<sup>b</sup> Greater than 85–90% of the total protein in tendon is collagen. This amount reflects the total protein homogenized into phosphate buffered saline, pH 7.0 (PBS). All of the extracted protein at this step is discarded.

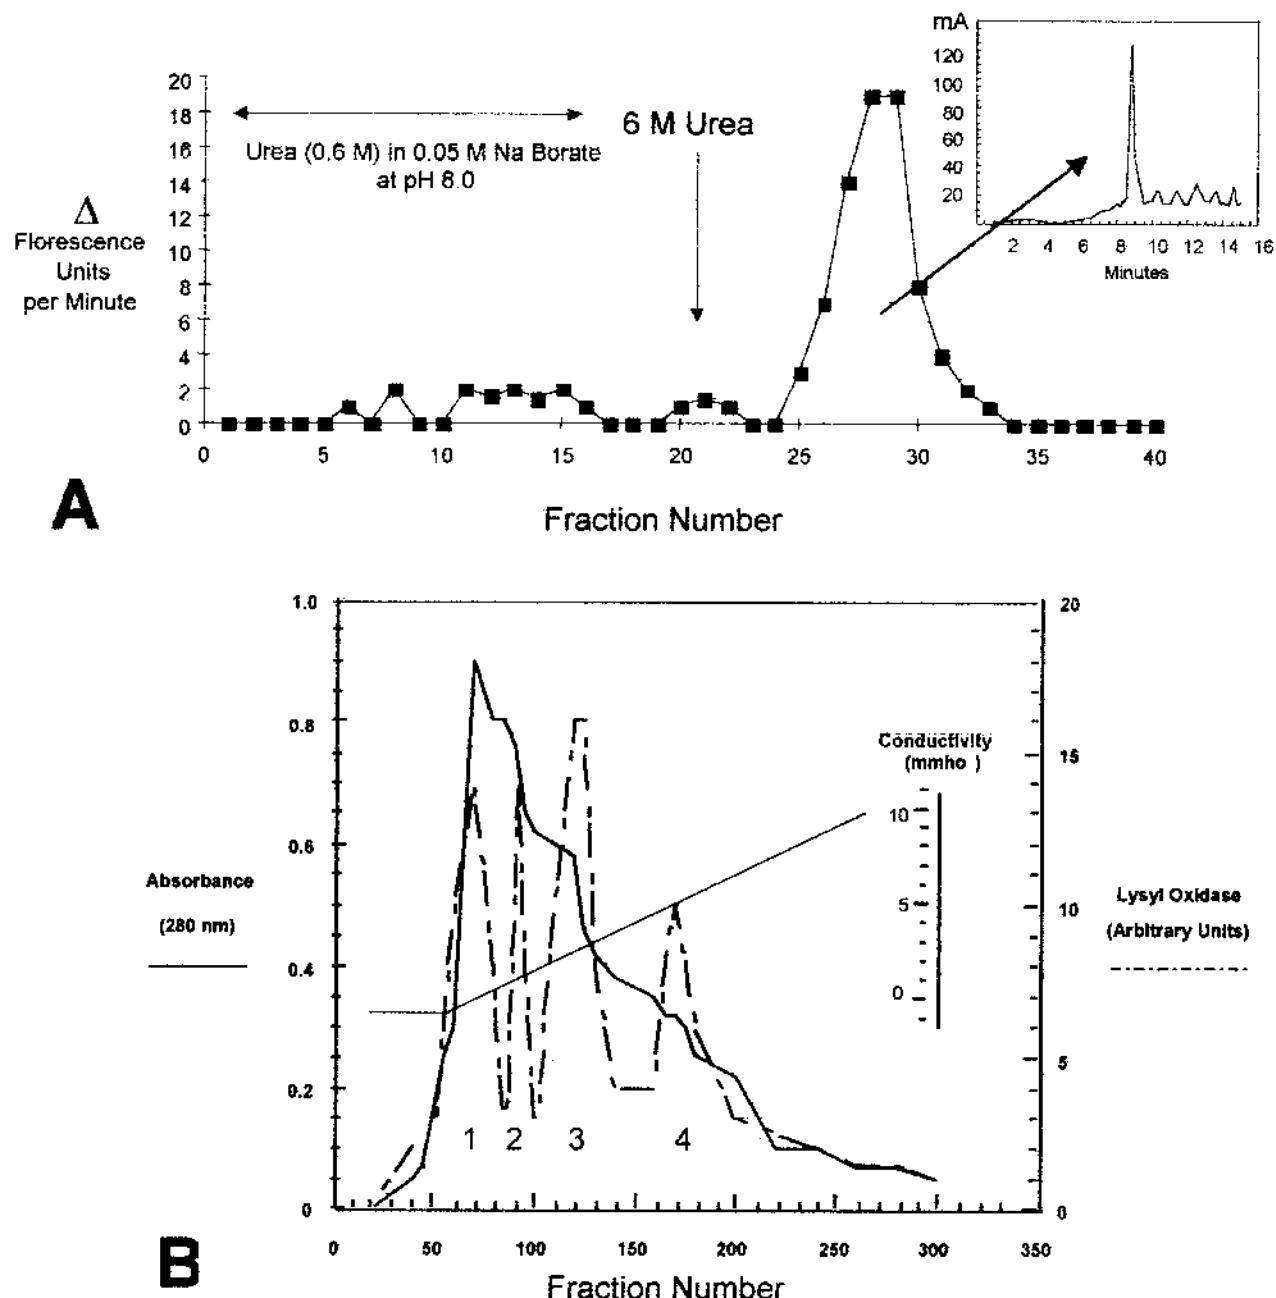

<sup>c</sup> One unit of activity is the production of one nanomol of H<sub>2</sub>O<sub>2</sub>/min/mg protein.

<sup>d</sup> About 15% of the total initial protein is extracted into urea and >90% of the total enzyme (16). For purposes of estimating indices of purification and recovery, this step is set at onefold and 100%, respectively.

<sup>e</sup> Affinity chromatography often results in >50-fold purification in a single step and enzyme that is >20% pure based on assessment using polyacrylamide gels. DEAE-cellulose chromatography may be useful in separating specific forms of isoforms of lysyl oxidase (see Fig. 2).

<sup>f</sup> High-performance liquid chromatography yields a product (following Step 5 or 6) that is suitable for amino acid sequencing.

<sup>g</sup> From Ref. 38.

**Figure 2** Lysyl oxidase purification. (A) Lysyl oxidase binds to Sephadex G-200. An elution profile for lysyl oxidase indicates that the enzyme is released only upon addition of 6 M urea. Further purification can be achieved by reversed-phase HPLC chromatography using conventional protocols for protein and peptide elution (small insert). (B) Separation of lysyl oxidase isoforms may be achieved using ion exchange chromatography. The elution of lysyl oxidase from skin, tendon, lung, or aorta from DEAE-cellulose. Columns result in four distinct isoforms, which are immunologically indistinguishable. The protein is applied in starting buffer (0.025 M sodium phosphate, pH 7.6, containing 6 M urea). Elution is achieved with a linear gradient of NaCl (equivalent to increasing the conductivity from ~0 to ~10 mmho<sup>-1</sup>).

matography is useful as a next step. At urea concentrations of < 1.0 M, lysyl oxidase binds tenaciously to columns of Sephadryl S-200, and elution can only be achieved using buffers containing 4–6 M urea (see Ref. 36 for additional details). The choice of column size depends on the amount of protein applied. Approximately 3 mL of hydrated gel/10–15 mg protein is adequate. Columns composed of Sephadryl S-200 and insoluble elastin (mixed 3 : 1 w/v) further improve resolution and separation from other proteins (Fig. 2). The dialyzed urea extract is loaded onto a Sephadryl S-200/insoluble elastin column. The column is washed with 3–5 column volumes of buffered 0.5 M urea (Step 3). Lysyl oxidase is then eluted with 6 M buffered urea. Columns of collagen and hexylamine-Sepharose, which are available commercially (Elastin Products, St. Louis, MO), can also be used instead of Sephadryl. At this point the enzyme is usually sufficiently pure for enzymatic studies, such as defining inhibitor profiles.

Step 5. If further purification is required, DEAE-cellulose chromatography or reversed-phase HPLC is an option. Prior to or following Sephadryl chromatography, selected fractions may be pumped onto columns of DEAE-cellulose (see Fig. 2). Lysyl oxidase often elutes as four chromatographically different isoforms, although distinguishing features that give rise to such forms have not been fully assessed (37). Reversed-phase HPLC (Fig. 2) can yield products that are suitable for amino acid sequencing (38).

Step 6. The enzyme is best stored at 4°C in 2–4 M urea solutions at concentrations of 20–40 µg/mL. Freezing or concentration, which results in aggregation, causes rapid loss of activity, i.e., in hours to a few days (16).

## Superoxide Dismutase

Hirokazu Hara, Tetsuo Adachi, and Kazuyuki Hirano

*Gifu Pharmaceutical University, Gifu, Japan*

### I. INTRODUCTION

Superoxide ( $O_2^-$ ), a free radical generated during the monovalent metabolic reduction of oxygen, is toxic to biological systems. The major enzymatic protector against superoxide in the body is superoxide dismutase (SOD; EC 1.15.1.1) which disproportionates the superoxide to hydrogen peroxide ( $H_2O_2$ ) and oxygen as follows:

Mitochondria and endoplasmic reticulum have been shown to produce superoxide as a consequence of autooxidation of electron transport chain components. Other sources of superoxide are cytosolic enzymes such as xanthine oxidase, and activated neutrophils. Under physiological conditions, the nonenzymatic dismutation of superoxide proceeds with a rate constant of approximately  $k = 10^5 M^{-1} sec^{-1}$ , and the reaction is accelerated by a factor of  $10^4$  in the presence of SOD.

### II. DISTRIBUTION OF SOD

SODs are proteins with metal ions at the active site. Four isoforms, copper,zinc-SOD (Cu,Zn-SOD), extracellular-SOD (EC-SOD), manganese-SOD (Mn-SOD), and iron-SOD (Fe-SOD), have been isolated so far from many species, and the cellular distribution pattern of these isoforms has been determined (1). Cu,Zn-SOD and EC-SOD, which are known to contain copper and zinc atoms, are found in eukaryotes. Cu,Zn-

SOD has been found in many kinds of animals (vertebrates and invertebrates), fungi and slime molds, and plants, and EC-SOD has been found in mammals and in pine trees. Fe-SOD and Mn-SOD are found in prokaryotes and in eukaryotes. Mn-SOD has been found in mammals, while Fe-SOD has not.

The cellular localization of Cu,Zn-SOD is different from that of EC-SOD. Cu,Zn-SOD is located in the cytosol and the stroma of chloroplasts, while EC-SOD is mostly located in the extracellular matrix, since it is a secretory protein and has an affinity for heparin and heparan sulfate. Mn-SOD is located in the mitochondrial matrix and the thylakoids of chloroplasts. Fe-SOD is found in the cytosol of bacteria and the stroma of chloroplasts.

The contents of Cu,Zn-SOD, Mn-SOD, and EC-SOD were determined in tissues from mammalian species (2). Various tissues contain the Cu,Zn-SOD activity, and Cu,Zn-SOD activities are especially high in metabolically active organs, such as liver and kidney. The Mn-SOD content is high in organs with high respiration, such as liver, kidney, and heart. The tissue distribution of EC-SOD is different from those of other isoforms, and it is present at high levels in lung, thyroid gland, and uterus. EC-SOD is the least abundant SOD isoform in tissues, and 90–99% of the EC-SOD in the body is located in the interstitial spaces of tissues. EC-SOD is a major SOD form in extracellular fluids such as plasma, lymph, and synovial fluid. Recently, it was reported that the blood vessel walls, particularly the walls of the arteries, contain large amounts of EC-SOD (3).

### III. PROPERTIES OF SOD PROTEINS

The characteristics of three SOD isoforms—Cu,Zn-SOD, Mn-SOD, and EC-SOD—are presented in Table 1. A comparison of the primary structures of several Cu,Zn-SODs are presented in Figure 1, and the sequences of human Cu,Zn-SOD and EC-SOD are shown in Figure 2.

Cu,Zn-SOD is a homodimer in which each subunit has one copper and one zinc atom. The molecular weight of Cu,Zn-SOD is  $\sim$  32,000. The amino acid sequences of Cu,Zn-SODs have been determined in various species. Human Cu,Zn-SOD consists of 153 amino acid residues. The amino acid sequences of various mammalian Cu,Zn-SOD show > 80% identity but are significantly different from those in yeast ( $\sim$  50% identity) and spinach ( $\sim$  50% identity) (Fig. 1) (4). The amino acid residues at the active site responsible for binding Cu and Zn, and the cysteine residues of a disulfide bond, are conserved in various species. The crystal structure analysis of bovine Cu,Zn-SOD at 2 Å resolutions was reported, and the disulfide bond, the metal atoms, and the amino acid residues to which they are bound were identified (5). Each subunit of Cu,Zn-SOD is composed primarily of eight antiparallel  $\beta$ -strands that form a flattened cylinder, plus three external loops. The Cu atom is bound by His44, -46, -61, and -118 of bovine enzymes (His46, -48, -63, and

**Table 1** Comparison of Human SOD Isoforms

	Cu,Zn-SOD	Mn-SOD	EC-SOD
Chromosomal location	21q22.1	6q25.2	4p16.3-q21
Amino acid length	153	198	222
Predicted MW	32 kDa	80 kDa	135 kDa

Glycosylation	—	—	+
Heparin affinity	—	—	+

-120 in human) with an uneven tetrahedral distortion from square planar geometry. The geometry of Zn atom ligands, His61, -69, -78, and Asp81 of bovine enzymes (His63, -71, -80, and Asp83 in human), is tetrahedral. The cysteine residues forming an intrasubunit disulfide bond Cys55-Cys144 of bovine enzyme (Cys57-Cys146 in human) are conserved in the primary structure of Cu,Zn-SODs (Fig. 1).

