 min and transfer 200  $\mu$ L into a new tube. Add same volume of 0.5% PPQ; measure the radioactivity in a liquid scintillation spectrometer. Blank should be made by adding 2 N HCl before adding the substrate.

#### D. Purification

The Welter and Salach's procedure (16) is widely used for purification of MAOA. Briefly, mitochondrial fraction containing 140–150 units of enzyme activity is homogenized with glass/Teflon homogenizer in 0.1 M triethanolamine HCl buffer, pH 7.2, to give a final concentration of 20 mg protein/mL. The homogenate is digested with 1 mg and 670 units of phospholipases C and A, respectively, per 500 mg of the total protein in the presence of 25 mM CaCl<sub>2</sub> at 25°C for 1 h. After centrifugation of the mixture at 43,000 g for 15 min at 15°C, the pellet is resuspended in the same buffer to give a concentration of 15 mg protein/mL, solubilized with Triton X-100 at a final concentration of 1 mg detergent/3 mg protein, and centrifuged at 43,000 g for 15 min at 15°C. For each 8 mL of resulting supernatant, add 0.5 g of dextran (average Mr 500,00) and 0.4 g of PEG (average Mr 8000) and centrifuge at 9500 g for 20 min.

This produces a two-phase system. The enzyme in the upper layer is precipitated by addition of PEG to 25%, resuspended in 20 mM sodium phosphate buffer, pH 7.2, solubilized by octylglucoside at 2 mg/mg protein and subjected to DEAE-Sepharose CL-6B column chromatography. The enzyme is eluted with a linear gradient of 20–250 mM potassium phosphate buffer, pH 7.0, containing 20% glycerol (w/v), 0.8% octylglucoside, 3 mM 2-mercaptoethanol, and 1 mM D-amphetamine. The buffer should first be made anaerobic and anaerobiosis should be maintained in the gradient chambers during the elution. This will result in partially purified MAOA. Further purification by

hydroxyapatite chromatography is not encouraged because it leads to obvious inactivation, although this can produce almost homogeneous MAOA.

MAOB can be purified essentially by the same method, but use Ficol, dextran, and PEG at the polymer partition step. MAOB will go to the interface between the upper (Ficol-PEG) and lower (dextran) layer, mainly in the solid material. See Salach (19) for details.

### III. AMINE OXIDASE (COPPER-CONTAINING)

The copper-containing amine oxidase (EC 1.4.3.6 amine:oxygen oxidoreductase [deaminating]) is obtainable from bacteria, fungi, higher plants, blood plasma, and various mammalian organs. Most of this type of enzymes contain a cofactor possessing one or more carbonyl groups, making them sensitive to inhibition by carbonyl reagents such as semicarbazide and are classified as semicarbazide-sensitive amine oxidase (SSAO). The enzyme is relatively abundant comprising at least 0.1% total soluble protein in etiolated pea seedling, but its function(s) remain unclear despite extensive study. Amine oxidases in *Lens* and *Pisum* are absent in ungerminated seeds, and appear during the early period of germination. The enzyme activity is greatest in the growing parts of the plant and decreases with maturity and senescence.

Plasma copper-containing amine oxidase is soluble, while in most tissues the enzymes appear to be membrane bound, as plasmalemmal enzymes, which may be capable of metabolizing extracellular amines. A possible role for the cellular amine oxidase is the regulation of histamine and polyamine levels, whereas the serum proteins have been speculated to control the level of circulating biogenic amines such as dopamine and phenylethylamine. For review articles, see references (20–27).

#### A. Properties as Protein

Copper amine oxidases are homodimers of 70–95 kDa subunits depending on the source (Table 3) (28–33). Each subunit contains one Cu(II) and a quinone cofactor. The enzyme-bound copper is removable by treatment with diethyldithiocarbamate at acidic pH. Inactive apoprotein recovers its original activity on addition of cupric ion. A quinone cofactor was identified as 2,4,5-trihydroxyphenylalanine quinone (TPQ or TOPA quinone) first in the bovine serum enzyme.

**Table 3** Molecular Properties of Some Cu-Containing Amine Oxidases

Enzyme source	Molecular weight (subunit)	Cu/mol	Absorption maxima	Yield starting material	Ref. No.	Ref. for cDNA cloning	Ref. for crystal structure
<i>Arthrobacter</i>	167,900 (82,250) <sup>a</sup>	2	480 nm $A_{480/280} = 0.0137$	92 mg/84 g wet weight	28	44 47	61
<i>Asp. niger</i>	150,000 (75,000)	1	490 ( $\epsilon = 5300 M^{-1} cm^{-1}$ )	427 mg/105 L culture	29	29	
Pea seedling	113,000 (77,000)	2	525 nm ( $\epsilon = 1200 M^{-1} cm^{-1}$ )	0.68 mg/2 kg seedling	30	48	60
Bovine plasma	180,000 (90,000)	2	480 nm	36 mg/5 L blood	31	46

Porcine aorta	200,000 (95,000, 102,000)		456 nm (+nitrophenyl hydrazine neutral pH)		33		

<sup>a</sup>Subunit mw.

Subsequently TPQ has been identified biochemically and its presence inferred from amino acid sequence homology in copper-containing amine oxidases from various sources (34–40).

Amine oxidase cDNA clones have been obtained from various sources, and the primary structure of the enzyme was deduced from the cDNAs (41–52). Sequence alignment of representative amino acid sequences of bacterial, yeast, plant, and mammalian amine oxidases suggests separate protein domains with a carboxyl-terminal domain encoding the cofactor consensus sequence and putative copper-binding sites, and a more divergent amino-terminal domain accommodating differing physiological functions and substrate specificities of these proteins. There are 33 completely conserved residues mainly within two regions: residues 286–459 in the pea enzyme, approximately centered on Tyr387, and the C-terminal end. In this enzyme the amino acid sequence of the phenylhydrazine-labeled peptide was determined to be VGNXDNDID, in which the X corresponds to Tyr387. TOPA quinone is posttranslationally generated by oxidation of a specific tyrosine precursor occurring in the consensus sequence of NYD/E in the active site of amine oxidases (53–57). The oxidation to TPQ is a spontaneous reaction mediated by the bound copper ion. Numerous studies point toward the presence of three histidines as ligands to copper in the enzyme. One HXH motif 40–50 residues toward the carboxyl terminus from the cofactor consensus sequence is conserved in all alignments.

Crystal structures have recently been reported for several amine oxidases (58–62).

## B. Properties as Enzyme

The enzyme catalyzes the oxidation by molecular oxygen of the primary amino group of di- and polyamines to corresponding amino aldehydes, hydrogen peroxide, and ammonia. The amino aldehyde products from putrescine, cadaverine, and spermidine spontaneously cyclize to  $\Delta 1$ -pyrroline,  $\Delta 1$ -piperidine, and 1,5-diazabicyclononane, respectively.

Substrate specificity varies widely among the different enzymes (Table 4) (20–32, 63, 64). The best substrates for all plant enzymes are putrescine and cadaverine. The relative reaction rates with some substrates are shown in Table 4.  $K_m$  values for putrescine seem to be of the same order of magnitude for all enzymes investigated (0.1 mM). The pH optimum is found around pH 7.0 with putrescine or cadaverine as substrate. Plasma and tissue amine oxidases also show considerable species-related variations in substrate specificity. Some endogenously occurring aromatic amines such as tyramine and tryptamine are metabolized well by copper-containing amine oxidase in homogenates of rat blood vessels, and also in vitro inhibition of the enzyme can potentiate vasoconstrictor actions of these amines in rat vascular preparations. These amines are poor substrates for human amine oxidase, thus complicating attempts to generalize possible physiological roles for these enzymes. The

**Table 4** Substrate Specificity of Some Cu-Containing Amine Oxidases

Enzyme source	Substrate	Kinetic parameters		Compound not oxidized	Ref.
		V or $k_{cat}$	$K_m$ (mM)		
<i>Arthrobacter</i>	methylamine	68 ( $\mu$ mole/min)	0.20	tyramine, spermine, putrescine	28
	ethylamine	85	0.15		
	benzylamine	32	3.76		
Yeast ( <i>Candida boidinii</i> , methylamine oxidase)	methylamine	2.41 (mmole/min/mg)	0.227	benzylamine	63
	ethylamine	5.05	0.77		
	phenylethylamine	0.815	0.11		
<i>Asp. niger</i>	n-hexylamine	100 (relative rate)		spermidine	29
	benzylamine	36.0			
	histamine	42.0			
	tyramine	109.8			
	putrescine	6.3			
Pea seedling	putrescine	165 ( $sec^{-1}$ )	0.19	cyclohexylamine (competitively inhibit, $K_i = 0.045$ mM), diethylamine	30
	cadaverine	498	0.065		
	spermidine	193	5.9		
Bovine plasma	butylamine	0.1 (relative rate)		ethylamine, tyramine, tryptamine, serotonin	64
	amylamine	2.5			
	heptylamine	5.4			
	benzylamine	6.1	0.025		
	spermine	10.0			
Bovine lung	kynuramine	1.0			
	benzyl amine	170 ( $sec^{-1}$ )	0.05		32
	phenylethylamine	62	1.19		
	methylamine	580	0.21		
	histamine	110	1.11		

endogenously occurring aliphatic amines methylamine and aminoacetone are metabolized in vitro to formaldehyde and methyglyoxal, respectively, by amine oxidase in some animal (including human) tissues suggesting the possibility of toxicological consequences of cellular function (21–23, 25–27).

Inhibitors are common to all these enzymes. Metal chelators such as diethyldithiocarbamate, cuprizone, *o*-phenanthroline, 2,2'-bipyridil, 8-hydroxyquinoline, and CN compounds inhibit Cu-containing amine oxidases noncompetitively with different sensitivities. Carbonyl group reagents irreversibly form adducts with the enzymes with concomitant loss of catalytic activity. The most effective agents are hydrazines (phenylhydrazine and benzylhydrazine), hydrazides (semicarbazide, thiosemicarbazide, and phenylsemicarbazide), hydroxylamine, isoniazide, and iproniazid (20–27).