Recently a cDNA of EC-SOD was isolated from a human placenta cDNA library and the primary structure of the enzyme was determined (6). Human EC-SOD is a tetrameric glycoprotein containing one copper and one zinc atom per one subunit. The molecular weight of EC-SOD is  $\sim$  135,000. EC-SOD has a putative signal sequence (18 amino acid residues), and the mature enzyme of EC-SOD consists of 222 amino acid residues. The presence of the signal sequence indicates

**Figure 1** Comparison of amino acid sequences of human, rat, bovine, horse, yeast, and spinach Cu,Zn-SODs. Asterisks indicate identical amino acid residues.

**Figure 2** Comparison of amino acid sequences of human Cu,Zn-SOD and human EC-SOD. Asterisks indicate identical amino acid residues. The bold letter indicates the N-glycosylation site. Cu and Zn indicate amino acid residues binding the metals. Cysteine residues forming a disulfide bond are Cys-57-Cys-146 in Cu,Zn-SOD and Cys-107-Cys-189 in EC-SOD.

that EC-SOD is a secreted protein. The N-terminal region (amino acid residues 1–95) of the mature enzyme shows no homology with other proteins, but the region corresponding to amino acid residues 96–193 shows ~50% homology with the carboxyl-terminal two-thirds of the sequences of eukaryotic Cu,Zn-SODs. The amino acid residues binding the Cu and Zn atoms (Cu atom ligands His96, -98, -113, and His163; Zn atom ligands His113, -121, -124, and Asp127) and the cysteines forming the intrasubunit disulfide bridge (Cys107-Cys189) in EC-SOD can all be identified with corresponding residues in Cu,Zn-SOD (Fig. 2). The carboxyl-terminal region (194–222), including nine amino acids with a positive charge, confers the affinity of EC-SOD for heparin and heparan sulfate. There is one deduced N-glycosylation site (Asn89).

The primary structure and three-dimensional structure of Mn-SOD show no homologies with those of Cu,Zn-SOD or EC-SOD (7).

#### IV. PROPERTIES OF ENZYMES

The rate constants of the catalytic reactions of all of the SOD isoforms are very similar, with values of  $\sim 1 \times 10^9 \text{ M}^{-1} \text{ sec}^{-1}$  (1). The enzymatic activities of Cu,Zn-SOD and EC-SOD are stable over a wide pH range, from pH 5 to 11 (8, 9). On the other hand, Mn-SOD has a lower pH resistance than other isoforms (8). SOD is a heat-stable enzyme, and Cu,Zn-SOD and EC-SOD are especially stable, up to 70°C, while Mn-SOD is stable up to 60°C (8, 9).

Since the central core active site portions of Cu,Zn-SOD and EC-SOD are conserved, the enzymatic properties of the two enzymes are very similar. However, the properties of Mn-SOD, which has no structural homology of active site with that of Cu,Zn-SOD and EC-SOD, are significantly different from those of the other two enzymes. Both Cu,Zn-SOD and EC-SOD are very sensitive to cyanide. The values of the IC<sub>50</sub> of cyanide for human Cu,Zn-SOD and human EC-SOD are 10 μM and 3 μM, respectively (10). In contrast, Mn-SOD is insensitive to cyanide and the enzymatic activity of Mn-SOD is not inhibited at 10 mM cyanide (11). All SOD isoforms are inhibited by azide. The values of the IC<sub>50</sub> of azide for Cu,Zn-SOD, Mn-SOD, and EC-SOD are 21, 20, and 6.5 mM, respectively (10, 12). Cu,Zn-SOD and EC-SOD are sensitive to H<sub>2</sub>O<sub>2</sub>, while Mn-SOD is resistant to it (10, 11). Cu,Zn-SOD and EC-SOD are inactivated at 1 mM H<sub>2</sub>O<sub>2</sub> with half-times of 9.3 and 6.2–7.1 min, respectively.

#### V. QUALITATIVE AND QUANTITATIVE DETERMINATION

Several methods for assaying SOD, such as the cytochrome C assay (13), nitro blue tetrazolium (NBT) assay (14, 15), nitrite assay (16), KO<sub>2</sub> assay (17), and enzyme-linked immunosorbent assay (ELISA) (18) have been reported. There are three SOD isozymes in eukaryotes and they have similar specific activity. The methods for assaying SOD activity (13–17) show total

SOD activity. When we want to know the activity of one of the SOD isozymes, it is necessary to separate them with reagents such as NaCN (for Mn-SOD) or pretreatment of samples with concanavalin A-Sepharose column (for EC-SOD) and/or immobilized antibodies (2). It is possible to assay one of the SOD isozymes exclusively with ELISA, because there are no immunological cross-reactivities among three SOD isozymes. ELISA is not a method for the assay of SOD activity, but rather for SOD protein measurement, while the other methods (13–17) are for the assay of activity. We describe here the procedure for the NBT assay and ELISA.

### A. NBT Assay

This assay was originally reported by Beauchamp and Fridovich (14). SOD catalyzes the dismutation reaction of superoxide generated by the xanthine-xanthine oxidase reaction. However, since superoxide cannot easily be detected directly by conventional analytical tools, this assay utilizes NBT as an indicator of superoxide. The SOD activity is defined as the ability to inhibit the reduction of NBT caused by superoxide. One unit of SOD activity is defined as the amount of protein which gives half-maximal inhibition. The SOD activity is usually expressed as units per milligram protein. The following NBT assay was reported by Oberley and Spitz (15). Diethylenetriaminepentaacetic acid (DETAPAC) is used as chelator in this assay to suppress interference by metal ions. Catalase is also necessary for protection of SODs against inactivation by H<sub>2</sub>O<sub>2</sub> formed in the reaction.

#### 1. Reagents

50 mM potassium phosphate buffer, pH 7.8  
Solution A: 50 mM potassium phosphate buffer, pH 7.8, containing 1.33 mM DETAPAC

Xanthine solution (prepare fresh every week): 1.8 mM xanthine in 50 mM potassium phosphate buffer, pH 7.8.

NBT solution (keep in brown bottle): 2.24 mM NBT in 50 mM potassium phosphate buffer, pH 7.8

Catalase solution: 40 units/mL catalase in 50 mM potassium phosphate buffer, pH 7.8

Xanthine oxidase solution (diluted only at time of assay): about 10<sup>-2</sup> units/mL xanthine oxidase in solution A

The final concentrations of the above reagents are 1 mM DETAPAC, 1 unit/mL catalase, 56 μM NBT, and 100 μM xanthine.

#### 2. Procedure

1. Mix the following solution for a 20-sample assay: 13 mL solution A, 0.5 mL catalase solution, 0.5 mL NBT solution, 1.1 mL xanthine solution, and 0.9 mL 50 mM potassium phosphate buffer, pH 7.8 (to measure total SOD activity), or 0.1 M NaCN in the buffer (to measure Mn-SOD activity).
2. Add 800 μL of this solution to a cuvette.
3. Add 100 μL of standard SOD or sample to the cuvette.
4. Add 100 μL xanthine oxidase solution to the cuvette.
5. Mix and monitor at 560 nm by spectrophotometer for several minutes.

#### 3. Comments

Dilute xanthine oxidase with solution A until the change of the absorbance rate without SOD (blank) is between 0.015 and 0.025/min at 560 nm.

The change of the absorbance rate is recorded for at least 2 min after a good straight line is first obtained.

To measure the Mn-SOD activity, the xanthine oxidase solution is added after the reaction mixture is incubated in the presence of 5 mM NaCN (final concentration) for at least 30 min and no more than 2 h.

It is necessary that NBT reductase activity and xanthine oxidase inhibitory activity in tissues are checked when SOD activities in extracts of tissues are measured.

### B. Enzyme-Linked Immunosorbent Assay

ELISA is a convenient and sensitive assay for the measurement of SODs. ELISAs for each of the SOD isoforms have been developed by various investigators. We describe here the procedure of ELISA for human Cu,Zn-SOD in our laboratory (19).

#### 1. Reagents

Coating buffer: 50 mM sodium carbonate buffer, pH 9.5, containing 0.02% sodium azide

Washing buffer: 10 mM sodium phosphate buffer, pH 7.4, containing 150 mM NaCl, 0.05% Tween 20, and 0.02% sodium azide

Blocking buffer: 10 mM sodium phosphate buffer, pH 7.4, containing 150 mM NaCl, 0.05% Tween 20, 0.02% sodium azide, and 1% bovine serum albumin (BSA)

Substrate solution: 0.1 M diethanolamine hydrochloride, pH 9.8, containing 0.5 mM MgCl<sub>2</sub>, 0.02% sodium azide, and 2.7 mM *p*-nitrophenyl-phosphate

5 N NaOH

Antibody against Cu,Zn-SOD

Alkaline phosphatase-labeled antibody against Cu,Zn-SOD

## 2. Procedure

1. Add 80  $\mu$ L of 50  $\mu$ g/mL Cu,Zn-SOD antibody dissolved in coating buffer to each well of a 96-well immunoplate, and leave the plate to stand overnight at 4°C.
2. Wash each well with washing buffer.
3. Add 300  $\mu$ L blocking buffer to block the remaining protein-binding sites, and leave the plate to stand at 4°C until use. Remove the blocking buffer before use.
4. Add 70  $\mu$ L sample or standard diluted with blocking buffer to the wells, and incubate the plate for 2 h at room temperature.
5. Wash three times with washing buffer.
6. Add 80  $\mu$ L alkaline phosphatase-labeled Cu,Zn-SOD antibody diluted with blocking buffer to each well, and incubate the plate for 2 h at room temperature.
7. Wash three times with washing buffer.
8. Add 150  $\mu$ L substrate solution to each well, and incubate the plate for 30 min at room temperature.
9. Stop the enzyme reaction by the addition of 50  $\mu$ L of 5 N NaOH.
10. Measure the absorbance at 415 nm.

## VI. PURIFICATION

Since Cu,Zn-SOD was first isolated from bovine erythrocytes in 1969 (13), Cu,Zn-SOD and other isoforms have been purified from various species (20–22). Generally, the purification of Cu,Zn-SOD was carried out by means of extraction with organic solvent, anion-exchange column chromatography, and gel filtration. We briefly describe a procedure for Cu,Zn-

SOD preparation from spinach leaves reported by Kitagawa et al. (22). All procedures are carried out at 4°C. Spinach leaves are homogenized with 0.1 M potassium phosphate buffer, pH 7.8, using a Waring blender. The homogenate is forced through cotton cloth and centrifuged at 24,000 g by a continuous centrifugation technique. The supernatant is precipitated with 40–80% saturated ammonium sulfate. The precipitate is dissolved and dialyzed against 10 mM potassium phosphate buffer, pH 7.8. The dialyzed solution is applied to a column of DEAE-Sepharose CL-6B. The column is eluted with a linear gradient (10–60 mM) of potassium phosphate, pH 7.8. Fractions with SOD activity are collected, concentrated, and applied to a column of Sephadryl S-200. The column is eluted with 20 mM potassium phosphate buffer. Active fractions are collected and concentrated.

### I. INTRODUCTION

Polyphenol oxidase, also known as tyrosinase, phenolase, catechol oxidase, catecholase, *o*-diphenol oxidase, monophenol oxidase, and cresolase, was discovered in mushrooms in 1856 by Schoenbein (1). The problem with naming the enzyme is that it may act on two general types of substrates, a monohydroxyphenol (such as *p*-cresol) to hydroxylate it in the *o*-position with respect to the original hydroxyl group (monophenol, L-dopa:oxygen oxidoreductase; EC 1.14.18.1 (2) [Eq. (1)]), and on *o*-dihydroxyphenols, such as catechol, oxidizing them by removal of the hydrogens of the hydroxyl groups, forming benzoquinones (1,2-benzenediol:oxygen oxidoreductase; EC 1.10.3.1 (2) [Eq. (2)]).

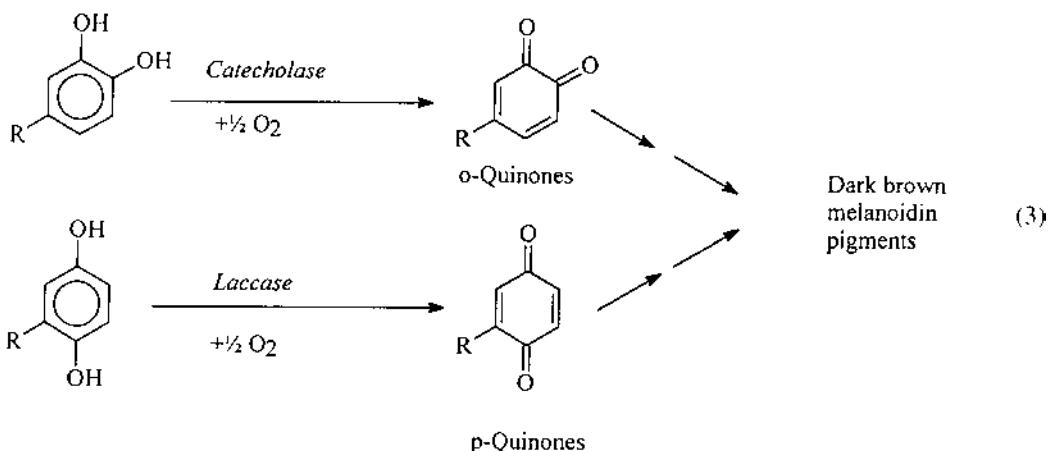

In this chapter, the first enzyme activity will be referred to as a monophenol oxidase and the second

as an *o*-diphenol oxidase. The monophenol oxidases generally also act as *o*-diphenol oxidases, often at a faster rate (3). Therefore, they are sometimes classified either as monophenol oxidases, *o*-diphenol oxidases, or both depending on substrates used. But not all *o*-diphenol oxidases can act as monophenol oxidases (4, 5). This view is not shared by all researchers in this field. The benzoquinones formed by *o*-diphenol oxidases are very reactive nonenzymatically with O<sub>2</sub>, sulfhydryl compounds, amines, amino acids, and proteins, so a variety of compounds, including melanin of the skin, are formed with colors including yellow, red, brown, and black.

A third type of “polyphenol oxidase” reaction occurs with the enzyme laccase (benzenediol:oxygen oxidoreductase EC 1.10.3.2 (2) [Eq. (3)]), acting on *p*-dihydroxy compounds, but not exclusively (Chapter 40), to give colored compounds. The laccases are also copper-containing enzymes, but the mechanistic oxidation pathway differs from that of the *o*-diphenol ox-

dases. The two types of enzymes can be distinguished by use of *p*-phenylene diamine or syringaldazine (these are substrates for laccase only).

Salicylhydroxamic acid and cinnamic acid inhibit only *o*-diphenol oxidases (6), while *p*-diphenol oxidases are selectively inhibited by quaternary ammonium compounds such as cetyl tetra-ammonium bromide (CTAB) (7). See also Flurkey et al. (8) and Chapter 40 on laccase in this handbook.

Polyphenol oxidases are found in many plant tissues (9, 10); in some fungi, especially those that produce brown filaments including edible mushrooms (11); and in many animals, including insects (12), mice (13), and humans (14). There are numerous genes in humans that affect pigmentation (15, 16). According to Witkop (14), there are at least 40 clinical manifestations of hypopigmentation and 27 of hyperpigmentation in humans, some leading to cancerous skin melanoma.

## II. IMPORTANCE TO FOOD QUALITY AND FOOD PROCESSING

Polyphenol oxidases are very important enzymes in determining the quality and economics of fruit and vegetable harvesting, storage, and processing (17–19). Bruises, cuts, and other mechanical damage during harvest, storage, and processing that allow O<sub>2</sub> penetration result in rapid browning in many fruits and vegetables. Up to one-half of some tropical fruits are lost for consumer consumption owing to browning, since the off-color, off-taste, and loss of nutritional quality are unacceptable to consumers. Apricots, apples, peaches, grapes, strawberries, and bananas (among others) and several tropical fruits and juices therefrom become brown, as do Irish potatoes and some lettuces

and other leafy vegetables. Black spot development in shrimp is a major economic problem.

Heat processing to inactivate polyphenol oxidase, especially in juices, is standard practice with certain fruits and vegetables. Some acceptable compounds such as ascorbic acid, thiol compounds, and sulfites may be added to prevent browning of cut fruits and vegetables (11). Cinnamic, *p*-coumaric, and ferulic acids can be added to apple juice (sometimes at < 0.01%) to prevent browning due to polyphenol oxidase (20). 4-Hexyl-resorcinol is a safe and effective inhibitor of enzymatic browning, is used in shrimp processing (21, 22), and prevents apple slice browning (23) among other fruits and vegetables. Browning of foods can also be prevented by removal of O<sub>2</sub>, acidification (if acceptability of the food permits), and removal of polyphenols by complexing with cyclodextrins and polyvinylpyrrolidone (24–26). Polyphenol oxidase levels in fruits and vegetables can be decreased by breeding and through biotechnology. An example of the use of biotechnology is the use of a specific antisense RNA to turn off expression of polyphenoloxidase in grape tissues (27).

Inclusion or decrease of O<sub>2</sub> and separation of polyphenol oxidase and substrate (phenols) provide excellent prevention from browning. Fruits and vegetables have “skins” (waxes and other O<sub>2</sub> impermeable compounds) on the surface that prevent O<sub>2</sub> absorption. As long as this protective skin is intact and the cellular tissue is undamaged, browning does not occur. In food processing and packaging O<sub>2</sub> can be excluded or reduced by use of gaseous N<sub>2</sub>, use of O<sub>2</sub>-impermeable coatings and films, and controlled atmospheric storage (O<sub>2</sub> reduced to the minimum needed to maintain cellular integrity at reduced temperature ( $\sim 5^\circ\text{C}$ )).

Color development due to polyphenol oxidase activity is desirable in the processing of tea, coffee, cocoa,

apple cider, prunes, black raisins, Black Mission figs, and zapote.

### III. PROPERTIES OF POLYPHENOL OXIDASES AS PROTEINS

#### A. Primary Sequences

Several amino acid sequences of propolyphenol oxidases and polyphenol oxidases are known, primarily from sequencing the gene. **Table 1** shows the similarities of nine plant PPO sequences. Another group of plant PPO sequences are depicted by a dendrogram (**Fig. 1**).

Whitaker (28) has compared the amino acid sequence relationships among polyphenol oxidases of higher plants, fungi, and higher animals known to 1995. The homologies (relative to potato 1) among the higher plant polyphenol oxidase gene sequences from potato 1, potato 2, tomato, and broad bean were 96.6% (potato 1 and 2), 92.2% (potato 1 and tomato), and 38.1% (potato 1 and broad bean). Among the fungi *S. glaucescens*, *S. antibioticus*, and *N. crassa*, the homologies were 87.5% (*S. glaucescens* with *S. antibioticus*) and 17.0% (*S. glaucescens* and *N. crassa*). Comparison between human and mouse polyphenol oxidases showed 41.0% homology. Overall, when potato 1 sequence was compared with those of *S. glaucescens*, *S. antibioticus*, *N. crassa*, and human and mouse polyphenol oxidases, there was 19.4%, 18.8%, 13.0%, 10.4%, and 10.9% homology, respectively. Only the primary sequences of *N. crassa* and *S. glaucescens* polyphenol oxidases were determined by the Edman degradation method on the mature protein.

The amino acid sequence homologies among the nine polyphenol oxidases (**Fig. 2**) are much higher when compared only in the active-site regions A and B (28). In active-site region A, of 26 amino acids, there is a range from 100% to 31% homology (**Table 2**). In active-site region B of 56 amino acids, the homology ranges from 96% to 34% (**Table 3**).

#### B. Molecular Weights

The presumed mature molecular weights of the 12 polyphenol oxidases listed in **Table 4** range from 30.7 kDa for *S. antibioticus* polyphenol oxidase to 128.0 kDa for mushroom polyphenol oxidase (with four sub-units). The potato, tomato, and broad bean polyphenol oxidases have molecular weights in the range of 56.5–58.1 kDa while grape polyphenol oxidases have molecular weights of 40.7 kDa. Three of the fungi polyphenol oxidases have molecular weights of 30.9–46.0 kDa, while mushroom polyphenol oxidase is 128.0 kDa. The human and mouse polyphenol oxidases are 62.6 and 57.8 kDa, respectively. With the exception of the polyphenol oxidases from *N. crassa*, *S. glaucescens*, and edible mushroom (*Agaricus bisporus*) (29, 30), the molecular weights are based on the gene sequence translated to amino acid sequence. Nothing is known about posttranslational modifications.

#### C. Secondary, Tertiary, and Quaternary Structure

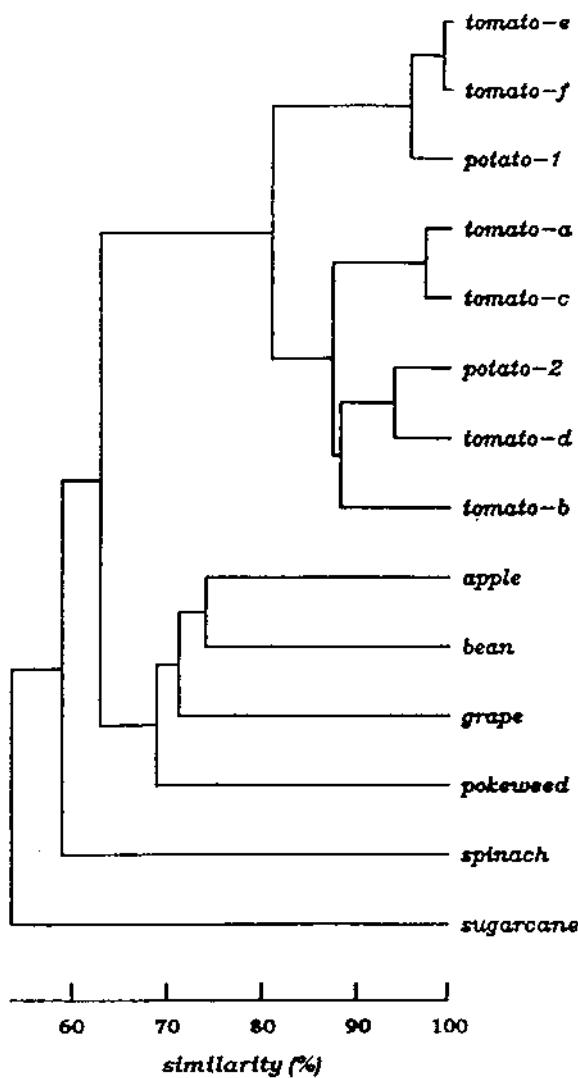

X-ray crystallography data have been published only for the sweet potato polyphenol oxidase (31, 32).

There are two isozymes of polyphenol oxidase in sweet potatoes of molecular masses 39.0 and 40.0

**Table 1** Similarity of the Aligned Plant PPO Sequences

	Tomato	Tobacco	Grenache grape	Sultana grape	Apple	Bean	Pokeweed	Spinach	Sugarcane
Tomato	100	90.48	59.52	60.03	56.97	56.8	55.2	53.74	43.2
Tobacco		100	58.01	58.52	56.49	56.83	53.83	51.43	43.68
Grenache grape			100	99.18	67.17	64.42	64.22	57.83	43.16
Sultana grape				100	67.34	64.42	64.4	57.73	43.09
Apple					100	69.7	63.03	54.88	45.29
Bean						100	62.69	56.84	43
Pokeweed							100	57.58	43.44
Spinach								100	40.42
Sugarcane									100

The GCG program OldDistances was used to calculate percent similarity among the plant PPOs from a complete PileUp alignment; part of this alignment is depicted in Figure 1. Genbank accession numbers are as follows: tomato, Z12837 S61013; tobacco, Y12501; Grenache grape, U83274; Sultana grape, Z27411; apple, D87670; bean, Z11702 S45506; pokeweed, D45385; spinach, X90869; sugarcane, U46014.

**Figure 1** Dendrogram illustrating the degree of similarity between the protein sequences of reported plant PPO genes. The Genbank accession numbers are apple (L29450), bean (Z11702), grape (Z27411), potato-1 (M95196), potato-2 (U22921), tomato-a (Z12833), tomato-b (Z12834), tomato-c (Z12834), tomato-d (Z12836), tomato-e (Z12837), tomato-f (Z12838), pokeweed (D34385), spinach (Z6655), and sugarcane (U846014). Sequences were aligned using the GCG programs PILEUP and FIGURE.

kDa (determined by MALDI-MS) (20). The sweet potato polyphenol oxidase molecular weight of 39.0 kDa has 345 amino acid residues, is a monomeric, ellipsoid molecule with dimensions of  $55 \times 45 \times 45\text{ }\text{\AA}$ . The secondary structure is primarily  $\alpha$ -helical in nature, with seven  $\alpha$ -helices and probably four short  $\beta$ -sheets with  $\beta$ - and  $\gamma$ -turns and random coils in the structure (Fig. 3). It appears to be an  $\alpha + \beta$  globular

protein. There are two disulfide bridges (Cys11–Cys28 and Cys27–Cys89). Each of the two active-site coppers is coordinated to three histidine residues on  $\alpha$ -helices. Copper of site A is coordinated to His88 of helix  $\alpha 2$  and His109 and His118 of helix  $\alpha 3$ . The copper of site B is coordinated to His240 and His244 of helix  $\alpha 6$  and His274 of helix  $\alpha 7$ .

As noted above, mushroom tyrosinase is thought to have quaternary structure (29, 30), probably composed of four subunits. The similarity of the subunits is uncertain. Based on gene sequences, there appear to be at least two isozymes of tyrosinase in mushrooms (33, 34).

#### IV. ENZYMATIC PROPERTIES OF POLYPHENOL OXIDASES

Some polyphenol oxidases oxidize both monophenols such as *p*-cresol, tyrosine etc. (monophenols), and diphenols such as catechol and *o*-dihydroxyphenylalanine [Eqs. (1) and (2)]. Lerch and Ettlinger (3) investigated the activity of pure *Streptomyces glaucescens* polyphenol oxidase (tyrosinase) on a large number of mono- and *o*-diphenols. In all cases, the *o*-diphenolase activity was greater than the monophenolase activity. The ratio of  $k_{\text{cat}}$  for activity on *o*-diphenol to that of  $k_{\text{cat}}$  for activity on the analogous monophenol ranged from 222 for homocatechol/*p*-cresol to 2.89 for 3,4-dihydroxyphenylacetic acid/*p*-hydroxyphenylacetic acid. The  $K_m$  values for the analogous *o*-diphenol to monophenol ranged from 1.00 to 7.88. Therefore,  $K_m$  and  $k_{\text{cat}}$  are both responsible for the large differences in activity on mono- and *o*-diphenols.

Table 5 shows some activity results of plant polyphenol oxidases on a limited number of mono- and *o*-diphenols. Polyphenol oxidase from peaches was not able to hydroxylate *p*-cresol or *p*-coumaric acid, and polyphenol oxidase from pears was not able to hydroxylate *p*-coumaric acid. The highest activities on monophenols were the 5.5% and 4% on *p*-cresol compared to that of catechol for potato and broad bean, respectively. Note also the variable relative activities on *o*-diphenols compared to that on catechol.