In addition to the protein absorbance maximum at 278 nm, the visible spectrum of the enzyme is characterized by a broad absorption peak centered around 500 nm which confers a typical pink color to purified

preparations of the enzyme (28–33). The extinction coefficient at 500 nm is  $4100\text{ M}^{-1}\text{ cm}^{-1}$  and at 278 nm is  $246,000\text{ M}^{-1}\text{ cm}^{-1}$  for highly purified *Lens* enzyme. The aerobic addition of phenylhydrazine and semicarbazide to the *Lens* enzyme is followed by the formation of a strong absorption band at 445 nm ( $\epsilon = 64,000\text{ M}^{-1}\text{ cm}^{-1}$ ), 492 nm ( $\epsilon = 8,600\text{ M}^{-1}\text{ cm}^{-1}$ ), and 360 nm ( $\epsilon = 34,800\text{ M}^{-1}\text{ cm}^{-1}$ ), respectively, concomitant with the disappearance of the absorption band at 500 nm. In anaerobiosis a stable yellow intermediate absorbing at 346, 432, and 462 nm is observed in the presence of substrates. Under this condition a Cu(I)-semiquinone state is generated by substrate reduction, and this intermediate may react directly with oxygen. The interaction of the *Lens* enzyme with primary amines gives rise to a covalent amino group quinone compound, a quinoketimine, which is converted to quinoaldimine. This releases the aldehyde product and forms a species containing Cu(II) and a reduced form of TPQ, aminocatechol, which coexists with the radical species containing Cu(I) and TPQ semiquinone. Finally, the semiquinone reacts with

oxygen and restores the oxidized enzyme, liberating ammonia and hydrogen peroxide (24, 65).

### C. Determination of Activity

The enzyme activity of amine oxidase is measured by various methods, including radiochemical, spectrophotometrical, and polarographical techniques. When necessary, MAO activity is inhibited by preincubation with 1 mM clorgyline or deprenyl.

In a radiochemical method (32, 66), the reaction is carried out at 37°C in a final volume of 225 µL of 50 mM potassium phosphate buffer, pH 7.2, with radio-labeled substrates (e.g., 20 µM [<sup>14</sup>C]benzylamine [3 mCi/mmol], 100 µM [<sup>14</sup>C]2-phenylethylamine [2.5 mCi/mmol], etc.) and is stopped by the addition of 100 µL of 2 M citric acid. Radioactively labeled products are extracted with toluene/ethyl acetate (1:1, v/v) containing 0.6% (w/v) 2,5-diphenyloxazole before liquid scintillation counting. In the assay for the activity toward methylamine (100 µM [<sup>14</sup>C]methylamine [1 mCi/mmol]) as substrate, the reaction is stopped by cooling the tube in an ice bath and the reaction product ([<sup>14</sup>C]formaldehyde) is separated from unchanged amine by the use of a 1-mL Amberlite C6-50 (carboxylic form) column.

In a polarographical method (67), the reaction is monitored with a Clark electrode using air as the gaseous phase. The standard reaction mixture (1 mL) contains 50 µg catalase and the reaction is started by the addition of a small volume of amine substrate (as hydrochloride) after at least 10 min preincubation.

The activity of partially purified enzyme in the presence of detergents can be determined spectrophotometrically by a peroxidase-linked method (68). Assay is conducted in 200 mM potassium phosphate buffer, pH 7.6, with 1 mM of benzylamine or putrescine as substrate, and 1 mM vanillic acid, 0.5 mM 4-aminoantipyrine, and 4 U/mL horseradish peroxidase, as chromogenic reagents. Absorbance change is monitored continuously at 498 nm ( $\epsilon_{498} = 4,654 \text{ M}^{-1}\text{cm}^{-1}$ ) by a spectrophotometer.

### D. Purification

The enzyme has been purified to homogeneity from bacteria, plant, and mammalian tissues by standard methods involving homogenization, salting out, and various chromatography techniques (28–33, 67).

One representative method for the plant enzyme is as follows (30). Eight-day-old lentil seedlings are homogenized in a Waring blender with water and the

homogenate is subjected to controlled heat treatment (48°C, 10 min) followed by centrifugation. To the supernatant ammonium sulfate is added to 70% saturation and centrifuged. The precipitate is dissolved in water, dialyzed, and loaded onto a DEAE-cellulose column equilibrated with 15 mM potassium phosphate buffer, pH 7, and eluted with the same buffer. The eluate containing the activity is diluted with an equal volume of water and applied to an AH-Sepharose 4B column. The enzyme is eluted with 50 mM potassium phosphate buffer, pH 7, with 43% recovery and 880-fold purification; 0.25 mg of the enzyme is obtained from 900 g of lentil seedling.

Membrane-bound amine oxidase has recently been purified from bovine lung microsomes (32). The enzyme is solubilized with Triton X-100 and purification is achieved, in the presence of detergent, by chromatography with Cibacron Blue 3GA-agarose, hydroxylapatite, *Lens culinaris* agarose, Resource Q-FPLC, and gel filtration on Superdex 200 HR-FPLC. The enzyme was purified 2320-fold from the microsomal membranes with an overall yield of 15%.

## Prolyl 4-Hydroxylase

**Robert B. Rucker, Ana Samimi, and Jerold A. Last**

*University of California, Davis, Davis, California, U.S.A.*

### I. INTRODUCTION

#### A. Chemical Reactions Catalyzed

Prolyl 4-hydroxylase catalyzes the formation of 4-hydroxyproline residues in collagens and a number of other proteins in both plants and animals, e.g., acetylcholine esterase, C1q component of complement, and elastin. Equation (1) shows the conversion of L-proline to L-hydroxyproline.

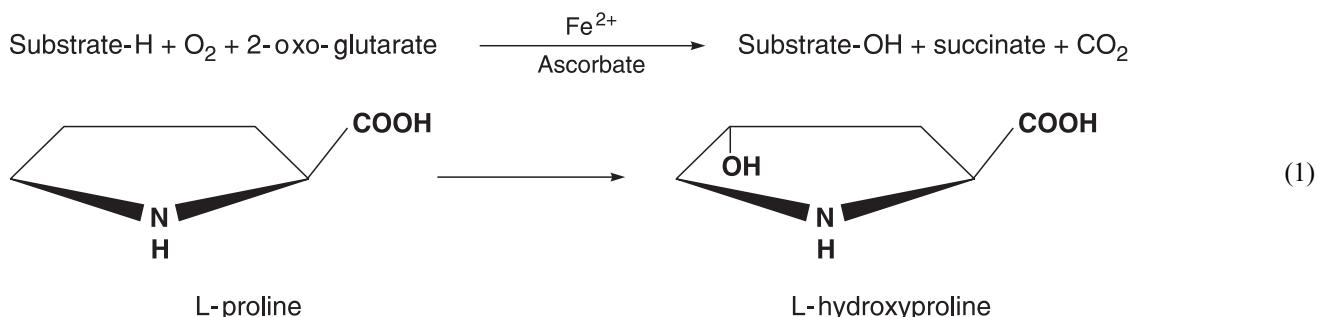

#### B. Chemical Structure of Substrates

In vertebrate animals, an -X-Pro-Gly- triplet fulfills the minimum sequence requirement for interaction with prolyl 4-hydroxylase, wherein the Pro residue is hydroxylated (1–3). For example, the Pro residue in the central position of -Gly-Pro-Pro- or -Pro-Gly-Pro is not hydroxylated. Moreover, in vertebrate animals, single polypeptide chains serve as substrates. Useful synthetic

substrates are (Pro-Pro-Gly)<sub>5</sub> or (Pro-Pro-Gly)<sub>10</sub>. In noncollagenous proteins, such as C1q complement, 4-hydroxyproline is found in -Ala-X-4Hyp-Gly- and -Gly-X-4-Hyp-Ala- sequences. In nonvertebrate collagens, Pro in the sequence, -Pro-Y-Gly-, is the preferred site of hydroxylation (1), and in plants, Ser-Pro-Pro-Pro-Pro- is the preferred sequence, in contrast to the -X-Pro-Gly- sequences in animals (4, 5). Polyproline-enriched sequences are common to plant structural proteins, e.g., the hydroxyproline-rich glycoproteins (4). The plant enzyme also recognizes and hydroxylates substrates with distinguishable secondary and tertiary structure (5).

#### C. Enzyme Commission Designation

The systematic name and number for prolyl 4-hydroxylase are 4-proline:2-oxo-glutarate dioxygenase and EC 1.14.11.2, respectively.

## **II. PHYSIOLOGICAL IMPORTANCE**

The formation of hydroxyproline is necessary for the intracellular assembly of procollagen polypeptide chains into helical structures. When collagen chains are underhydroxylated, helical formation is impaired and collagen is retained within the cell. As a consequence, underhydroxylation of collagen leads to decreased collagen production (1–3, 6). In plants, increased hydroxyproline-rich glycoprotein synthesis is associated with wound healing and resistance to fungal infections. Impaired hydroxylation impairs the ability to respond to infections and wounds, particularly situations wherein encapsulation of a foreign substance is a requisite (5).

## **III. LOCATION IN TISSUES**

Prolyl 4-hydroxylase is found in the rough endoplasmic reticulum in loose association with the cistern inner membrane. Prolyl hydroxylation takes place while the polypeptide chain is growing on the ribosome. In plants, hydroxylation also occurs within the cistern of the rough endoplasmic reticulum. The enzyme is ubiquitous, wherever collagen is found in animals or hydroxyproline-rich glycoproteins are found in plants (1–5).

## **IV. COMMERCIAL APPLICATIONS**

There are few commercial applications for prolyl hydroxylase per se. However, inhibitors of prolyl hydroxylase are considered valuable if they can effectively modulate wound healing or abnormal collagen deposition.

## **V. PHYSICAL AND CHEMICAL PROPERTIES**

The descriptions that follow apply mostly to vertebrate prolyl 4-hydroxylase. For additional descriptions regarding plant prolyl 4-hydroxylase or prolyl 3-hydroxylase, the reader should refer to references 3–5 and 7, respectively.