There is some disagreement by researchers on whether or not all polyphenol oxidases can perform the hydroxylation step [Eq. (1)]. As shown in Eq. (1) a reducing compound,  $\text{BH}_2$ , is required in the reaction.  $\text{BH}_2$  is an *o*-diphenol such as catechol. If no  $\text{BH}_2$  is present, some polyphenol oxidases appear to be able to slowly produce  $\text{BH}_2$  during a lag period in the initial reaction with a monophenol (Fig. 4). The *in vivo* nat-

**Figure 2** Amino acid sequence relationships in and near the active sites of potato (Pot 1 and Pot 2), tomato (Tom A and Tom B), broad bean (BB), *S. glaucescens* (S.g.), *S. antibioticus* (S.a.), *Neurospora crass* (N.c.), *Homo sapiens* (H.s.), *Mus musculus* (M.m.), putative mouse transcript 4 (pMT 4) polyphenol oxidases, hemocyanin E (spider, *Euryopelma californicum*) and hemocyanin D (spider, *E. californicum*). Shown are regions A and B containing the presumed copper-binding histidine residues. The Cu indicates histidines that ligand to copper in *N. crassa* polyphenol oxidase, and presumably in the other polyphenol oxidases and hemocyanins. The - indicates that the sequence is the same as for POT1. (From Ref. 28.)

ure of BH<sub>2</sub> is not known. Lerch and Ettlinger (3) reported lag periods of 0.32–16.0 min for *S. glaucescens* polyphenol oxidase acting on N-acetyl-L-tyrosine hydrazide and *p*-hydroxyphenylacetic acid, respectively. Whitaker (unpublished data) showed that 1 × 10<sup>-7</sup> M 4-methylcatechol added to mushroom polyphenol oxidase, along with *p*-cresol, was able to eliminate the 9-min lag period entirely. Equation (4) shows that the BH<sub>2</sub> acts on the Cu(II) *met* form to reduce the two coppers to Cu(I) (*deoxy* form), which can then bind O<sub>2</sub> and oxidize the monophenol substrate to the *o*-diphenol. Would similar experiments with other polyphenol oxidases show that all polyphenol oxidases can do both types of reactions?

Kinetically, the mechanism of peach polyphenol oxidase (5) and *S. glaucescens* polyphenol oxidase (3) followed an ordered BiBi mechanism (Fig. 5). The O<sub>2</sub> must bind first to the *deoxy* form (Cu(I) state) of the enzyme followed by phenol. The ordered BiBi mechanism assumes that the products come off in the order of the benzoquinone followed by the hydrogen peroxide. This author does not know of published experimental data to support this assumption.

The overall proposed mechanism of action of polyphenol oxidase is shown in Figure 6. The top part shows the pathway for oxidation of *o*-diphenols. The *met* form (at the No. 1 position in the A cycle) is thought to be the “resting” form of the enzyme when

**Table 2** Amino Acid Sequence Homologies Among Nine Polyphenol Oxidases in Active Site Region A

Source	AA sequence region	Identical AA	% Homology
Pot 1	110–135	26 <sup>a</sup>	100
Pot 2	110–135	26	100

<i>M.m.</i>	191–216	8	31

<sup>a</sup>The number 26 amino acid residues includes amino acid residues + spaces for alignment. (Taken from Figure 2.)

no substrate is present. Addition of *o*-diphenol (catechol; BH<sub>2</sub>) binds to the *met* Cu(II) form (#2) producing the *deoxy* [Cu(I)] form of the enzyme (and *o*-benzoquinone). The *deoxy* form binds O<sub>2</sub> (#3) to give the *oxy* form [Cu(II)] which then binds a molecule of *o*-diphenol (#4) to give the enzyme Cu(II) · O<sub>2</sub> · diphenol ternary complex. Two hydrogens are removed to give the benzoquinone (#5) and the *met* form of the enzyme in a complete cycle.

Depending on substrate available, the *oxy* form of the enzyme (produced as above from the *met* form) can bind a monophenol (Pathway B) (#1') which is oxidized to the *o*-diphenol (#2') and recycles through the B pathway via the diphenol intermediate to the *deoxy* form (#4') which can bind O<sub>2</sub> to form the *oxy* form (#5'), etc. The *met* form, reduced to the *deoxy* form by an *o*-diphenol (Fig. 6), can also be reduced to the *deoxy* form by other reducing compounds (ascorbic acid,

<sup>a</sup> There are two peaks of polyphenol oxidase activity from a Sephadex G-100 column (40.7 and 29.0 MW). The 40.7-kDa peak has the most activity.

Source: Whitaker, 1998, unpublished data.

hydroxylamine, dithionite) and by H<sub>2</sub>O<sub>2</sub> in the presence of O<sub>2</sub> (39). The overall mechanism indicates there are three different steps in Figure 6 leading to oxidation of *o*-diphenols to benzoquinone.

Polyphenol oxidases are irreversibly inactivated during the oxidation of substrate to product. Golani-Goldhirsh and Whitaker (40) calculated that inactivation of mushroom polyphenol oxidase occurs at the rate of approximately one in 5000 turnovers of the substrate to product (an efficiency of ~0.02%). But complete inactivation of the enzyme can occur in 2–3 min reaction with substrate (with no added reductant such as ascorbic acid). The inactivation is due to a free radical-catalyzed fragmentation of one or more of the six histidine residues that bind the two coppers at the active site. The fragmentation leads to loss of histidine and release of copper (40–42). Reaction inactivation of *N. crassa* polyphenol oxidase is due to loss of His306 in the active site (42).

Golan-Goldhirsh et al. (43) later showed that ascorbic acid, copper, and O<sub>2</sub> mimic the above reaction not only with polyphenol oxidase but also with ovalbumin, Kunitz trypsin inhibitor, bovine serum albumin, and small histidine-containing peptides, leading to loss of most of the histidine residues in 24 h at 25°C. In the case of mushroom polyphenol oxidase, the histidine residues of the protein are converted by the free radical process in the absence of mono- or diphenols, but require O<sub>2</sub>, to several products including aspartic acid (major product), glycine, alanine, and urea (stoichiometric with the aspartic acid formation). Free radi-

**Figure 4** Theoretical graph for the velocity of product formation from oxidation of monophenols by polyphenol oxidases in the absence of  $\text{BH}_2$ . There is an initial lag period followed by maximum velocity and then slowing of the velocity as the enzyme undergoes reaction inactivation. The negative velocity phase is due to melanin formation, which absorbs at a different wavelength.

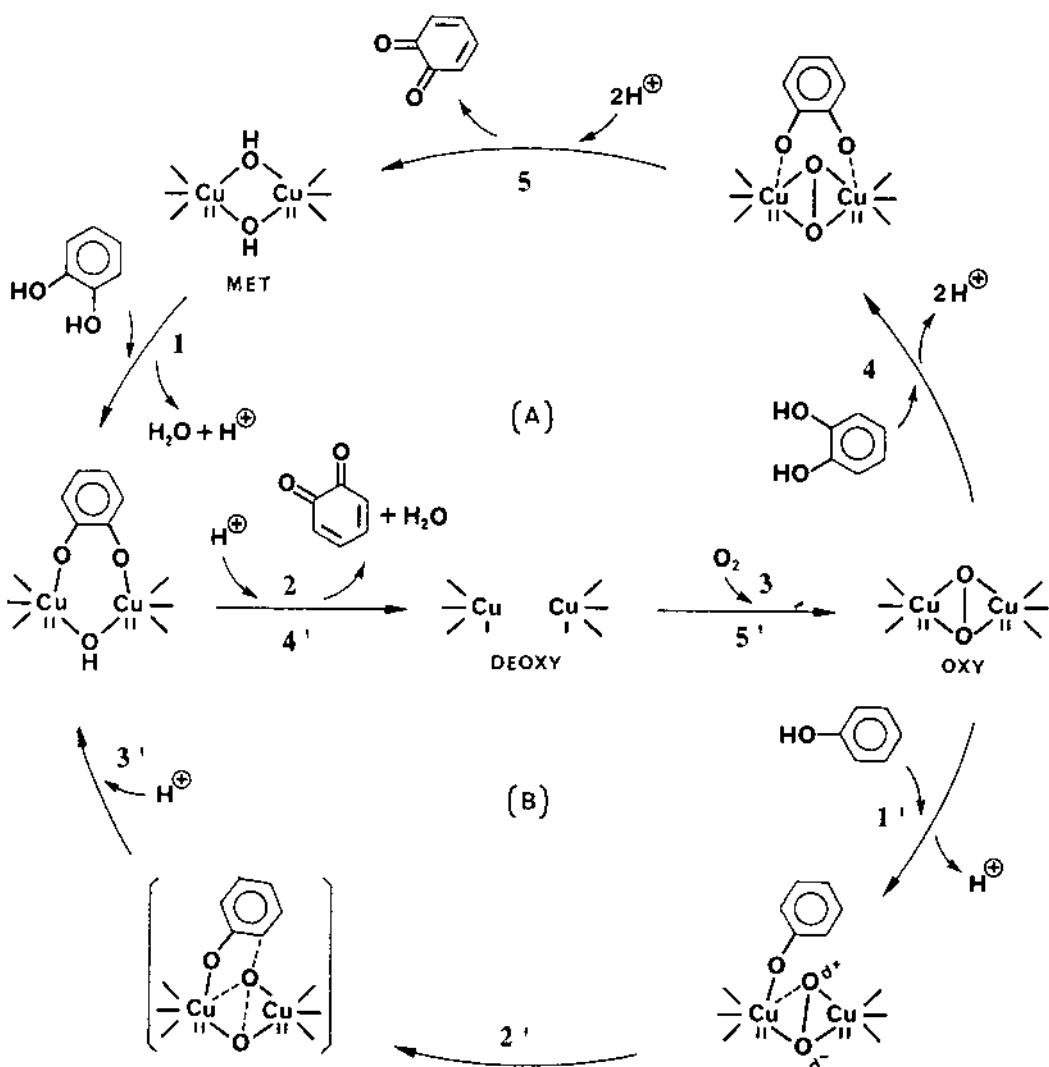

cals due to semiquinone formation of the substrate can be detected during polyphenol oxidase-catalyzed reactions (44, 45; Sugumara et al., cited in 46) in insect cuticle formation by polyphenol oxidase. Free radical formation (11) requires  $\text{O}_2$ , a reducing agent (we used ascorbic acid only), a histidine residue (histidine in small peptides are also fragmented), and  $\text{Cu}(\text{II})$  (we could not detect  $\text{Cu}(\text{I})$  formation by bathocuproine disulfonate in the reaction). The specific free radical formed has not been identified yet, to the authors' knowledge.

**Figure 5** (Top) Effect of  $\text{O}_2$  and chlorogenic acid concentrations on initial velocity,  $v_0$ , of pear polyphenol oxidase-B catalyzed reactions. The reactions were followed with an oxygen electrode at pH 4.0 and  $30.0^\circ\text{C}$ , permitting initial  $v_0$  to be determined. (Bottom) Kinetic mechanism for pear polyphenol oxidase-B catalysis, diagrammed according to the Cleland nomenclature for an Ordered Sequential Bi-Bi Mechanism. P is an *o*-diphenol; B is an *o*-benzoquinone;  $\text{E} \cdot \text{O}_2$  is a binary enzyme- $\text{O}_2$  complex;  $\text{E} \cdot \text{O}_2 \cdot \text{P}$  is a ternary enzyme- $\text{O}_2$ -*o*-diphenol complex, and  $\text{E} \cdot \text{H}_2\text{O} \cdot \text{B}$  is a ternary enzyme- $\text{H}_2\text{O}$ -*o*-benzoquinone complex. (From Ref. 5.)

## V. MEASUREMENT OF POLYPHENOL OXIDASE ACTIVITY

The two main methods of measuring polyphenol oxidase activity are spectrophotometry and polarography. There are strong advocates of each method, including statements that both methods are unreliable (47, 48). The basis of the unreliability is caused by the further nonenzymatic oxidation of the benzoquinone formed. As shown by Mayer et al. (47), results from the two are identical very early on in the reaction (Table 6), but by 54 sec the difference is 28%. Note that  $\text{O}_2$  consumption measurements contribute primarily to the difference because of the continued nonenzymatic oxidation of benzoquinone and other intermediate products. For example, the oxidation of 4-methyl catechol to 4-methyl-2,3-benzoquinone requires 1.0 equivalent of  $\text{O}_2$ , while further reactions (generally nonenzymatic) require 1.4 additional equivalents of  $\text{O}_2$ . But, as shown by Whitaker (28), there is also a decrease in

**Figure 6** Proposed kinetic scheme depicting the mechanisms of oxidation of *o*-diphenol (catechol [A]) and monophenol (phenol [B]) by *Neurospora crassa* polyphenol oxidase. (From Refs. 37, 38.)

absorbance after  $\sim 2$  min as the benzoquinone is converted to other products that do not absorb maximally at the wavelength of benzoquinones. Therefore, it is critical to obtain initial velocity ( $v_0$ ) early on in the reaction. As shown by Eqs. (1) and (2), the oxidation of monophenols to benzoquinone plus  $H_2O$  requires two equivalents of oxygen, while oxidation of *o*-diphenols to benzoquinone requires one equivalent of oxygen.

In reactions involving monophenols, a lag phase is generally observed (see Fig. 4). As shown in Eq. (1) and Figure 6,  $BH_2$  is required to reduce the *met* form of polyphenol oxidase to the *deoxy* form that can bind  $O_2$ . Addition of as little as  $1 \times 10^{-7} M$  catechol to the reaction can eliminate the lag period.

In the measurement of monophenol activities, the rate of conversion of the intermediate product (an *o*-diphenol) to the benzoquinone is generally measured. But in some cases,  $k_{cat}$  values for the monophenol and product *o*-diphenol can be very similar (3). Examples are shown in Table 7.

The monophenol oxidation can be measured uniquely by use of  $^{18}O$ -labeled  $O_2$  or tritium-labeled substrate.

#### A. Measurement of Monophenolase Activity

##### 1. Use of Tritium-Labeled Substrate

As shown in Eq. (1), one atom of oxygen (from  $O_2$ ) is covalently attached to the 2 position of *p*-cresol, along

**Table 6** Comparison of the Spectrophotometric and Polarographic ( $O_2$  electrode) Methods of Measuring Apple Catechol Oxidase Using 4-Methyl Catechol as Substrate

Time (sec)	(1) <sup>a</sup> Quinone Formed ( $\mu\text{mol}$ )	(2) <sup>b</sup> $O_2$ consumption ( $\mu\text{mol}$ )	Ratio <sup>c</sup> (2)/(1)
18	0.256	0.261	1.02
54	0.512	0.653	1.28
93.6	0.768	1.133	1.48
198	1.024	1.568	1.53
480	1.408	2.464	1.75

<sup>a</sup> Measured spectrophotometrically.

<sup>b</sup> Measured polarographically.

<sup>c</sup> *o*-Benzoquinone formation from 4-methylcatechol consumes 1 gram-atom of  $O_2$  per mole of catechol, whereas conversion of 4-methylcatechol to melanin consumes 2.4 gram-atoms  $O_2$  per mole of catechol oxidized.

Source: Ref. 47.

with a H to give 4-methyl catechol. By the use of the 2-tritiated *p*-cresol, tritium will be released into the aqueous phase. During the initial phase of the reaction (between 0 and 60 sec), the rate of release of tritium should give a good measure of the initial velocity of the hydroxylation step. The remaining tritiated *p*-cresol must be removed by chromatography or by an adsorption method.

## 2. Use of $^{18}\text{O}$ -Labeled $O_2$

As shown by Eq. (1), one atom of oxygen (from  $^{18}\text{O}_2$ ) will be covalently attached to the 2 position of *p*-cresol, along with a H to give 4-methyl catechol with an  $^{18}\text{O}$

label. The unincorporated  $^{18}\text{O}_2$  can be flushed from the solution by  $\text{N}_2$ , or the water can be distilled from the solids, and the water collected to measure the increase in  $^{18}\text{O}$  level of the water, or the 4-methyl catechol, in the presence of a reducing agent such as ascorbic acid, can be obtained. The increase in  $^{18}\text{O}$  in the product will give a measure of the velocity of the monophenol oxidase reaction.

## 3. Spectrophotometric Method at 280 nm

An easier method than those in 1 and 2 above is to measure the increase in absorbance at 280 nm due to the formation of 4-methyl catechol from *p*-cresol. Again, the measurements must be made within the first 30–90 sec of beginning of the reaction.

## 4. Use of Diphenol Conversion Rates to *o*-Benzoquinone

$K_m$  values for monophenols are in the range of  $4.5 \times 10^{-5} M$  (*N*-chloroacetyl-L-tyrosine ester ester) to  $5.34 \times 10^{-3} M$  (glycyl-L-tyrosine) for the *S. glaucescens* polyphenol oxidase (3) and  $2.62 \times 10^{-4} M$  and  $4.62 \times 10^{-4} M$  for L-tyrosine methyl ester for the  $\gamma$ - and  $\alpha$ -isozymes of mushroom polyphenol oxidase (30). When the  $K_m$  and  $k_{\text{cat}}$  values of the monophenol and *o*-diphenol substrates are similar, the observed rates of the reactions of benzoquinone formation will be contributed by both rate constants ( $v_0 = k_2(E)_0(S)_0 / ((k_2 + k_3)/k_2 k_3) + (S)_0$ ).

See discussion below for methodology to use.

**Table 7** Ratios of  $k_{\text{cat}}/K_m$  and  $k_{\text{cat}}/k_{\text{cat}}$ , in Parentheses, for Some Monophenol/*o*-Diphenol Substrate Pairs

## B. Measurement of *o*-Diphenol Oxidase Activity

Reports of  $K_m$  values for *S. glaucescens* enzyme activity on *o*-diphenols range from  $3.72 \times 10^{-4} M$  for caffeic acid to  $1.50 \times 10^{-2} M$  for 3,4-dihydroxy-D-phenylalanine (3). For mushroom isozymes  $\alpha$  and  $\gamma$ ,  $K_m$  values are  $3.75 \times 10^{-4} M$  and  $4.00 \times 10^{-4} M$ , respectively (30). Other reports of  $K_m$  include those of Wong et al. (4) where  $K_m$  values for catechol and peach polyphenol oxidase were 6.6, 4.2, 7.0, and 36.0 mM for isozymes A, B, C, and D, respectively, and of Rivas and Whitaker (5) with pear isozymes A and B, where  $K_m$ s were 20.9 and 33.9 mM for pyrocatechol, 8.0 and 5.8 mM for 4-methyl catechol, 16.1 and 11.9 mM for chlorogenic acid, and 3.1 and 1.6 mM for d-catechin, respectively. These  $K_m$  values permit one to use an appropriate concentration of substrate for measuring activities.

### 1. Spectrophotometric Method

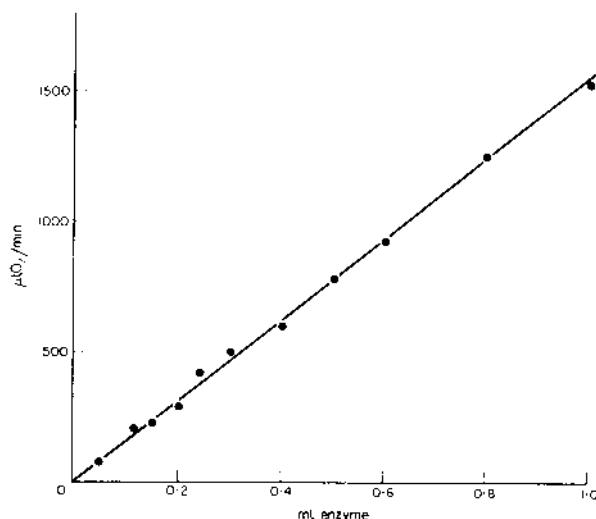

In the author's laboratory, *o*-diphenol oxidase activity is generally determined using catechol or 4-methyl catechol (prepared fresh daily) by mixing 4.00 mL of 0.1 M sodium phosphate buffer, pH 7.0, 0.50 mL of  $5.00 \times 10^{-2} M$  4-methylcatechol (final concentration  $5.00 \times 10^{-3} M$ ) and adding 0.50 mL of polyphenol oxidase of a concentration that gives a change in absorbance of  $\sim 0.100/\text{min}$ . The wavelength used is 395 nm; the  $\epsilon_m$  for 4-methylbenzo-2,3-quinone is  $1.350 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$  at 395 nm.

Absorbance should be measured with a recording spectrophotometer so that  $v_0$  can be determined precisely at the very early stage of the reaction for reasons discussed above. The temperature and pH should also be controlled.

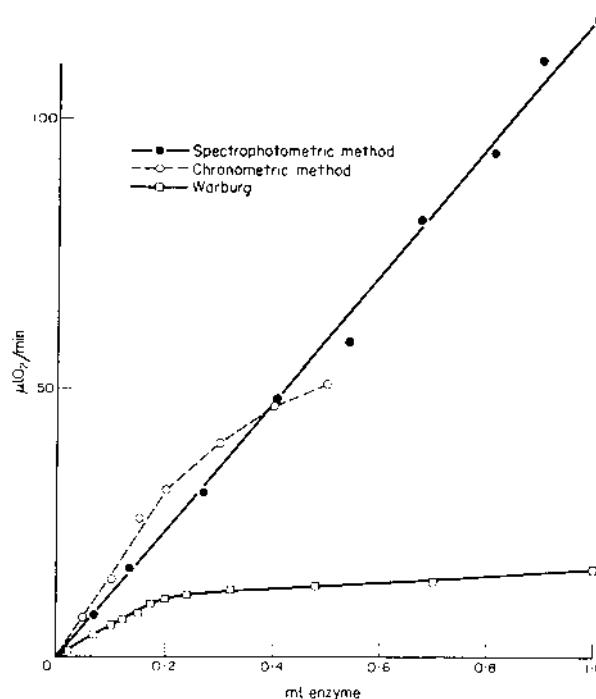

### 2. Polarographic Method

The polarographic method, also called the  $\text{O}_2$ -electrode method, determines the rate of  $\text{O}_2$  uptake. As shown in Figures 7 and 8 and Table 6, the  $\text{O}_2$  electrode and spectrophotometric methods give linear relationships over a wide range of enzyme concentrations. The chronometric method measures the lag time before browning occurs or ascorbic acid is exhausted, and the manometric method ( $\text{O}_2$  uptake) does not give linear relationships between enzyme concentration and  $\text{O}_2$  uptake.

The concentration of enzyme, substrate, buffers, and pH used may be the same as described for the spectrophotometric method (above). Specific conditions are also given in the legends of Figures 7 and 8 (47).

**Figure 7** Relationship between enzyme concentration and  $\mu\text{L O}_2$  consumed by oxidation of 4-methyl catechol by apple catechol oxidase, using an  $\text{O}_2$  electrode. The reaction was performed in phosphate-citrate buffer, pH 5.1 with  $5 \times 10^{-3} M$  4-methyl catechol and stock solution of  $50 \mu\text{g}$  enzyme protein/mL. (From Ref. 47.)

**Figure 8** Relationship between enzyme concentration and  $\mu\text{L O}_2$  consumed by oxidation of 4-methyl catechol by apple catechol oxidase using spectrophotometric, chronometric, and Warburg techniques. The reaction was performed under the experimental conditions given in Figure 7. (From Ref. 47.)

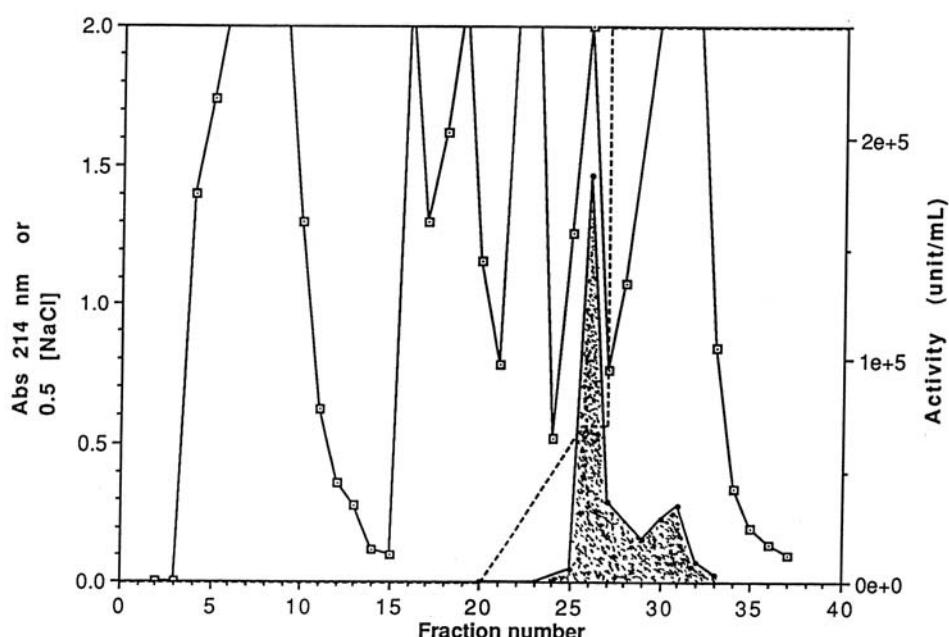

## VI. PURIFICATION OF POLYPHENOL OXIDASES

Purification of polyphenol oxidase must be done without any development of browning. Otherwise, the polyphenol oxidase will be modified by reaction of the  $\epsilon$ -amino group of lysyl residues with the *o*-benzoquinone. Modification leads artificially to several bands with activity as shown by gel electrophoresis or by column chromatography (E. Ramírez and J.R. Whitaker, unpublished data).

Several methods have been used by the authors to prevent browning. The tissue was frozen in dry ice or Freon (4, 5), lyophilized, and the powder extracted repeatedly with cold ( $-5$  to  $-10^{\circ}\text{C}$ ) acetone to remove the phenolic compounds. This method of removing phenols with acetone, while used widely in the 1950s to 1970s, has been shown to modify proteins under certain conditions. We have found Freon to be a good method for rapidly freezing the tissue (5). More recently, we have used  $0.03\text{ M}$  ascorbic acid and insoluble polyvinyl polypyrrolidone with frozen whole grapes to prevent browning by binding the phenols. This gave an extract that did not brown. We have

also successfully used ascorbic acid and Sephadex G-25 to bind the phenols. This is done at  $0^{\circ}\text{C}$ .