### **A. Molecular Weight and Structural Characteristics**

The enzyme from human placenta and chick embryos exists as a heterotetramer (an  $\alpha_2\beta_2$  tetramer) with a

molecular weight of 240,000. The cDNA encoding the enzyme has been characterized from chicken, human, and rat (1–3). The  $\alpha$ -subunit from mammalian sources is 64,000 daltons. The  $\alpha$ -subunit contains the active site, but does not have detectable prolyl hydroxylase activity unless assembled as the heterotetramer. The  $\beta$ -subunit has a molecular weight of 60,000 daltons. Although in most animals both the  $\alpha$ - and  $\beta$ -subunits are necessary for activity, prolyl 4-hydroxylase activity in algae and some plants is structurally related to only the  $\alpha$ -subunit (7).

The  $\beta$ -subunit is identical to the enzyme protein disulfide isomerase (8–11). The  $\beta$ -subunits also provide retention and docking signals for prolyl hydroxylase within the endoplasmic reticulum (2). In addition, Wilson et al. (9) have provided data that the  $\beta$ -subunit acts as a chaperone for procollagen chain assembly. Of interest, there is also partial sequence homology between the  $\beta$ -subunit and thyroid hormone-binding protein, phospholipase C, thioredoxin, and the estrogen-binding domain of the estrogen receptor (2, 3).

### **B. Genes and Posttranslational Modifications**

The cDNA for prolyl hydroxylase has been cloned and the active enzyme expressed in insect cells using a baculovirus vector (12). When the  $\alpha$ - and  $\beta$ -subunit cDNAs are expressed separately in baculovirus, neither has prolyl 4-hydroxylase activity, but when they are expressed together, prolyl 4-hydroxylase activity is observed (12). The gene coding for the  $\alpha$ -subunit sequence has been mapped to the human chromosome 10 (q21.3–23.1 region), while the  $\beta$ -subunit maps to human chromosome 17 q25, the same chromosome that contains the gene for the type I collagen  $\alpha$ -chains (13, 14, 15).

With regard to posttranslational processing, the  $\alpha$ -subunit contains 16 residues of mannose, one residue of galactose, and two residues of N-acetylglucosamine. The  $\beta$ -subunit contains two residues of mannose and three residues of galactose (2, 3). Using a cell-free system, John and Bulleid (12) have shown that enzyme assembly is redox sensitive and ATP dependent. The assembled subunits are intramolecularly crosslinked by disulfide bonds.

## **VI. ENZYMATIC PROPERTIES**

### **A. Substrates**

As noted above, the peptides (Pro-Pro-Gly)<sub>5</sub> or (Pro-Pro-Gly)<sub>10</sub> are excellent substrates for detection

of prolyl 4-hydroxylase activity. The  $K_m$ s for these substrates are in the 1–10  $\mu\text{M}$  range.

## B. Effect of Environmental Factors

Mammalian prolyl 4-hydroxylase is often assayed at the physiological pH and temperature corresponding to that of the source. Activity is lost upon freeze/thawing and concentration. The enzyme is best stored at –20°C in ethylene glycol.

## C. Cofactors and Proposed Mechanism

The reaction mechanism involves the following proposed sequence of scheme:

### Phase I

### Phase II

\*Ascorbic acid is essential in keeping both iron and the enzyme in a reduced state. Enzyme activity is lost after four to six catalytic turns if a strong reducing agent, such as ascorbic acid, is not present. The  $K_m$  values for  $\text{Fe}^{2+}$ , 2-OG, and ascorbate are 2, 5, and 100  $\mu\text{M}$ , respectively. 2-OG, 2-oxoglutarate; Succ, succinate.

## D. Inhibitors

Several classes of inhibitors for prolyl hydroxylase have been described, including proline analogs, agents that interfere with 2-oxoglutarate or cofactor binding, and peptides containing 5-oxoproline (1–3). Table 1 lists various inhibitors and their modes of action.

## VII. DETERMINATION OF ACTIVITY

The standard prolyl 4-hydroxylase assay is based on the release of tritium from underhydroxylated procollagen  $\alpha$ -chains (1, 27). Although tedious to prepare and sometimes variable in consistency, tritiated procollagen substrate can be used in assays that are reliable in providing good relative values for enzyme activity when appropriately standardized. The procedure for substrate preparation is largely adapted from Peterkofsky and DiBlasio (28), Kivirikko and Myllyla (1) and Kivirikko et al. (2). The method may be used to prepare a [ $^3\text{H}$ ]-L-proline labeled collagen substrate of high specific activity.

### A. Substrate Preparation

Step 1. Chick embryo calvaria (15 days old) are incubated in the presence of [2,3,4,5- $^3\text{H}$ ]proline (16 Ci/mmole [New England Nuclear, MA] in the proline-free basal medium (Dulbecco's modified Eagle's medium [DME], GIBCO, Long Island, NY) with  $\alpha$ - $\alpha'$ -dipyridyl to inhibit endogenous hydroxylation of procollagen chains. First, a basal medium is prepared containing DME with  $\text{NaHCO}_3$  (3.7 g/L), penicillin (100 units/mL), streptomycin (100  $\mu\text{g}/\text{mL}$ ), and sodium ascorbate (50  $\mu\text{g}/\text{mL}$ ) added. This medium is adjusted to pH 7.6.

Step 2. From 100 to 200 calvaria should be used. The calvaria (one per 0.5 mL) are first incubated in the basal DME medium without isotope addition at 39–40°C for 1 h.

Step 3. Next, the calvaria are transferred to basal DME, but with the following additions: sodium pyruvate (1.0 mM),  $\alpha$ , $\alpha'$ -dipyridyl (0.2  $\mu\text{M}$ ), and L-[2,3,4,5- $^3\text{H}$ ]proline at 5 Ci/mL. Culture flasks are flushed with 95% oxygen 5%  $\text{CO}_2$ , capped, and the incubation is continued for 12–24 h.

Step 4. The calvaria are harvested by decanting the medium. The decanted medium is saved, centrifuged (2000 g for 10 min) to remove particulate material, and dialyzed against distilled water to remove unincorporated [ $^3\text{H}$ ]-L-proline. Following dialysis, the medium is stored (–20°C) and saved for Step 5.

Step 5. The decanted calvaria are homogenized in 0.5 M acetic acid (1:5 w/v) using a Polytron (Brinkman Instruments) and extracted twice (12 h each with agitation at 4°C). Since the dialyzed medium contains collagen, it is added to the acetic acid extracts. The combination is exhaustively dialyzed against 0.05 M Tris, pH 7.4, until < 100 dpm of [ $^3\text{H}$ ]-L-proline is detected per mL dialysate.

**Table 1** Examples of Prolyl 4-Hydroxylase Inhibitors

Inhibitor	Description	Ref.
Active-site modification		
Diethyl pyrocarbonate	Modification of active site histidine residues, $K_i \sim 10 \mu\text{M}$	7
Substrate binding		
Mimosine	$\text{IC}_{50} \sim 100 \mu\text{M}$	16, 17
S4682	$K_i \sim 150 \text{nM}$	18
Iron chelation		
Pirfenidone (methyl-1-phenyl-2-[ <sup>1</sup> H]-pyridone)	Can be used in vivo (0.5% of diet, w/w)	19
HOE 077 (2,4-pyridine dicarboxylic acid bis[2-methoxyethyl] amide)	Can be used in vivo (200 $\mu\text{g/g}$ dry food)	20
$\alpha, \alpha'$ -dipyridyl and related compounds	Classical inhibitor of prolyl and other iron-requiring hydroxylases, $K_i \sim 1 \mu\text{M}$	21, 22
2,2'-bisbipyridine-5,5'-dicarboxylic acid	Most potent inhibitor of its type, $K_i \sim 50\text{--}100 \text{nM}$ . Note: 2,2'-bipyridines lacking a 5-carboxylate are poor inhibitors	23
2-Oxo-glutarate binding		
2,7,8-trihydroxyanthraquinone	Competes with 2-oxo-glutarate, $K_i \sim 40 \text{nM}$	24
Oxalylalanine and oxalylglycine	Structural analogs of 2-oxoglutarate in which the $\text{CH}_2$ moiety is replaced by -NH-, $K_i \sim 100\text{--}200 \text{nM}$	25, 26

Step 6. Following dialysis, the material is aliquoted and frozen until use. Note, however, that the storage of tritiated samples in the frozen state can result in some tritium exchange with water. Additional dialysis prior to use or passage through a Sephadex G-10 column equilibrated in sample buffer to remove tritiated water is often necessary. As a quality control measure, the collagenous nature of the substrate may be assessed by digestion overnight with purified bacterial collagenase (1). The digested material is divided into two portions: one that was dialyzed against 0.05 M Tris buffer at pH 7.8 and one that was not dialyzed. Loss of > 80% of the tritium following collagenase digestion and dialysis indicates that most of the labeled material is collagen.

## B. Assay for Prolyl Hydroxylase

Step 1. The assay reaction mixture (0.5 mL) should contain 80  $\mu\text{M}$   $\text{FeSO}_4$ , 0.5 mM 2-oxo-glutarate, 0.1 mM dithiothreitol, 2.0 mM sodium ascorbate, 1 mg bovine serum albumin, and 300 units of catalase dissolved in 0.05 M Tris-HCl buffer, pH 7.8. The substrate should contain at least 100,000 dpm of tritium. Prior to its addition, the substrate should be boiled for 8–10 min to denature the collagen. Reaction mixtures are incubated at 37°C for 1 h on a rotating platform in

13 × 100 mm glass culture tubes, and the reaction is stopped by freezing.

Step 2. The tritiated water that is released (Step 1) is collected by vacuum distillation (60°C) and radioactivity determined (1). Hughes (27) has described a simple method for measuring release of tritium that may also be considered. A useful variant of this assay is to use ion-exchange chromatography to separate the tritiated substrate from tritiated water (28), allowing one to omit the vacuum distillation step and the need for specialized equipment (see chapter on Lysyl Oxidase).

Step 3. Data are expressed as tritium released per mg protein and tissue weight of the extract or DNA in the sample. This assay is reliable when at least 10 ng of prolyl 4-hydroxylase is present in samples. The assay is also useful for semiquantification, if standardized by using purified or partially purified prolyl 4-hydroxylase as a reference. The assay is linear over the range of 5–50 ng of enzyme.