The following method (E. Ramírez and J.R. Whitaker, unpublished data) was used to purify grape polyphenol oxidase to homogeneity for crystallization for x-ray structure determinations. Acceptable extraction yields were obtained only when a maximum of 250 g of grapes per batch were used as starting material. Attempts to extract PPO from larger batches were unsuccessful, owing to insufficient mechanical agitation during the second extraction step because of high viscosity of the solution. All steps were done at  $4^{\circ}\text{C}$ . In a typical extraction, 100–200 g of frozen whole Grenache grapes were blended in a Waring blender for 5 min at low speed with 2 volumes (w/v) of buffer A (100 mM sodium phosphate, 0.03 M ascorbic acid, pH 6.5) and 10% PVPP. Pulp was separated by centrifugation (23,000 g, 30 min) and the supernatant discarded. It contained no PPO activity. The precipitate was transferred to a beaker with 1 volume of buffer B (100 mM sodium phosphate, 0.1% Triton X-100, pH 6.5) and 2.5% PVPP. This suspension was mechanically stirred for 30 min. After centrifugation (23,000 g, 30 min) the precipitate was discarded and

**Figure 9** Mono Q [ $\text{R}-\text{CH}_2-\text{N}^+(\text{CH}_3)_3$ ] HR 5/5 column chromatography of grape polyphenol oxidase. Protein was eluted initially with a sodium chloride linear gradient (0–0.3 M), held for 2 mL at 0.3 M sodium chloride, and then stepped up to 1 M (dashed line). Activity of polyphenol oxidase is indicated by closed circles (and shaded area). Protein is indicated by open squares. The small peak of activity at Fraction No. 30 is that designated as Mono Q II in the text.

**Table 8** Purification of Grenache Grape Leaf Polyphenol Oxidase

Sample	Activity (units/mL) $\times 10^{-3}$	Protein ( $\mu\text{g}/\text{mL}$ )	Spec. activity (units/mg) $10^{-3}$	Volume (mL)	Total protein (mg)	Total activity (units $\times 10^{-3}$ )	Yield (%)	Purification (fold)
Extraction	3.64	53.1	68.5	2267	120	8250	100	1.00
40% AS (sum)	13.8	26.9	513	480	12.9	6620	80.0	7.47
95% AS (sum)	90.2	272	332	22	5.98	1980	24.0	4.82
Mono QI	164	260	631	3	0.78	492	6.75	9.19
Mono QII	33.3	105	317	14	1.47	466	5.64	4.63

the supernatant was concentrated by ultrafiltration (Amicon microconcentrator, Diaflo PM10 membrane).

The concentrated solution was brought to 40% saturation with ammonium sulfate, let stand for 30 min, centrifuged, and the precipitate discarded. The supernatant was further brought to 95% saturation with ammonium sulfate, let stand for 30 min, centrifuged, and the supernatant separated. The supernatant still contained 50% of total activity; owing to very low protein concentration, some PPO remained in solution. The precipitate was stored at 4°C (or frozen) until all extractions were done.

The precipitates from all extractions were combined, dissolved in a minimal amount of buffer (5 mM sodium phosphate buffer, pH 8.0), and dialyzed with 200 volumes of the same buffer. The sample was applied to a Mono Q [(R-CH<sub>2</sub>-N<sup>+</sup>(CH<sub>3</sub>)<sub>3</sub>] HR 5/5 column linked to an FPLC system and the polyphenol oxidase was eluted with 0.3 M NaCl in the 5 mM sodium phosphate buffer, pH 8.0, as shown in Figure 9 (Mono Q I peak; at Fraction No. 26). A second, smaller peak (Mono Q II) with polyphenol oxidase activity and brown color was eluted with 1 M NaCl at Fraction No. 31. Native PAGE of Mono Q I peak showed only one protein band (Coomassie Blue R-250 stain) and one concomitant activity band (stained with 8 mM catechol, 0.06% 3-methyl-2-benzothiazolinone hydrazone [MBTH]). Native PAGE of the Mono Q II peak gave five protein bands, all of them active. Most likely, these are modified PPO owing to reaction with PPO-produced benzoquinones. The purification of Grenache PPO is summarized in Table 8. We used the first peak (Mono Q I) for crystallization, which corresponded to unmodified polyphenol oxidase as indicated by no brown color.

Protein was determined using the 1976 Bradford assay (48) or by following the absorbance at 214 nm for column chromatography. Activity was determined by a modification of the colorimetric method described by Ponting and Joslyn (49) using 5 mM catechol as

substrate and measuring the initial change in absorbance at 420 mM (pH 6.5, 25°C). One unit of activity is defined as an increase in absorbance of 0.001/min.

The  $M_r$  of the mature PPO was determined on gel filtration columns.  $M_r$  was  $41.2 \pm 2$  kDa (replications = 4) on Sephadex G-75 (fine), 34.6 kDa on Superose 12 column (50), 28.0 kDa on TSKgel G3000 SW, and 22.9 kDa on TSKgel 2000 SW. Superose 12 columns are known to give  $M_r$  values that are too low (51). Note that the  $M_r$  values on TSK gels are even lower than those on Superose 12. All standard proteins were the same (bovine serum albumin, ovalbumin,  $\beta$ -lactoglobulin [dimer], chymotrypsinogen, and ribonuclease A). Based on our use of Sephadex columns for  $M_r$  determination for 37 years, we suggest the correct  $M_r$  is near 41.2 kDa.

## Laccase

**William H. Flurkey**

*Indiana State University, Terre Haute, Indiana, U.S.A.*

### I. INTRODUCTION

Laccase was first discovered in the latex of *Rhus vernicifera*, Japanese lacquer tree, by Yoshida in 1883 (1) where it was observed to catalyze the oxidation of urushiol. The enzyme was “rediscovered” and named some 10 years later (1894–1896) by Bertrand (2), who found the enzyme in the lac trees and mushrooms. Laborde (3) also reported the existence of the enzyme in mushrooms in 1896. Laccase is a multicopper enzyme member of the blue-colored oxidase family (for reviews see 4–15). Laccase catalyzes the four-electron reduction of molecular oxygen to water. A variety of compounds, including substituted monophenols, *o*- and *p*-diphenols, methoxyphenols, aminophenols, aryl amines, and even some inorganic ions (i.e., potassium ferrocyanide), can serve as the electron donors in the reaction and are oxidized in the process (Table 1).

In general, laccases can oxidize a variety of *p*-diphenols, resulting in the production of *p*-diquinones (Fig. 1a). Oxidation of syringaldazine, a common laccase substrate, also proceeds through a free radical intermediate followed by formation of a quinone (Fig. 1b). The oxidation and formation of free radicals as semi-quinones also occurs when laccase acts as a dimethoxyphenol oxidase (Fig. 1c). With some substrates, this free radical formation leads to coupling reactions and/or generation of quinone products. For example, *Rhus* laccase can act upon urushiol to yield coupled products (Fig. 1d), and plant laccases have been found to oxidize monolignols into dimers and trimers (Fig. 1e).

Fungal laccases have also been found to convert syringylglycol guaiacol ethers into a variety of products containing aldehyde, carboxylic acid, ester, or quinone groups (Fig. 1f). Depending on the type of substrate and the type of laccase, a variety of products can be formed.

Chemical structures of some of the artificial substrates used to monitor laccase are shown in Figure 2. This list includes di- and tri-phenols, methoxy and amino phenols, phenylamine and phenylamine-like compounds and heterocyclic compounds. 2,2'-azino-bis-(3-ethylbenzthiazoline-6-sulfonic acid; ABTS) is currently one of the more common laccase substrates.

Laccase is classified as an oxidoreductase (benzene-diol:oxygen oxidoreductase; EC 1.10.3.2). However, there is still apparent confusion over its Enzyme Commission (EC) classification number since there are recent publications about laccase using an EC number of 1.10.3.1 (*p*-diphenol:oxygen oxidoreductase) and 1.14.18.1 (*p*-diphenol:oxygen oxidoreductase) in the current literature.

### II. IMPORTANCE TO QUALITY OF FOOD

The importance of laccase to the quality of food is directly related to its proposed biological function. Laccases are found in a variety of plants, fungi, and even some bacteria. In higher plants, laccases are thought to be involved in lignification and detoxification/protection. In fungi, laccases produce colored pig-

ferrocyanide	ascorbic acid	1,2,4,5-tetramethoxybenzene

ments during chestnut blight pathogenic infections. Although laccases are different from lignin peroxidases, Mn peroxidases, and other peroxidases, they can utilize some of the same substrates, but they are proposed to be a less strong oxidant than these peroxidases. Because laccases can oxidize a variety of phenolic and phenolic-like compounds, they can also cause browning-like reactions in fruits and vegetables. The browning reactions decrease consumer product appeal, nutritional value, and marketability. The association of fungal laccases with many plant and fruit products poses other potential problems related to browning and crosslinking of polymeric material, and could affect product characteristics and properties during storage and processing.

### III. LOCATION OF LACCASE

#### A. Tissue Localization

In plants, laccase has been located in lignifying xylem cells where it is associated with cell walls. Extracellular laccase is secreted by plant cell cultures. In these culture conditions, laccase was not found in the cytoplasm, but it was associated with cell walls. An epidermal location of laccase was indicated in stem tissue.

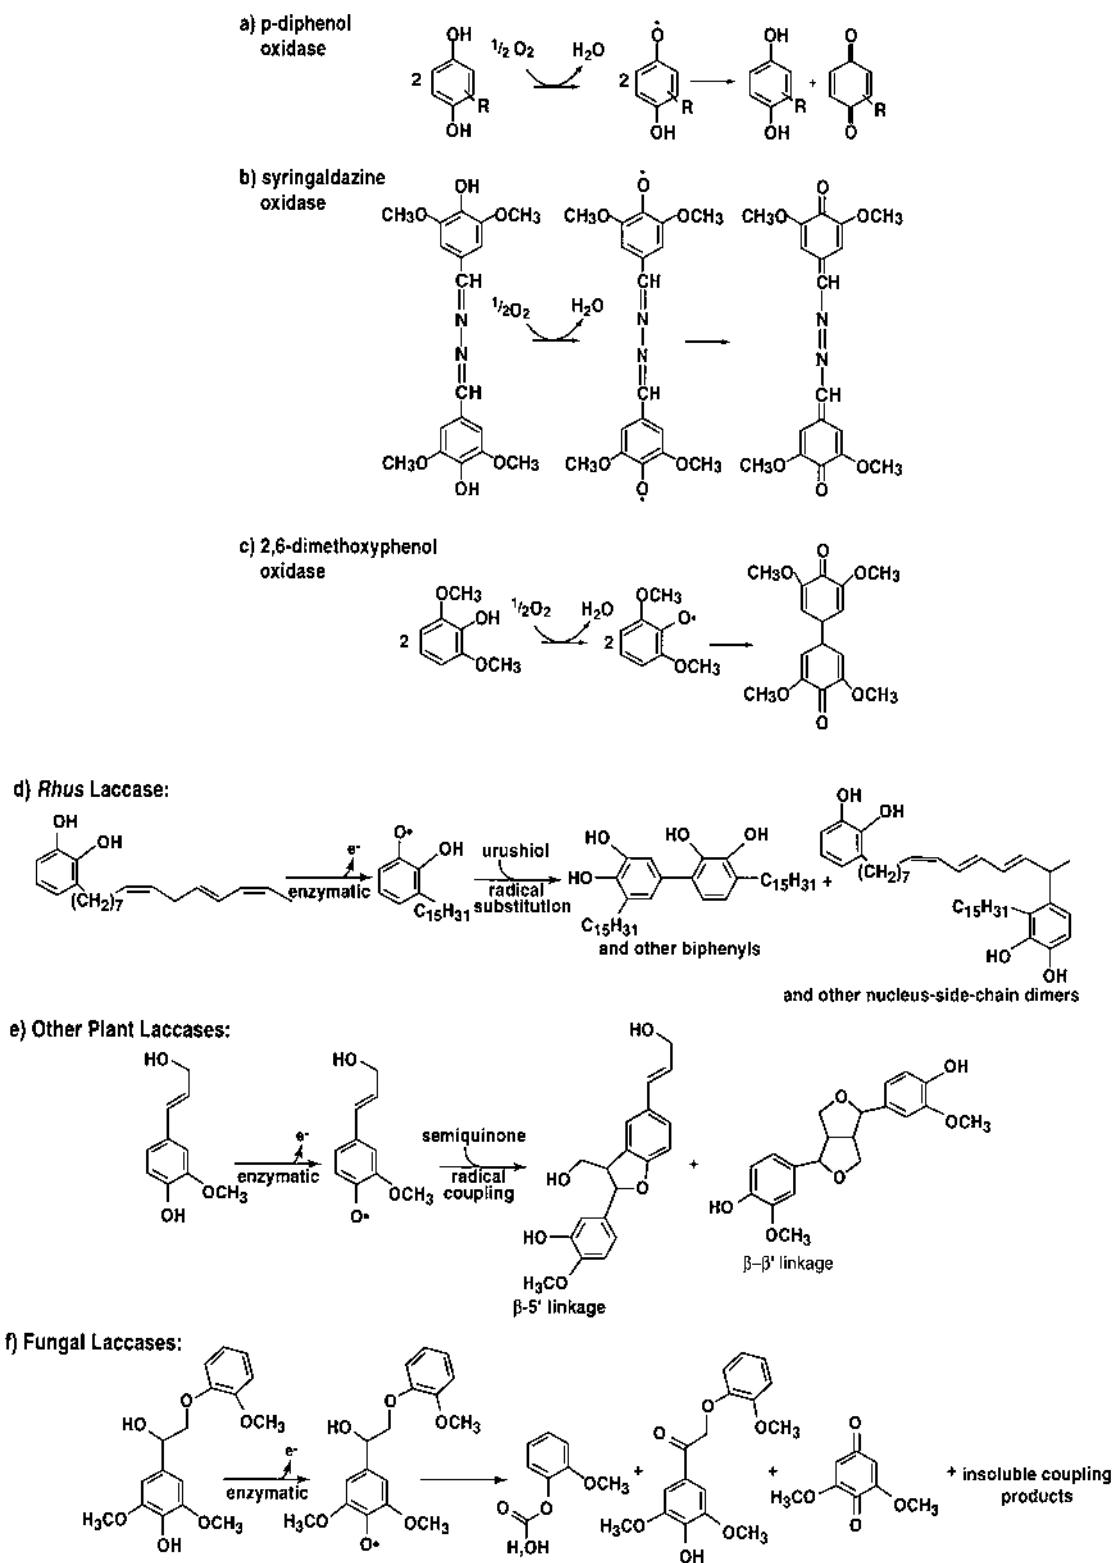

#### B. Methods for Determining Location

Spot tests, either of liquid culture samples or cultures grown on solid media, have relied on the use of colored