The same procedures may be used to prepare [<sup>14</sup>C]-L-proline-labeled collagen as substrate. About 40,000–50,000 dpm of [<sup>14</sup>C]-L-proline-labeled collagen is needed per assay. This substrate may be stored for long periods (10–16 months), in contrast to the tritiated substrate. [<sup>14</sup>C]-L-hydroxyproline formed during the enzymatic reaction can be measured following hydrolysis (6 N HCl, 12–24 h, 98°C) by any procedure

that allows precise and reliable measurement of [ $^{14}\text{C}$ ] as hydroxyproline.

Prolyl 4-hydroxylase activity can also be assayed by the decarboxylation of 2-oxo-[1- $^{14}\text{C}$ ]glutarate. In this case, the assay mixture can be similar to that described above, except 1 mg/mL ( $\text{Pro-Pro-Gly}_{10}$ ) is used as substrate (1). The reaction is followed by measuring the release of  $^{14}\text{CO}_2$  (for additional details see Ref. 29).

### VIII. PROLYL 4-HYDROXYLASE PURIFICATION

For purification of prolyl 4-hydroxylase, we use a procedure adapted from Kivirikko and Myllyla (1). The procedure is simple and based on the affinity of the enzyme for poly-L-proline linked to agarose, elution with a low-molecular-weight poly-L-proline peptide, and gel filtration. Using this method, prolyl 4-hydroxylase has been isolated from a number of sources, e.g., chick embryos, cultured fibroblasts, and skin. Steps in purification are as follows.

Step 1. Poly-L-proline (MW 500–20,000) may be obtained from a number of commercial sources. Poly-L-proline is coupled to agarose by cyanogen bromide activation. Commercially available forms of activated agarose are also available from a number of vendors, which simplifies this process. Briefly, 100 mL of 4% agarose is used (Sepharose 4B, Pharmacia, washed twice with deionized water). Cyanogen bromide (25 g) is added, and the reaction is allowed to proceed for 15–20 min at 4–8°C with stirring. The pH is maintained at 11.0 by addition of a saturated solution of NaOH. The mixture is next washed on a Buchner funnel using a solution containing 0.14 M NaCl and 0.1 M  $\text{NaHCO}_3$ , pH 9.0. When the pH reaches 9.9–9.5, the coupling reaction is carried out by stirring into the gel ~1 g of poly-L-proline (MW 30,000). The reaction is allowed to proceed overnight and the final gel product is washed extensively with water, followed by buffer containing 0.1 M NaCl, 0.1 M glycine, 10 mM dithiothreitol, and 0.01 M Tris-HCl adjusted to pH 7.8. The efficiency of coupling can be estimated by taking an aliquot of the gel, subjecting the aliquot to hydrolysis in 6 M HCl (98°C for 16 h), and measuring the total proline content by standard procedures for amino acid analysis. The poly-L-proline content should be 3–5 mg/mL gel.

Step 2. Next, the gel is poured into a column with a bed volume of 40–60 mL and equilibrated with enzyme buffer (1 M NaCl, 0.1 M glycine, 10  $\mu\text{M}$

dithiothreitol, and 0.01 M Tris-HCl buffer, pH adjusted to 7.8).

Step 3. A crude enzyme extract is prepared by homogenizing from 200 to 1000 g of tissue in enzyme buffer (1 M NaCl, 0.1 M glycine, 10  $\mu\text{M}$  dithiothreitol, and 0.01 M Tris-HCl buffer, pH adjusted to 7.8 containing 0.1% Triton X-100). The extract should be 1:4 w/v. The homogenization is usually carried out using a Waring blender. For tendon, skin, aortae, we have found that first “powdering” small pieces of the tissue (3–5 g each) in a commercial blender (appropriately vented) or with a mortar and pestle in the presence of liquid nitrogen increases the yield of enzyme.

Step 4. The homogenate is allowed to stand with occasional stirring for 15 min and then centrifuged at 15,000 g for 30 min. This and subsequent steps are carried out at 4–8°C unless stated otherwise. This step may be repeated.

Step 5. Solid  $(\text{NH}_4)_2\text{SO}_4$  is slowly stirred into the supernatant fraction from Step 4 to a final concentration of 25%. After centrifugation at 15,000 g for 20 min, the pellet is discarded and solid  $(\text{NH}_4)_2\text{SO}_4$  is slowly stirred into the supernatant fraction to a final concentration of 70% saturation. Following centrifugation (15,000 g for 20 min), this pellet is dissolved into buffer (see above) and aliquots (corresponding to 50 g tissue) are dialyzed to remove  $(\text{NH}_4)_2\text{SO}_4$  and then stored at –20°C.

Step 6. When enzyme is needed, an aliquot of the  $(\text{NH}_4)_2\text{SO}_4$  fraction is thawed and adjusted with buffer to yield ~10 mg of soluble protein/mL. The sample is passed through the affinity column at a flow rate of about 40–60 mL/h, and the column is washed with enzyme buffer until the absorbance of the eluate (at 230 nm) is 0.05 or less. The enzyme is then eluted with 20 mL enzyme buffer containing 3 mg poly-L-proline/mL (MW < 6000). The column may be regenerated by washing with 6 M urea and re-equilibration with enzyme buffer.

Step 7. The pooled fractions containing activity are concentrated to ~2 mL using an Amicon ultrafiltration cell.

Step 8. For further purification, this sample is centrifuged at 20,000 g for 10 min, and the clear supernatant is applied to an 8% agarose gel column (BioGel A-1.5m, 200–400 mesh, 1.5 × 90 cm, Bio-Rad, Richmond, CA). Prior to application of the sample, the column is equilibrated with enzyme buffer. Following application of the sample, the column is eluted with enzyme buffer. Fractions are collected and their absorbance is monitored (230 nm). The frac-

tions containing activity are pooled and concentrated by ultrafiltration. Since poly-L-proline eventually adsorbs to the column, after three or four uses the column packing should be discarded.

This procedure is highly specific for prolyl hydroxylase and usually results in a several thousand-fold purification.

**Note added in proof:** Since submission of this chapter, several relevant articles have appeared. Briefly, isoforms of prolyl hydroxylase generated by alternative splicing have been identified in both human and mouse (30). Prolyl hydroxylase  $\alpha$ (I) gene is inducible by hypoxia (31), providing an explanation for observations made more than 20 years ago that hypoxia increases its enzymatic activity.

## Lysyl Hydroxylase

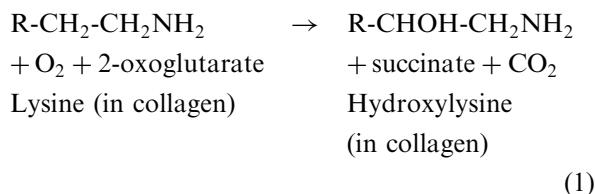

Ana Samimi, Jerold A. Last, Lucas C. Armstrong, and Robert B. Rucker

*University of California, Davis, Davis, California, U.S.A.*

## I. INTRODUCTION

## A. Chemical Reactions Catalyzed

Lysyl hydroxylase catalyzes the oxidation of specific lysine residues in collagen to hydroxylysine. The reaction sequence is given in Eq. (1)

where R = (HOOC-(CH<sub>2</sub>)<sub>2</sub>-NH<sub>2</sub>)

## B. Chemical Structure of Substrates

The enzyme recognizes the sequence X-Lys-Gly. In some types of collagen, hydroxylation of lysine residues occurs at the end of  $\alpha$ -chains in the short non-triple-helical region where there is recognition of triplet sequences, e.g., X-Lys-Ser and X-Lys-Ala. In addition to collagens, the lysine in sequences X-Lys-Ser, X-Lys-Ala, and X-Lys in arginine-rich histone proteins can also be hydroxylated (1). Evidence now points to the possibility that different isozymes of lysyl hydroxylase are responsible for catalyzing these varied substrate recognition sequences. Lysine vasopressin, which has the structure Cys-Thr-Phe-Gln-Asn-Cys-Pro-Lys-Gly-NH<sub>2</sub>, and lysine-rich histone, which contains X-Lys-Gly sequences, also act as substrates of lysyl

hydroxylase. The tripeptide Lys-Gly-Pro is not hydroxylated whereas a tripeptide Ile-Lys-Gly is hydroxylated by lysyl hydroxylase. This indicates a minimum structural requirement of an X-Lys-Gly triplet for this enzyme.

Studies with synthetic peptides have shown that the amino acid sequences, as well as the peptide chain length and peptide conformations, are critical for determining their specificity as substrates. Ile-Lys-Gly, (Ile-Lys-Gly)<sub>2</sub>, and (Ile-Lys-Gly)<sub>5</sub>-Phe have been shown to have, respectively, Lys  $K_m$ s of 4, 1, and 0.14  $\mu\text{M}$  (2). The conformation of the peptide may regulate the extent of hydroxylation of the peptide. It has been suggested that a  $\beta$ -bend involving the lysine to be hydroxylated is required for lysyl hydroxylase recognition (3). Some amino acid sequences around the Y positioned lysine can in effect prevent hydroxylation of the lysine by exerting a conformational change not inherently recognizable to the enzyme.

### C. Enzyme Commission Designation

Lysyl hydroxylase, classified as a member of the keto-glutarate-dependent dioxygenase family, has the official name of lysine:2-oxoglutarate 5-dioxygenase and an EC number of 1.14.11.4.

## II. PHYSIOLOGICAL IMPORTANCE

The conversion of collagen-bound lysine to hydroxylysine alters the properties of the collagen crosslinks.

e.g., instead of Schiff-base products and simple aldimines, ketoamine derivatives also become possibilities. Further, hydroxylation provides a site for the O-glycosylation of collagen (4). Both functions are important determinants of the final structure and properties of the mature collagen fibres. The O-glycosylation results in the addition of either galactose as a monosaccharide or glucosylgalactose as a disaccharide linked to the hydroxylysyl residue(s).

Nascent collagen  $\alpha$ -chains, not triple helical collagen, are the substrates for lysyl hydroxylase. Generally nonhelical lysyl residues are preferred sites of hydroxylation over residues occurring in the helical regions of the collagen chain. However, this property is related to the rate of folding of the collagen molecule; overhydroxylation of helical lysyl residues occurs under conditions of delayed or impaired assembly of the triple helical form of collagen (5–7). Lysyl residues in denatured (nonhelical) collagen may also be hydroxylated by the enzyme (8). There are differential hydroxylation levels in different collagens; type IV is relatively heavily hydroxylated as compared, for example, with types I or III collagens. In addition, lysyl residues in the same collagen type may be differentially hydroxylated (and glycosylated) in different tissues. Bone collagen (type I) contains relatively more hydroxylysine than type I collagen from lung, skin, or liver, and hypertrophied tendon contains relatively more hydroxylysine than does normal tendon (9). There are also apparent age-related variations in the level of lysine hydroxylation in collagen (10). Finally, hydroxylysine also occurs in noncollagenous proteins that have a triple helical collagenlike domain in their structure, such as C1q (complement component), acetyl cholinesterase, and other related proteins (1).

Evidence for the biological importance of collagen lysine hydroxylation catalyzed by lysyl hydroxylase comes from patients with Ehlers Danlos Syndrome Type VI, who exhibit thin skin, loose joints, and ocular disruption. These patients are deficient in collagen hydroxylysine and lysyl hydroxylase activity. In several such patients, defects in the lysyl hydroxylase gene have been identified (6, 7, 11). Increases in collagen lysine hydroxylation and/or lysyl hydroxylase activity have been described in a number of pathological conditions, including dimethylnitrosamine-induced liver fibrosis (12) and bleomycin-induced pulmonary fibrosis (13). Abnormal hydroxylation of lysyl residues causes changes in the ratios of hydroxylysinoleucine (HLNL) and dihydroxylysinoleucine (DHLNL), two lysine- and/or hydroxylysine-derived crosslinks,

and may thereby affect the tensile strength of the collagen fibrils in the tissues involved (14, 15).

### III. LOCATION IN TISSUES

Lysyl hydroxylase is an intracellular enzyme found within the lumen of the rough endoplasmic reticulum, where it comes in contact with nascent collagen chains prior to their folding. It can hydroxylate lysyl residues on unfolded nascent collagen chains, but has no demonstrable activity on triple helical collagen. This enzyme is ubiquitous, wherever collagen is found; that is, all organs of the body contain some level of this enzyme. In Northern blot analysis of total RNA or poly (A)<sup>+</sup> mRNA from various adult rat tissues, the rat lysyl hydroxylase cDNA probe (the so-called type I lysyl hydroxylase; see below) hybridizes to a 3.2-kb mRNA in all tissues, with highest levels of expression in liver, lung, heart, and cartilage.

### IV. COMMERCIAL APPLICATIONS

There are none at this time. The enzyme has been notoriously difficult to purify, is sparingly soluble in aqueous buffers, and is fairly labile (16). Thus, pure enzyme is not easily prepared, and has mainly been produced by recombinant DNA techniques. Since the enzyme is a glycoprotein, its cognate DNA has to be expressed in an eukaryotic vector such as a baculovirus system (17, 18) to prepare active enzyme. Inhibitors of lysyl hydroxylase such as minoxidil (19) may have future biomedical or clinical applications as preventive agents for various fibrotic disorders, but none has yet been approved for this indication because of their toxicity.

### V. PHYSICAL AND CHEMICAL PROPERTIES

The descriptions that follow apply to vertebrate lysyl hydroxylase.

#### A. Molecular Weight

The enzyme has been purified from human placenta and chick embryos, and it chromatographs as a homodimer of two identical 85,000-MW  $\alpha$ -subunits on a gel filtration column (20).

## B. Structural Characteristics

The cDNA encoding the enzyme has been characterized from chicken, human, and rat (17, 21, 22). Although the sequence does not closely resemble any other known protein, there is much homology in the C-terminal region between various species. The C-terminal region also contains two histidyl residues that may be conserved between different members of the  $\alpha$ -ketoglutarate-dependent dioxygenase family (23).

The lysyl hydroxylase cDNA sequence has little similarity to the prolyl 4-hydroxylase  $\alpha$ - or  $\beta$ -subunit cDNA sequences (21, 22). The rat cDNA encodes a protein of 728 amino acids, and has an overall homology at the protein level of 91% and 77% to the human and chicken lysyl hydroxylases, respectively.

Two histidyl residues in the chicken lysyl hydroxylase and other members of the  $\alpha$  ketoglutarate-dependent dioxygenase family have been identified as possible catalytic sites (11). These histidyl residues are conserved in the rat lysyl hydroxylase, and indeed the sequence around these histidyl residues is also perfectly conserved between human and rat. It has been proposed that two histidyl residues, located 30–50 amino acids apart in the primary sequence which are conserved in different members of the  $\alpha$ -ketoglutarate-dependent dioxygenase family, may be involved in cofactor binding (23). Conservation of the histidyl residues and surrounding residues in the rat lysyl hydroxylase supports this hypothesis. Although these enzymes can be inactivated by diethylpyrocarbonate, a histidine reactive reagent, the direct involvement of these particular residues in cofactor binding has not been demonstrated (23).

### 1. Genes

There are three known isoforms (from DNA sequences) arising from different, although closely related, genes (18, 24). Isoform-1 in the human gene (PLOD) has been mapped to chromosome 1p36.3-36.2 (22). Isoform-2 has been mapped in human gene (PLOD2) at 3q23-q24 (25), and isoform-3 has been mapped to the human gene (PLOD3) at chromosome 7q36 (24).

### 2. Posttranslational Processing

Lysyl hydroxylase is a glycoprotein wherein the asparagine-linked carbohydrate units are critical for the enzyme's activity. Four consensus sites for N-linked glycosylation are found in the rat lysyl hydroxylase. Three of these are in the same location as in the

human and the chicken lysyl hydroxylases. Interestingly, Asn163 in the human lysyl hydroxylase has been replaced with a serine at the corresponding residue 164 in the rat, while Ser176 in the human enzyme has been converted to a consensus glycosylation site asparagine at residue 177 in the rat (17–19). It is not known which of these sites is glycosylated in the mature protein.

## VI. ENZYMATIC PROPERTIES

### A. Substrates

Several synthetic peptides have been shown to be good substrates for determining lysyl hydroxylase activity. In addition to lysine vasopressin and (Ile-Lys-Gly)<sub>2</sub> (as mentioned earlier), Ala-Arg-Gly-Ile-Lys-Gly-Ile-Arg-Gly-Phe-Ser-Gly, Ala-Arg-Gly-Met-Lys-Gly-His-Arg-Gly-(Pro-Pro-Gly)<sub>4</sub> and (Pro-Pro-Gly)<sub>4</sub>-Ala-Arg-Gly-Met-Lys-Gly-His-Arg-Gly-(Pro-Pro-Gly)<sub>4</sub> can be used in enzymatic assays. Their respective  $K_m$ 's are 1.1, 2.0, 0.4, 0.2, and 0.2  $\mu\text{M}$  (2).

Underhydroxylated procollagen substrate can also be prepared from chick calvaria or chick embryo tendon (20).

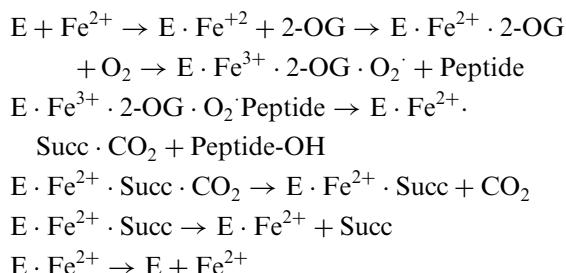

### B. Effects of Environmental Factors

Vertebrate lysyl hydroxylase is assayed under physiological conditions of 37°C and pH 7.8. Activity is lost by 50% after one freeze-thaw cycle or several days at 4°C. In ethylene glycol, the enzyme is fairly stable and can be stored at -20°C for several months.

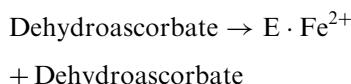

### C. Proposed Mechanism

Lysyl hydroxylase and prolyl-4-hydroxylase are very similar in their substrate and cofactor requirements. Both enzymes are therefore classified as  $\alpha$ -ketoglutarate-dependent dioxygenases, which couple hydroxylation to the conversion of oxygen and  $\alpha$ -ketoglutarate to succinate and CO<sub>2</sub>. These enzymes also require Fe<sup>2+</sup> and ascorbate as cofactors. Furthermore, both prolyl 4-hydroxylase and lysyl hydroxylase require that the hydroxylated amino acid be in the Y position of the (X-Y-Gly)<sub>n</sub> collagen motif.

The following reaction sequence is involved in the hydroxylation of lysyl residues by lysyl hydroxylase:

If the enzyme is oxidized it can be reduced by ascorbic acid and is therefore regenerated to undergo further catalytic reaction cycles (see reaction below). The  $K_m$  values for  $Fe^{2+}$ , 2-OG, and ascorbate using procollagen as a substrate are: 2, 70, and 200  $\mu M$ , respectively (Table 1).

#### D. Inhibitors

Inhibitors of lysyl hydroxylase can be grouped as given in Table 2 (1, 4).

## VII. DETERMINATION OF ACTIVITY

### A. Determination of Tritiated Water Release

Determination of lysyl hydroxylase activity by tritiated water release is conveniently performed by a modification of the method of Peterkofsky and DiBlasio (27), as described in detail elsewhere (13). For direct determination of tritiated procollagen substrate in assay mixtures, the trichloroacetic acid-precipitable material from the enzymatic reaction after addition of lysyl

hydroxylase is digested with 18 units of type VII collagenase (Sigma, St. Louis, MO) for 24 h at 37°C. The reaction mixture is fractionated by passage through a Centricon 10 ultrafiltration unit (Amicon, Beverly, MA). The separated fractions are hydrolyzed in 6 N HCl at 110°C overnight. HPLC separation of hydroxylysine and lysine in hydrolysates is performed by isocratic reversed-phase HPLC. A Beckman C18 Ultrasphere column ( $0.46 \times 25$  cm) is equilibrated and run with 23% 1-propanol, 0.3% sodium dodecyl sulfate, 0.01 M phosphate, pH 2.84, as the elution solvent (28). Fractions from the HPLC are collected and mixed with an appropriate scintillation cocktail and radioactivity determined.