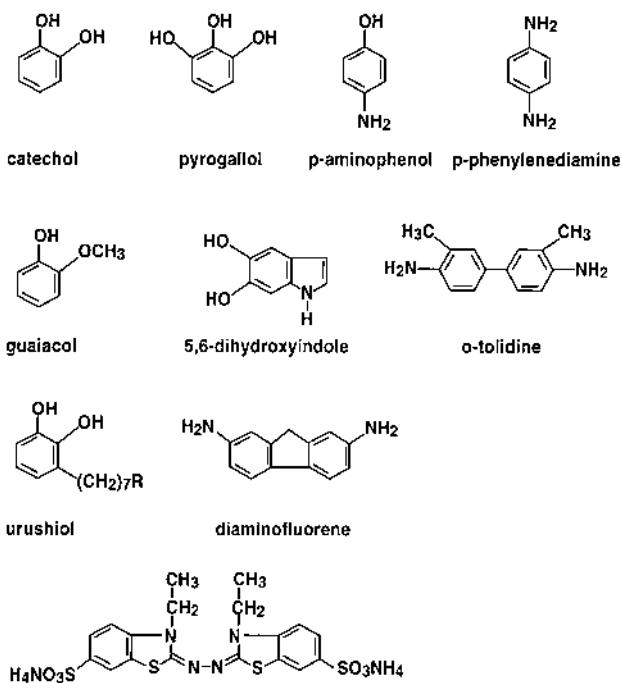

products formed during enzymatic oxidations. Some of these tests have been used to distinguish white rot fungi from brown rot fungi and have been used for taxonomic classification. Immunocytochemical location of the fungal laccase from *Rigidoporous lignosus* grown on wood was carried out using antilaccase polyclonal sera and immunogold labeling (17). These studies found laccase to be located in fungal cytoplasm, in vesicle-like structures at the plasmalemma, in the cell wall, and in the extracellular slime layer connecting fungal cells to wood. In liquid-grown cultures of the fungus *Coprinus congregatus*, laccase located in the hyphal tips was suggested to be involved with sclerita/primordia formation (18).

In plants, cytochemical localization of laccase has relied upon the use of syringaldazine, 2,7-diaminofluorene (DAF), 2,2'-azinobis(3-ethylbenzthiazoline-6-sulfonate; ABTS), and 4-methylcatechol as substrates. Laccase was localized to active lignifying zones of xylem cells in loblolly pine sections using DAF as a substrate (19). Similarly, cytochemical localization of laccase in tobacco stem cells was found in the outermost lignifying zones in xylem tissue (20). Driouch et al. (21) found laccase excreted in the extracellular medium and associated with cell walls in sycamore cell cultures by cytochemical and immunocytochemical methods. In contrast, De Marco and Roubelakis-Angelakis (22) observed laccase in areas where lignification was thought to occur in tobacco protoplasts.

Tissue printing of stem cross sections using 4-methyl catechol and syringaldazine as cytochemical substrates

**Figure 1** Types of reactions catalyzed by laccases. Reactions appearing in (a)–(c) were taken from Sanchez-Amat and Solano (16) and reactions appearing in (d)–(f) were taken from Solomon et al. (6).

**Figure 2** Chemical structures of substrates used to monitor laccase activity.

coupled with immunolabeling located laccase in the epidermal tissue (21). In petiole tissues, laccase was located in lignifying cell walls of xylem and epidermal cells. All cytochemical methods must employ some method to distinguish peroxidase and tyrosinase (catechol oxidase, phenol oxidase) from laccase. Peroxidase can be distinguished from laccase by samples treated with and without hydrogen peroxide and by including catalase in the incubation medium to remove hydrogen peroxide. A variety of tyrosinase inhibitors (i.e., tropolone, SHAM (salicylhydroxamic acid), 4-hexylresorcinol) can be included in the incubation medium to block tyrosinase activity without affecting laccase activity.

#### IV. UTILIZATION OF LACCASE IN FOOD

Besides its use as a bleaching agent in the wood pulp and paper industry, laccase has been used in dechlorination and for removal of phenolic compounds from wastewater. In relation to the food industry, laccase has been used in assays for phenols in natural juices (23). It has also been used as a biosensor for determination of polyphenols/catechols in tea (24). Immobilized laccase has been used to remove phenols

from apple juice (25) and in must and wine (26). Lante et al. (27) also reported the use of laccase as a stabilizer during must and wine processing. Soft rot in some crop plants and gray rot in grapes are a result of *Botrytis cinerea* infection. The extracellular laccases produced by *B. cinerea* are apparently involved in pathogenesis (28). Thus, laccase may have detrimental effects on infected food products.

Laccase is extremely important for lignin degradation in providing compost material and nutrients during mushroom cultivation. Constitutively produced laccase increases during growth of *Agaricus bisporus* on compost and declines when fruit formation occurs (29). Laccase seems to be associated with vegetative growth. Extracellular laccases (ECLs) have also been used to define distinct species/strains in *Agaricus bisporus* and can be used as phylogenetic markers (30).

Recently, Figueroa-Espinoza and Rouau (31) reported the use of laccase to crosslink wheat arabinoxylans in model systems. This crosslinking affected the structure and properties of nonstarch polysaccharides, including gelation properties. The potential effects on food functionality related to this observation have yet to be determined.

Other commercial uses for laccases involve lignin degradation, bioadhesives, biosensors, bioremediation, removal of phenolic compounds from waste water, use in enzyme assays and immunosensors, and applications in organic synthesis (4).

#### V. MOLECULAR PROPERTIES OF LACCASE

##### A. Molecular Weight

Fungal and plant laccases vary considerably in size. Depending on the method of size estimation (ultracentrifugation, size exclusion, electrophoresis, predicted size from gene sequence), the molecular size of laccase ranges from 40 to 100 kDa. The more common size range is from 60 to 80 kDa, however. Most laccases are active as monomeric subunits, but dimeric and other multimeric combinations of the monomeric subunits have been reported.

##### B. Structure

Laccases sequenced by protein or DNA methods have been shown to be composed of a single polypeptide containing 500–580 amino acids (4, 5, and references therein). They are synthesized with an N-terminal leader peptide that is cleaved after translation. The

mature polypeptide contains N- and O-linked glycosylation sites, four copper atoms, and two or three disulfide bonds. Because laccase has not been crystallized and analyzed by x-ray crystallography, the secondary and tertiary structures are unknown. However, laccases do show some amino acid homology and similarity to ascorbate oxidase and ceruloplasmin, especially at the copper-binding sites. Because of this homology, the hypothetical secondary and tertiary structures are thought to be very similar to ascorbate oxidase.

Using this homology and similarity as model, three domains found in ascorbate oxidase are postulated to be present in laccase (4, 9). These domains in ascorbate oxidase are composed of  $\beta$ -barrel/ $\beta$ -strand motifs. By analogy to ascorbate oxidase, domain 1 should contain  $\beta$ -pleated sheets forming a  $\beta$ -sandwich motif. Domain 2 should contain  $\beta$ -pleated sheets and short stretches of  $\alpha$ -helices. Domain 3 should contain two five-stranded  $\beta$ -pleated sheets forming a  $\beta$ -barrel and short  $\alpha$ -helix stretches. Support of this comparative analogy comes from differentially scanning calorimetry, which has suggested the presence of three domains in laccase (32).

Predictive structural features would suggest that domain 1 would be connected to domain 3 by disulfide bonds. Overall, predictions suggest there would appear to be very little  $\alpha$ -helix, a large percentage of  $\beta$ -sheets, and several types of turns. The C-terminal end may be blocked, buried, and/or susceptible to limited proteolysis. In general, laccase is predicted to show more homology to ascorbate oxidase than ceruloplasmin, plastocyanin, or azurin (4, 5, and references therein). Based on amino acid sequence homology, laccase has homology to ascorbate oxidase in the Cu-binding ligands, linkage of domains 1 and 3, the trinuclear Cu center, and the C-terminus. See Table 2 for a comparison of the amino acids in the copper binding sites for 10 laccases and three ascorbate oxidases. Comparisons of the blue oxidases suggest gene duplication from an ancestral blue copper protein. Even though laccase and tyrosinase both contain a type 3 copper center, this center is distinctly different in laccase (6). There is apparently little to no homology of laccase to the copper-binding regions of tyrosinase. Complete sequence information for cloned or determined sequences is available (4, 5).

### C. Isoforms

Isoforms of laccase have been found in both fungi and plants. These isoforms differ in their size, charge, and kinetic properties. Some of these isoforms are due to

multiple genes coding for the enzyme (33). Because many laccases are glycoproteins, isoform differences can arise from variations in carbohydrate content, linkages between carbohydrate units, and location of linkages to the polypeptide backbone. Heterogeneity due to carbohydrate content/structure can arise posttranslationally and after excretion. Other isoforms and enzyme inactivation can arise from limited proteolysis (34). Because laccases are often associated with phenolic material, the potential for artifactual protein modification during synthesis, excretion, culture conditions, and isolation also exists. Support for this comes from finding a "yellow" laccase that apparently is a modified form of the original "blue" laccase because of modification of a copper center by lignin phenolics (35).

## VI. ENZYME PROPERTIES

### A. Substrate Specificity

Although laccase can utilize a variety of substrates as electron donors, few recent reports have examined substrate specificity in terms of  $k_{cat}/K_m$ . In general, plant and fungal laccases have low substrate specificity (high  $K_m$ ) in the mM range for organic substrates. Other studies have shown that the  $k_{cat}/K_m$  is correlated with the substrate oxidation potential (6). These observations have suggested that laccase has no phenolic substrate binding pocket and oxidation takes place by direct transfer of an electron(s) through an outer sphere mechanism to the T1 Cu-binding site (6). Physiological substrates for plant laccases include *p*-coumaryl, coniferyl, and sinapyl alcohols in which laccase can cause oxidative coupling of the substrates (6, 19). Physiological substrates for fungal laccases depend on the role laccase plays. A list of natural and artificial substrates for laccase appears in Table 1.

### B. Effect of Environmental Factors

Many laccases have pH optima in the acidic pH range (pH 3–6), although some alkaline pH optima have been reported (Table 3). In general, fungal laccases usually have lower pH optima than plant laccases; however, the pH optimum is often dependent upon which substrate is chosen to assay laccase. The type of product formed also depends on the pH and the substrate. For example, at pH 3.5 two products were identified from oxidation of syringic acid by laccase while at higher pH values four different products were observed (7). The pH stability of the laccase iso-

forms varies considerably. Some are stable over a wide pH range (pH 3–7) while others are more pH sensitive.

Many laccases are relatively heat stable, but specific thermal stability properties are associated with each laccase isoform (Table 3). Half-lives of 30 min at 50–65°C for laccase isoforms are not uncommon, while temperature optima are generally > 50°C.

### C. Inhibitors

Laccases are inhibited by a variety of compounds that can be classified into groups such as Cu chelators, reducing agents, detergents, and free radical scavengers. Cu chelators include EDTA, CN<sup>−</sup>, sodium azide, and diethyldithiocarbamic acid. Cetyltrimethyl-ammonium bromide (CTAB), a cationic detergent, seems to inhibit some laccases in a competitive or noncompetitive manner (36). Short-chain carboxylic acids have also been reported to inhibit some laccases (37). Desferal inhibits laccase by deactivating phenoxy radicals (38). Tiron, a superoxide ion and hydroxyl ion quinone scavenger, also decreased the activity of laccase-like oxidases in tobacco xylem (39). Halides, especially F<sup>−</sup>, are potent inhibitors of laccase (40). N-Hydroxyglycine has been reported to be a specific inhibitor of laccase by Murao et al. (41) and later by others (42–44). However, recent work in our laboratory suggests this may be an artifact (data not shown).

### D. Mechanism of Action

Laccases contain three copper centers. The type 1 copper center (T1) is responsible for the blue color of the protein because of the intense absorption at 600 nm. T1 centers also show small hyperfine splitting in an electron paramagnetic spectrum (EPR). Type 1 centers are proposed to involve the 1e<sup>−</sup> oxidation of the substrate. Type 2 (T2), or normal copper centers, have no absorption to the visible spectrum and show EPR spectrum characteristic of tetragonal Cu complexes. Type 3 centers (T3) contain two copper ions and are termed coupled binuclear copper centers. They have no EPR signals but do absorb in the UV spectrum (330 nm). In laccases, T2 and T3 centers form a trinuclear copper cluster. This cluster is responsible for the 4e<sup>−</sup> reduction of molecular oxygen to water.

The exact mechanism for laccase catalysis has not been elucidated. A proposed mechanism appears in the work by Solomon et al. (6). In this mechanism an electron from the substrate is transferred to the T1 copper site. The site transfers an e<sup>−</sup> to the T2–T3 sites. Reduction of the trinuclear cluster is thought to occur by either sequential reduction of each copper in the trinuclear cluster or by reduction of the T3 copper pair by T1 and T2. Because there are a total of 4 Cu ions, a variety of intermediates with different Cu oxidation states in the copper sites have been postulated. A somewhat different mechanistic scheme is

presented in the review by Yaropolov (8). In all of the proposed mechanisms, all  $e^-$  pass through the T1 site first.