### B. Decarboxylation of 2-Oxo[1- $^{14}\text{C}$ ]Glutarate

This assay is based on the determination of the stoichiometric release of  $^{14}\text{CO}_2$  from 2-oxo[1- $^{14}\text{C}$ ]glutarate during the enzymatic assay. Synthetic peptides can be utilized as substrates instead of natural procollagen substrates, which allow for a more rapid and simple assay (20).

The procedure involves sequential addition of substrate, enzyme, and cofactors (ferrous iron, ascorbate, and 2-oxo[1- $^{14}\text{C}$ ]glutarate), as well as supplements bovine serum albumin, catalase, and dithiothreitol to the assay mixture, which is maintained at a pH of 7.8 in 0.05 M Tris-HCl buffer. The assay mixture is kept on ice until the final compound is added, after which it is immediately sealed with a rubber stopper containing a  $1.5 \times 3.0$  cm Whatman filter paper saturated with NCS hung from a wire hook. NCS is a quaternary amine that is sold as a proprietary product of Amersham Pharmacia Biotech. Incubation is at 37°C in a shaker water bath for 30–40 min. The vials are then transferred to an ice bath where they are acidified

**Table 1** Recombinant and Native Lysyl Hydroxylase Kinetics

	$K_m$					(cpm $^3\text{H}/\text{h}/\text{mg} \times 10^{-5}$ )
	Ascorbate	$\alpha$ -Ketoglutarate $\mu M$	$O_2$ $\mu M$	$Fe^{2+}$ $\mu M$	Procollagen pM	
Recombinant lysyl hydroxylase (rat)	122	106	ND	ND	100	60
Lysyl hydroxylase (chick embryo)	220	70	ND	2	10	20.2

**Table 2** Lysyl Hydroxylase Inhibitors

Inhibitor	Description
Interference with Fe <sup>2+</sup> binding	
Zn <sup>2+</sup>	Competes with Fe <sup>2+</sup> ; 5 μM
α, α'-dipyridyl	Chelates Fe <sup>2+</sup>
Interference with O <sub>2</sub> binding	
Zn, Cu superoxide dismutase	Dismutation of activated oxygen; 30 μM
Nitroblue tetrazolium	Scavenges activated oxygen
Interference with 2-oxoglutarate binding	
Pyridine 2,4-dicarboxylate	Competes with 2-OG; 50 μM
Pyridine 2,5-dicarboxylate	Competes with 2-OG; 150 μM
Some TCA cycle intermediates	Compete with 2-OG
Coumalic acid	Suicide substrate, 2-OG analog; > 2 mM
Active site interference	
Diethyl pyrocarbonate	A histidine reactive reagent, > 50% inhibition at 50 μM
Mechanism unclear	
Minoxidil	> 50% inhibition at > 50 μM

by injection of an equal volume of KH<sub>2</sub>PO<sub>4</sub>, pH 5.0, buffer. The reaction is allowed to incubate at room temperature for 30 min, after which the filters are placed in a toluene-based scintillation cocktail (20).

### VIII. LYSYL HYDROXYLASE PURIFICATION

All steps are carried out at 4°C. Chick embryos (14 days old; 50–100 embryos) are homogenized (1:4) in an enzyme buffer (0.2 M NaCl, 0.1 M glycine, 10 μM dithiothreitol, 0.02 M Tris-HCl buffer, pH 7.5, containing 0.1% Triton X 100 and 60% (v/v) glycerol). This homogenate is centrifuged at 15,000g for 30 min and then subjected to ammonium sulfate precipitation. The supernatant is saturated to 17% with solid (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and centrifuged at 15,000g for 20 min, the pellet is discarded, and the supernatant is once again saturated to 55% with (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and centrifuged at 15,000g for 20 min. This pellet is dissolved in the enzyme buffer and dialyzed against two 16-L volumes of the same buffer supplemented with 0.003 M MnCl<sub>2</sub> overnight. The dialyzed fraction is adjusted to ~ 20 mg protein/mL and next passed (flow rate, 40–50 mL/h) through a concanavalin A-agarose affinity column (40–50 mL of packed gel) equilibrated with the dialysis buffer. Lysyl hydroxylase is then competitively eluted with methyl α-D-glucoside (1 M) dissolved in the enzyme buffer and ethylene glycol (40%:60%, v/v).

The effluent from chromatography on concanavalin A-agarose is next dialyzed overnight against enzyme

buffer in preparation for collagen-agarose affinity chromatography. The collagen-agarose affinity column is prepared by coupling citrate-soluble calf skin collagen to cyanogen bromide-activated agarose (20). The entire dialysate is applied to the collagen-agarose column. The enzyme is eluted from the column with enzyme buffer containing 60% (v/v) ethylene glycol.

As a final step, the enzyme fractions containing activity are concentrated to 2–3 mL by ultrafiltration using an Amicon PM30 membrane. The concentrated sample is centrifuged at 20,000 g for 10 min and the supernatant fraction is loaded onto an 8% agarose gel column (Bio-Gel A 1.5 m, 200–4000 mesh, Bio-Rad, 1 × 90 cm). The final purified enzyme is subsequently eluted with enzyme buffer. This process usually results in a 5000 to 10,000-fold increase in specific activity with a recovery of 2–6%. The enzyme fractions in ethylene glycol are the most stable. There is often a large loss of activity during the gel filtration step (20).

The purified enzyme has a molecular weight of 180 kDa determined by gel filtration column chromatography under nondenaturing conditions, while it migrates at 85 kDa in polyacrylamide gels in the presence of SDS. As noted above, the enzyme is a homodimer (16). Since the protein expressed by insect cells infected with baculovirus containing the lysyl hydroxylase cDNA sequence from rat is active with the addition of cofactors such as ascorbate, α-ketoglutarate, and ferrous iron (17), it is likely that no other cofactors remain to be discovered. That insect cells infected with baculovirus containing the lysyl hydroxylase cDNA express lysyl hydroxylase with a similar specific activity to that of the chick embryo lysyl hydroxylase

confirms that lysyl hydroxylase does not require protein disulfide isomerase or any other mammalian protein for its activity (**Table 2**) (17).

**Note added in proof:** Since submission of this chapter, several relevant articles have appeared. Briefly, the lysyl hydroxylase 3 isoform not only catalyzes the hydroxylation of lysyl residues on collagen, but the pure enzyme also is a collagen glucosyltransferase, catalyzing the addition of glucose to galactosyl residues on collagen hydroxylysines (29). Thus, LH3 is also galactosylhydroxylysyl glucosyltransferase, EC 2.4.1.66. Neither LH1 nor LH2 possess this additional activity. A specific 40 amino acid-long sequence in the C-terminal end of lysyl hydroxylase has been identified that is responsible for its membrane binding and localization in the endoplasmic reticulum (30). An important role for hydroxylysine and its glycosylated forms in collagen may be regulation of the rate of fibrillogenesis and determination of the morphology of the fibers produced (31).

### I. INTRODUCTION

#### A Chemical Reactions Catalyzed

Lysyl oxidase is a copper-containing enzyme that catalyzes the oxidative deamination of amine substrates according to Eq. (1)

#### B. Chemical Structure of Substrates

Substrates include simple monoamines, diamines, and/or the  $\epsilon$ -amine function of lysyl and/or hydroxylysyl residues in oligopeptides and proteins that range from histone (1) to collagen and elastin (2). For polypeptides, the location and chemical properties of vicinal dicarboxylic amino acid residues adjacent to potentially oxidizable lysyl residues influence the efficiency of lysyl oxidation (3).

#### C. Enzyme Commission Designation

Lysyl oxidase is an amine oxidase with the numerical designation of EC 1.4.3.13.

### II. PHYSIOLOGICAL IMPORTANCE

Lysyl oxidase is a key enzyme in the growth and development of all higher animals (4, 5). Both intracellular

and extracellular forms of the enzyme exist. Although the mechanism(s) of action remains unclear, there is loss of expression of lysyl oxidase in malignant cells (6). It is speculated that the intracellular form(s) of lysyl oxidase targets oncogenic and growth-promoting transcription factors as substrates. Two examples are the RAS oncogene and IRF-1 transcription factor (7–9). Moreover, lysyl oxidase is also found in the cell nucleus (10).

Within the extracellular matrix (ECM), lysyl oxidase catalyzes the crosslinking of the collagens and elastin. Developmental processes beyond gastrulation are blocked when lysyl oxidase is inhibited (11–13).

For the food chemist, a general knowledge of lysyl oxidase function is essential. In general, the location and types of cross links in collagen and elastin have profound influence on their tensile and elastic properties. For example, an increase in the amount, or a change in the distribution, of crosslinked collagen in edible meats affects rheological properties (4, 14). In addition, crosslinking renders collagen and elastin less susceptible to proteolysis (15). Therefore, a decrease in lysyl oxidase activity is often associated with increased proteolysis of collagens and elastin, or altered tensile and elastic properties.

### III. LOCATION IN TISSUES

Lysyl oxidase is found in highest concentrations in tissues enriched in collagen and elastin, ranging from 20 to 400  $\mu\text{g/g}$  tissue (16). For cellular localization

studies, poly- or monoclonal antibodies have been used against lysyl oxidase or synthetic peptide sequences for a given form of lysyl oxidase. Methods for detection range from indirect immunofluorescence (17) to immunocytochemical approaches employing confocal microscopy (10). Four separate genes have been identified to date that may produce a distinct family of lysyl oxidase proteins (see below). Most of the comments herein apply to the forms of lysyl oxidase designated as 1 or 2 (also known as lysyl oxidase-like protein, LoxL). Lysyl oxidase 1 is usually found in tissues containing fibrillar collagens or elastin, whereas lysyl oxidase-like protein is often found in tissues enriched in nonfibrillar collagens, i.e., laminar or basement membrane collagens (2, 18).

Recently, lysyl oxidase-like 2 and 3 have also been identified as separate genes. LoxL 2 appears to be one of the lysyl oxidases that is involved in tumor suppression and is present in reproductive tissue (18–20). LoxL 3 has yet to be fully characterized, but it is expressed in response to cell senescence (21).

#### IV. COMMERCIAL APPLICATIONS

There are no commercial applications for the enzyme at this time. A potential long-range use of genetically engineered lysyl oxidase might be crosslinking of collagens for gelling purposes.

#### V. PHYSICAL AND CHEMICAL PROPERTIES

The descriptions that follow apply mostly to extracellular forms of lysyl oxidase.

##### A. Molecular Weight

Human lysyl oxidase is first expressed as a polypeptide of 417 amino acid residues (MW 48,000), including a signal peptide of 21 amino acids (Table 1; Fig. 1). The active form of the enzyme has a MW of ~30,000.

##### B. Structural Characteristics

The translated primary amino acid sequences from human genomic, human, rat, and mouse lysyl oxidase cDNAs indicate a highly conserved primary structure. Likewise, computer-predicted secondary structure appears similar for lysyl oxidases from different animals (Fig. 1; Table 1).

#### C. Genes and Posttranslational Processing

##### 1. Genes

The human lysyl oxidase gene resides on chromosome 5 while the mouse homologue is on chromosome 18 (22, 23). Three additional lysyl oxidase-like (LoxL) genes have also been identified. LoxL 1 is localized on chromosome 15 in humans (24). Its complete sequence is encoded by seven exons distributed throughout 25kb of genomic DNA. Exons 2–6 encode the region of greatest homology to lysyl oxidase. LoxL 2 maps to chromosome 8 (19). LoxL 2 (21) shares some sequence similarity to lysyl oxidase 1, e.g., 48% in protein domains transcribed and translated from exons 2–6. LoxL 3 is an 87-kDa protein and maps to human chromosome 2. This form of lysyl oxidase is also novel, since it contains four scavenger receptor cysteine-rich domains, which are not present in other known forms of lysyl oxidase.

Northern blot analysis of smooth muscle or fibroblast mRNA often results in two to four mRNA species of 5.5, 4.3, 2.4, and 2 kb in size (2) corresponding to lysyl oxidase and the lysyl oxidase-like proteins.

##### 2. Posttranslational Processing

The “pre” part of pre-prolysyl oxidase is removed by a protease that cleaves at the peptide bond between Cys<sub>21</sub> and Ala<sub>22</sub> (Fig. 1), giving prolysyl oxidase. Prolysyl oxidase is N-glycosylated at two sites (residues 91–93 and 138–140 in the rat enzyme) in the region of the propeptide (Fig. 1; Table 1). These residues are lost when the propeptide is cleaved by a prolysyl-oxidase peptidase located on the external cell surface (2). For activation of lysyl oxidase, oxidation of a tyrosyl residue (Table 1) within the active site of the enzyme to peptidyl trihydroxyphenylalanine (TOPA) and eventually to the quinone, topaquinone (TPQ), or alternatively dihydroxyphenylalanine (DOPA), is essential. This cofactor is generated after copper is incorporated into the apoenzyme. In subsequent steps, a lysine derivative is formed—i.e., lysyl tyrosine quinone (Fig. 1) (25). This product is formed by the addition of the lysyl amine to topaquinone with the loss of water or by the direct addition to DOPA.

#### VI. ENZYMATIC PROPERTIES

##### A. Substrates

When synthetic oligopeptides are used as substrates, e.g. acetyl-(Gly)<sub>n</sub>-Lys-(Gly)<sub>n</sub>-CONH<sub>2</sub> ( $n = 1–5$ ), the

Underlined and highlighted are sites associated with: leader sequence cleavage (*Cys-Ala*), glycosylations (*Ans-Arg-Thr*), prolysyl oxidase peptide cleavage to lysyl oxidase (*Gly-Asp-Asp*), potential trypsin-like proteinase cleavage sites (*Arg-Arg* and *Arg-Arg-Arg*), the proposed copper binding region (*Trp-His-Ser-Cys-His-Gln-His-Tyr-His-Ser*), and the location of the *Lys* and *Tyr* associated with lysine tyrosylquinone formation (39, 40, and Refs. cited).

$k_{\text{cat}}/K_m$  increases with increasing peptide length. Insertion of a Glu residue immediately preceding the Lys residue causes an increase in the  $k_{\text{cat}}/K_m \sim 10$ -fold over that for -Lys-Glu- and about fivefold over sequences containing only Lys. Replacement of Glu with Gln increases the  $K_m$  and lowers  $k_{\text{cat}}/K_m$ . Changes in  $k_{\text{cat}}/K_m$  also respond to the carbon chain length of the vicinal amino acid at this position. In particular, decreasing the carbon chain length decreases  $k_{\text{cat}}/K_m$  (26, 27). For simple aliphatic mono- and particularly diamines, as the carbon chain length decreases, such compounds become poorer substrates; e.g., ethylenediamine is an irreversible inhibitor of lysyl oxidase (28). The  $K_m$ s for simple amine substrates are in the 100  $\mu\text{M}$  to mM range (see Ref. 2 and Refs. cited within). The  $K_m$  for the oxidation of

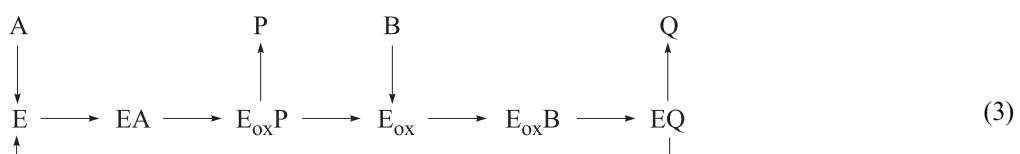

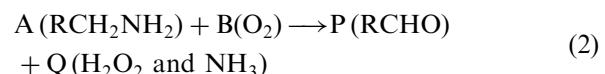

recombinant tropoelastin (MW  $\sim 70,000$ , 56 residues of Lys per 1000 total residues) is  $\sim 5 \mu\text{M}$  (29).

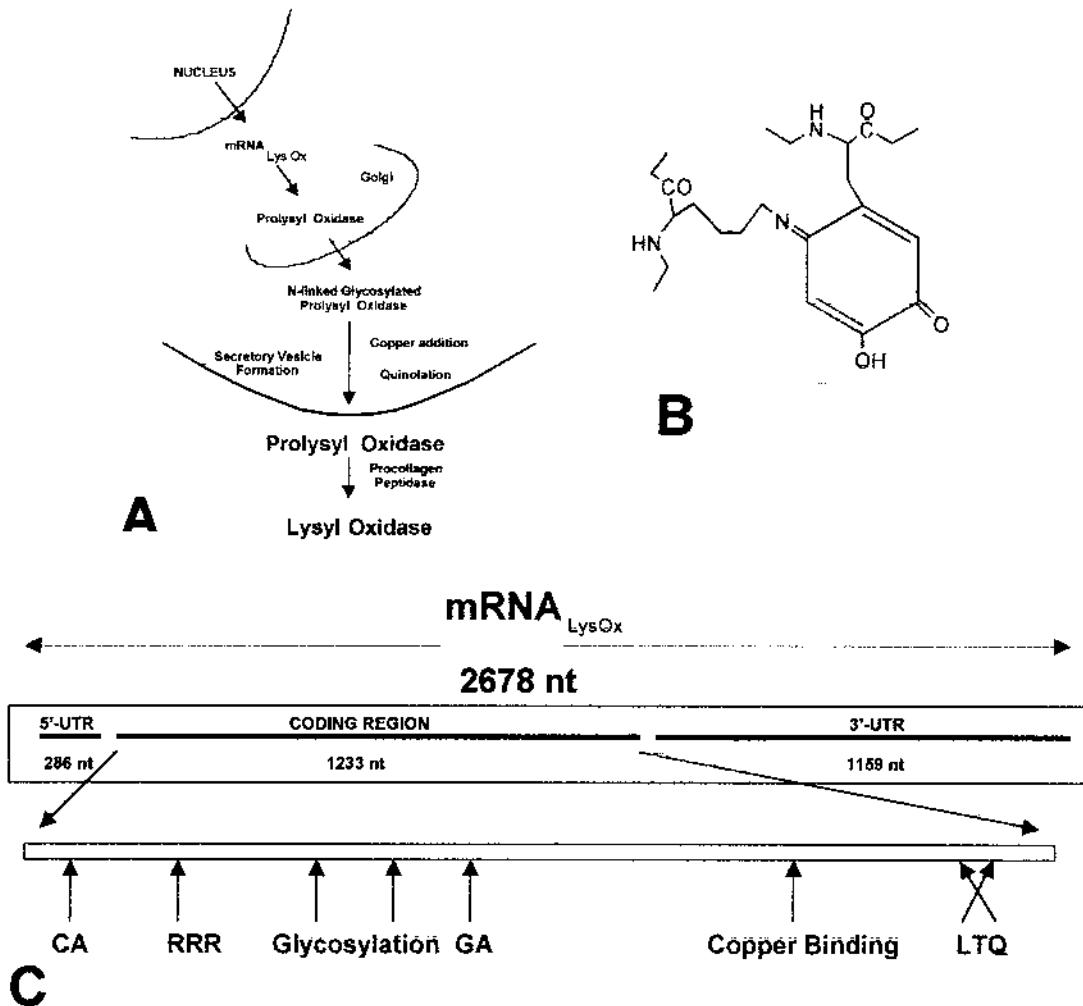

## B. Effect of Environmental Factors

Lysyl oxidase is optimally active at pH 7.8–8.6 and 50–60°C. No externally added cofactors are required, since copper and TPQ are tightly associated with the enzyme.

## C. Proposed Mechanism

Lysyl oxidase carries out oxidative deaminations by a classical Ping-Pong mechanism [Eqs. (2) and (3)]

**Figure 1** Lysyl oxidase processing. (A) Lysyl oxidase is first synthesized as a 46-kDa pre-proenzyme. In steps associated with Golgi and post-Golgi processing, N-linked glycosylation, copper binding, and quinone cofactor formation occur (5). A part of this process is the packaging of lysyl oxidase into vesicles for eventual secretion. At the cell surface, prolysyl oxidase is cleaved to lysyl oxidase by the same enzyme that carries out procollagen cleavage to collagen. (B) The figure insert shows the structure of lysyl tyrosine quinone. This cofactor is formed as a product of posttranslational modification following the insertion of copper into lysyl oxidase. (C) The diagram corresponds to lysyl oxidase mRNA. The size of the coding, 3'- and 5'-untranslated regions, and the approximate location of modifications that occur in pre-prolysyl oxidase are depicted. Lysyl oxidase mRNA arises from a gene that is ~ 15 kb.

Shah et al. (30) have studied selected aspects of this mechanism. To iterate, substrate efficiency often decreases with decreased carbon chain length. Regarding the two half reactions, enzyme reoxidation is the most rate-limiting step. <sup>1</sup>H NMR spectroscopy of the alcohol that is reductively derived (nonenzymatically) from the aldehyde product of the lysyl oxidase-catalyzed oxidation of deuterated tyramine indicates that the pro-S, but not the pro-R, alpha-deuteron is catalytically abstracted. As Shah et

al. (30) noted, such stereospecificity and proton exchange uniquely differentiates lysyl oxidase from most of the other semicarbazide-sensitive amine oxidases.

#### D. Inhibitors

The most potent inhibitors are derivatives of semicarbazides and aminoallylnitriles, e.g.,  $\beta$ -aminopropionitrile (BAPN). BAPN administration *in vivo* promotes

degeneration of arteries, increased friability of the skin, and bone fragility. In direct assays of lysyl oxidase activity, BAPN has a  $K_i$  of  $\sim 10\text{--}20 \mu\text{M}$ . Other compounds that act as pseudo-substrates and/or potential inhibitors are the aminoalkylaziridines, homocysteine thiolactone, selenohomocysteine lactone, and homoserine lactone. Liu et al. (31) showed that the activities of plasma amine oxidase and diamine oxidase are only partially inhibited at concentrations of the sulfur or selenium lactones that fully inhibit lysyl oxidase. Homocysteine thiolactone, selenohomocysteine lactone, and homoserine lactone are found to be competitive, irreversible inhibitors of lysyl oxidase, with  $K_i$  values of  $\sim 20$ , 8, and  $420 \mu\text{M}$ , respectively. The first-order rate constants for inactivation ( $k_2$ ) of the enzyme vary from 0.12 to 0.18 to  $0.28 \text{ min}^{-1}$  for the Se-, thio-, and *O*-lactones, respectively.

## VII. DETERMINATION OF ACTIVITY

### A. Natural Substrates

The classical substrate for assessing lysyl oxidase activity is prepared using aortae or calveria from 10- to 16-day-old chick embryos (32). Briefly, the aortae or calveria are incubated in Eagle's medium devoid of L-lysine, but containing  $^3\text{H}$ -6-L-lysine or  $^3\text{H}$ -4,5-L-lysine in amounts sufficient to cause 200,000–400,000 dpm ( $\sim 3\text{--}6 \text{ kBq}$ ) of tritium to be incorporated per aorta or calveria. Standard procedures are used for the tissue culture (95/5%  $\text{O}_2/\text{CO}_2$ , 39–41°C for 18–24 h) employing vessels that allow convenient recovery of the tissue. BAPN is added at  $50 \mu\text{g/mL}$  to inhibit endogenous lysyl oxidase activity. Usually 3–5 g fresh tissue (100–200 aortae) is cultured to prepare a single lot of substrate. Following incubation, the tissue is homogenized in saline containing 1 mM L-lysine. The tissue is recovered by centrifugation (10,000g, 30 min) and repeatedly washed to remove unincorporated radiochemically labeled L-lysine. Following a final wash in 0.01 M HCl, the tissue residue is lyophilized and stored at room temperature in a desiccator.

In typical assays, tissue extracts containing enzyme (equivalent of 250 ng or more of lysyl oxidase) are added to assay mixtures that contain at least one aorta or calveria equivalent of substrate suspended in 0.1 M sodium borate buffer containing 0.15 M NaCl, pH 8.0. The samples are next incubated at 45°C for 2, 4, 6, and 12 h (assay volume 1.5–2.0 mL). Assays are performed with substrate alone, with enzyme, or with enzyme preincubated for 30 min in the presence of 50

$\mu\text{M}$  of  $\beta$ -aminopropionitrile/mL assay buffer. Released tritium is recovered by distillation.

Alternatively, the reactions may be stopped by the addition of 0.2 mL of 3 M trichloroacetic acid. Released tritium is determined after centrifugation of individual samples and passage of the supernatant fraction through a column of AG50W-X8(H) resin (1 × 4 cm). After a wash with two to three column volumes of distilled water, an aliquot of the combined fractions is assayed for radioactivity by liquid scintillation spectrometry (33). The data are expressed as radioactivity released per unit time per weight of tissue or unit of protein or DNA.

### B. Simple Amine Substrates

The assay described by Trackman et al. (34) based on cadaverine oxidation is a good method for routine assays. However, the lysyl oxidase preparation must be free of endogenous inhibitors, high levels of catalase, and natural substrates (5). The assay also requires the equivalent of 1–2  $\mu\text{g}$  of enzyme per assay. The oxidation of cadaverine is measured in a coupled assay system utilizing horseradish peroxidase to measure the  $\text{H}_2\text{O}_2$  formed [see Eq. (1)]. In typical assays, samples (equivalent to 50–200 mg of tissue homogenate) are fragmented and ground in liquid nitrogen using a metal mortar and pestle. Next, readily soluble protein is extracted into 2–3 mL of phosphate-buffered (10 mM, pH 7.6) saline for 1–2 h. The tissue is recovered by centrifugation (10,000 g for 30 min), and the pellet is rehomogenized into 3 mL of 6 M urea buffered with 100 mM sodium borate at pH 8.2. This homogenate is extracted at least two times (4°C for 8–12 h) with agitation, and the supernatant fraction is collected (10,000 g for 30 min) and combined.

Assays (3 mL total volume) must contain 0.25 mg of sodium homovanillate,  $40 \mu\text{g}$  horseradish peroxidase, urea extract (equivalent to  $\sim 1 \mu\text{g}$  of lysyl oxidase; usually 0.5 mL urea extract), 3.33 mM cadaverine, and sodium borate buffer (50 mM, pH 8.2). The fluorescence resulting from homovanillate oxidation is monitored continuously at 315 nm excitation and 425 nm emission for 10–20 min at 45°C. Production of  $\text{H}_2\text{O}_2$  is usually linear for 20–40 min. Lysine-rich peptides and proteins can also be used as substrates, if nM amounts of potentially oxidizable amine functions are present in the assay mixture. For example, if resources are available to prepare recombinant proteins, recombinant tropoelastin could be considered as a substrate (29).

Although aldehyde production and NH<sub>3</sub> can also be measured, the low sensitivity, inconvenience, and potential of interfering substances, e.g., NH<sub>3</sub> associated with the use of urea (see Sec. VIII), compromise their use for routine measurements or as endpoints for kinetic assays.

## VIII. PURIFICATION

The methodological steps that follow may be applied to sources of lysyl oxidase containing > 50 µg enzyme/g tissue. In general, lysyl oxidase may be purified to homogeneity by differential extraction procedures and sequential chromatography using columns of collagen, elastin-hexamine-Sepharose, DEAE-cellulose, and/or Sephadryl S-200. The end product is usually the activated or fully processed form of lysyl oxidase (~30 kDa). Lysyl oxidase from some tissues, e.g., skin, may copurify with an associated protein, a tyrosine-rich associated matrix protein (35).

### A. Purification Steps (Table 2)

Step 1. To prepare connective tissue for subsequent homogenization, the tissue is frozen and pulverized in liquid nitrogen using a mortar and pestle or a blender vented to allow the escape of nitrogen. Next, the pulverized tissue (tendon, skin, aorta) is homogenized in

phosphate-buffered (10 mM, pH 7.6) saline at 1:5 w/v. This step is repeated two or three times using the tissue pellet recovered following centrifugation (10,000g, 30 min at 4°C). At the onset of purification, it is important to remove endogenous inhibitors and native substrates that inhibit lysyl oxidase activity. Little lysyl oxidase activity is lost in these initial washes, since lysyl oxidase is tightly bound to the ECM (16 and Refs. cited within).

Step 2. The tissue is next homogenized in buffered 6 M urea (sodium borate or phosphate, 50 mM, pH 7.8–8.0). Three extractions (1:4 w/v) are repeated with constant agitation or stirring and are usually sufficient to extract all measurable activity. The enzyme is most easily concentrated by precipitation using ammonium sulfate. (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> is added to the combined urea extracts to 50% saturation. The resulting precipitate is collected by centrifugation (10,000g, 30 min).

Step 3. The product from Step 2 is next suspended in buffered 0.5 M urea to give ~20 mg protein per mL. (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> is removed (by dialysis against 0.5 M urea in 0.05 M sodium phosphate or borate buffer, pH 7.8–8.0) or chromatography on columns of Sephadex G-10 (Pharmacia Co., Uppsala, Sweden). Note, however, that the presence of some urea is essential in all subsequent steps to maintain lysyl oxidase in a nonaggregated state. If aggregated, there is loss of activity.

Step 4. Depending on the goal for the purification, either affinity chromatography or ion-exchange chro-

**Table 2** Lysyl Oxidase Purification<sup>a</sup>

Steps	Volume (mL)	Total Protein (mg)	Specific activity <sup>b</sup>	Fold purification	Recovery (%)
1. PBS extraction <sup>b</sup>	150	~3000–6000 <sup>c</sup>	NA <sup>c</sup>	—	—
2. Urea extraction	120	500–600 <sup>d</sup>	0.8–0.9	~1	~100 <sup>d</sup>
3. Concentration (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	10	300–400	1.1–1.5	~1.3	~100
4. Dialysis	25	300–400	0.9–1.1	~1.1	~100
5. Sephadryl S-200/elastin <sup>e,f</sup> or	10	6	65–70	70–80	90–95
6. DEAE-cellulose chromatography <sup>c,f</sup>	50	40–60	100–150	125–190	50–60
7. HPLC <sup>g</sup>	1	2–3	~200	~200	40–70

<sup>a</sup> The summary is based on using 10 g of chick tendon as the enzyme source, which normally contains 200 µg/g or more lysyl oxidase.