### E. $K_m$ and $k_{cat}$ Values

$K_m$  values for organic laccase substrates are generally in the 0.1–10 mM range for a variety of phenolic and phenolic amine-like compounds (6, 8, 40). Some hydroxyindole derivatives, such as 5,6-dihydroxyindole, have  $K_m$  values < 0.1 mM (45). For molecular oxygen as the second substrate,  $K_m$  values are in the order of  $10^{-5}$  M and  $V_{max}$  values are 50 to 300 M $^{-1}$  sec $^{-1}$  (8).  $k_{cat}/K_m$  values versus electron reduction potentials at the T1 site show a positive correlation (6). As a result, comparisons between different laccases and different substrates correspond to redox potentials between the T1 site and the electron donor substrates.  $k_{cat}$  values range from 70 to 2000 sec $^{-1}$  (8) or from 100 to 3600 min $^{-1}$  (40). According to Xu,  $k_{cat}/K_m$  differences in a variety of substituted phenolic substrates were associated with changes in  $k_{cat}$  primarily (40). Turnover numbers (expressed as  $k_{cat}$ ) are generally larger than individual intramolecular electron transfer rate constants (8).

### F. Inhibitors and Other Physicochemical Data

Surprisingly, there appear to be few data for  $E_{act}$ ,  $\Delta H^\ddagger$ ,  $\Delta G^\ddagger$ , or  $\Delta S^\ddagger$  with regard to laccase. More data are available relating to electron reduction potential differences in native and modified laccases. Most data for inhibition of laccases are reported in terms of percent inhibition relative to some control/standard. A few reports have determined  $I_{50}$  values for selected inhibitors. Because there are few if any specific inhibitors of laccase, few data are available for  $K_i$  values. Walker and McCallion (36) examined the effect of CTAB, a cationic detergent, on several *p*-diphenol oxidases. Using CTAB,  $K_i$  values ranged from 0.25 to 23 mM depending on the substrate and source of laccase. Desferal has a high  $I_{50}$  for laccase (38), while N-hydroxyglycine was shown to have a low  $I_{50}$  for *Coriolus vesicolor* laccase of 0.1  $\mu$ M (41). Faure et al. (43) also determined the  $I_{50}$  for N-hydroxyglycine using *Pyricularia oryzae* and *A. lipoferum* laccases and *o*-aminophenol, *p*-aminophenol, and syringaldazine as substrates. These  $I_{50}$  values ranged from 50 to 800  $\mu$ M. Caution must be used when interpreting data with N-hydroxyglycine because it may not inhibit the enzyme but might interact with the products of the reaction (51).

### G. Unique Properties

Laccase catalyzes a variety of reactions including oxidation, coupling of free radical intermediates, carbon–carbon bond cleavage, polymerization, and crosslinking. Oxidative and nonoxidative decarboxylation of phenolic compounds have also been reported. Hydroxyindole derivatives are also acted upon by plant and fungal laccases. Laccase oxidizes ascorbic acid in the absence of a phenol-like substrate. More recently, laccase contamination in commercial tyrosinase preparations was responsible for the novel conversion of dimethoxy allyl phenol to its corresponding quinone methide instead of tyrosinase (46).

## VII. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

### A. Assay Conditions

In general, most laccases are assayed in buffers of pH 3–8 with variations in buffer concentrations from 10 to 100 mM. Changes in phenolic substrates can be monitored spectrophotometrically using continuous, fixed end points, and scanning absorption methods. Assay volumes vary from 1 to 3 mL for spectrophotometric assays and 3–4 mL for oxygen consumption assays. There is no one best method for determining laccase activity because of the differences in substrate and pH preference for each laccase isoform. A suitable substrate, pH, and buffer must be determined experimentally for each laccase.

Colorimetric assays have employed four different substrates that give uniquely colored products—2,6-dimethoxyphenol (DMP; brown), ABTS (blue-green), syringaldazine (SYR; pink), *o*-toluidine (TOL; blue). For example, 3 mL of 5 mM DMP, freshly prepared in buffer, can be monitored at 468 nm ( $\epsilon = 14,800 \text{ M}^{-1} \text{ cm}^{-1}$ ) after the addition of 5–50  $\mu$ L enzyme. Likewise, 3 mL of 0.5 mM ABTS, prepared fresh in buffer, can be monitored at 420 nm ( $\epsilon = 36,800 \text{ M}^{-1} \text{ cm}^{-1}$ ). With the third substrate, stock solutions of 1–5 mM syringaldazine are dissolved in 95% ethanol. Because of the limited solubility of syringaldazine, assays for laccase usually contain 10% ethanol. Even then, syringaldazine precipitates out of solution with time. The assay solution, usually 1 mL, contains 20–50  $\mu$ M concentrations of syringaldazine dissolved in buffer and is monitored at 525 nm ( $\epsilon = 65,000 \text{ M}^{-1} \text{ cm}^{-1}$ ). Because of turbidity at this wavelength, blank assays in a reference cell should contain all assay components except enzyme. With the fourth substrate, toluidine stock solu-

tions (5–40 mM) are also dissolved in 95% ethanol. Assay solutions, usually 3 mL, contain 1–5 mM toluidine when added to buffer so that the ethanol concentration remains below 10% (v/v). Five to 50  $\mu$ L of enzyme is added to initiate the reaction, and the product is monitored at either 366 nm (UV) or 630 nm (VIS). Because the  $\epsilon$  is not known for toluidine, units of enzyme activity are expressed in absorbance changes per min. For substrates with known  $\epsilon$  values, enzyme activity is expressed in either changes in absorbance per min or  $\mu$ mol product formed per min.

Oxygen uptake assays can be determined using Clark-type oxygen electrodes by YSL, Hansatech, or Rankin Brothers. Air-saturated buffers are commonly used as the oxygen source and are  $\sim$  240–280  $\mu$ M in oxygen. Reactions using any of the methods are normally carried out at ambient temperatures, although some reactions have been carried out at 30°C. Oxygen uptake assays must have the temperature controlled more precisely, because oxygen solubility in aqueous solutions is temperature dependent and the enzyme reaction rate is affected by temperature. Water-insoluble substrates or those with limited aqueous solubility are sometimes dissolved in a polar solvent (ethanol, methanol, dimethylsulfoxide) to make stock solutions. Oxygen has a greater solubility in some polar solvents than aqueous buffer solutions; therefore the amount of dissolved oxygen may increase with the addition of substrates dissolved in these solvents. Most laccase assays can tolerate at least 10% ethanol, but this depends on the source of laccase and its stability.

Using oxygen uptake assays for example, a 4-mL assay volume of 0.5 mM ABTS is pre-equilibrated until the percent oxygen reaches a steady value. Enzyme is added (5–25  $\mu$ L) and the oxygen uptake is followed for 1–10 min, depending on the substrate and enzyme concentration. Units of enzyme are expressed in % O<sub>2</sub> consumed per min or  $\mu$ L of O<sub>2</sub> consumed per min. If the exact concentration of O<sub>2</sub> can be determined in the air-saturated buffer, then units may be expressed in  $\mu$ mol O<sub>2</sub> consumed per min.

## B. Natural and Synthetic Substrates

The natural substrate for fungal laccase is presumably lignin. This lignin can originate from pulp Kraft or sulfite-type processed softwoods and hardwoods. Plant laccases, on the other hand, use monolignols (coniferyl, sinapyl, and *p*-coumaryl alcohols) as substrates to produce water-insoluble dehydrogenation polymers (DHPs). Oxidation and oligomerization of

monolignols is usually monitored using high-performance liquid chromatography size exclusion chromatography (HPLC-SEC). The following method, in which production of DHPs were made from coniferyl alcohol, is a summary from Sterjades et al. (47, 48). Coniferyl alcohol (10 mM) in 20 mM phosphate buffer (pH 6.8) was incubated for 24 h with laccase ( $\sim$  5  $\mu$ g) isolated from cultured sycamore maple cells. DHPs were recovered from the reaction by centrifugation at 48,000 g for 30 min. The precipitates were resuspended in water and centrifuged again. This resuspension–centrifugation cycle was repeated for a total of three times. DHPs were dissolved in dimethylformamide and diluted to a concentration of 10  $\mu$ g/mL for analysis by HPLC-SEC. DHPs were separated on an 8  $\times$  300 mm Showdex KD-802 Millipore HPLC column (styrene divinylbenzene gels) equilibrated in dimethylformamide and 100 mM LiBr. Separations were carried out at 55°C with a flow rate of 1 mL/min. Column eluants were monitored at 280 nm. Several peaks of polymerized monomeric material larger in size than coniferyl alcohol were observed. To monitor the oxidation of coniferyl alcohol during this process, the reactions were scanned from 230 to 400 nm at various time intervals. In comparison to control reaction, mixtures that contained no enzyme, a decline in absorbance at 264 nm occurs. Depending on the choice of initial substrates, new absorption peaks sometimes appear at lower wavelengths.

Other substrates used to monitor laccase activity are listed in Table 1. Spot tests for laccase have used ABTS, gum guaiac,  $\alpha$ -naphthol, syringaldazine, and *o*-toluidine as substrates. ABTS, *o*- and *p*-phenylenediamine, *o*-dianisidine, syringaldazine, 4-methoxy- $\alpha$ -naphthol, tetramethylphenylenediamine, and tetra-methyl benzidine have been used for histochemical localization of laccase in plants and fungi.

## C. Unique Factors That Affect Enzyme Activity

Several factors affect the ability to obtain meaningful assays for laccase. One factor is halide inhibition. Although F<sup>−</sup> is a very potent inhibitor of laccase ( $I_{50}$  of 0.02–0.5 mM),  $I_{50}$  values for Cl<sup>−</sup> range from 0.05 to 600 mM for plant and fungal laccases (39). Chloride ions are often found in buffers and may have some effect on the enzyme during purification and in buffer preparation. Short-chain carboxylic acids, including acetic acid, also inhibit laccase. Since acetic acid/acetate is present in some buffers used for the assay of laccase, they may also affect the enzyme. The pH affects the type of products produced (8) and kinetic

parameters ( $K_m$ ,  $V_{max}$ ,  $k_{cat}$ ). Inhibition of the enzyme also increases as the pH is increased and when the ionic strength is increased.

Peroxidases can utilize many of the same substrates as laccase (i.e., syringaldazine, ABTS, tolidine, guaiacol, etc.). If care is not taken to eliminate or distinguish peroxidase from laccase, estimation of laccase activity or reactions attributed to laccase can be misinterpreted. The presence of peroxidase activity is usually monitored with a suitable electron donor in the presence or absence of hydrogen peroxide. Catalase can be added to laccase assays to remove any hydrogen peroxide formed, thus eliminating reactions which might arise from peroxidase.

Tyrosinase can also use many of the same substrates as laccase (i.e., catechol, dopa, phenylenediamine, pyrogallol). This activity can be eliminated by using specific tyrosinase inhibitors (tropolone, salicylhydroxamic acid, 4-hexylresorcinol) in assays for laccase (44). However, these inhibitors may react with products during the oxidation process and can possibly interfere with laccase estimations. Catalase can be added to remove endogenous hydrogen peroxide; however, oxidation of some phenolic substrates has been attributed to peroxidatic activity of catalase.

## VIII. PURIFICATION OF LACCASES

### A. Methods

There is no best method for the purification of laccase because of the varied number of isoforms and different characteristics. Laccases have been purified most often from extracellular fluids from fungal and plant cell cultures. In general, fungal laccase purifications employ some method for removal of cells (filtration, centrifugation) followed by concentration of the extracellular fluid using ultrafiltration or precipitation methods (ethanol, ammonium sulfate). The dialyzed and concentrated extract has been subjected to ion-exchange chromatography (IEC). IEC methods have utilized chromatography on DEAE-cellulose, QAE and mono Q columns at low salt concentrations near physiological pH. Laccase isoforms are eluted from the exchangers using increasing linear salt gradients (i.e., 0–0.5 M NaCl) depending on how tightly the enzyme binds to the exchanger. IEC can be preceded or followed by size exclusion chromatography (SEC). Typical SEC methods have used Superose-12, Superdex 75, Sephadex G-100, and Sephadex S-200. In many cases, the enzyme is highly purified after concentra-

tion after IEC and SEC. When necessary, further purification methods have employed hydrophobic interaction chromatography (HIC) on phenyl Sepharose using initial buffers containing high ammonium sulfate concentration. Enzyme is eluted by decreasing the salt concentration stepwise or by gradient elution.

The following method is a summary of the purification of laccases from *Trametes villosa* by Yaver et al. (49). The fungus was grown in a defined medium at room temperature. The defined medium depends on the type of fungi cultured. After 4 days, 1.3 mM (final concentration) 2,5-xylidine was added to induce laccase production. Cultures were allowed to grow another 24 h before filtering, high-speed centrifugation, and concentrating the filtrate using an Amicon S1Y100 ultrafiltration membrane. After dialysis, the sample was subjected to IEC on a Q-Sepharose (Pharmacia) column equilibrated with 10 mM Tris (pH 7.7).

Some laccase activity was not adsorbed onto the IEC resin and was eluted with buffer. Two other peaks of laccase activity were adsorbed onto the column and separated by a linear 0–0.5 M NaCl gradient elution. The three laccase peaks were pooled separately, concentrated by Centricon-10 concentrators (Amicon), and subjected to SEC on a Superdex 75 column (Pharmacia). SEC columns were equilibrated in 10 mM Tris (pH 8) containing 150 mM NaCl. Active fractions were pooled, resulting in three different laccase fractions, identified as *neutral* (laccase 3), *neutral-acidic* (laccase 2), and *acidic* (laccase 1) forms (Table 4).

All three laccases showed the same apparent MW of 60–70 kDa after SDS-PAGE. SEC suggested a native size of 130 kDa. Laccase 1 consisted of a single isoform with a pI of 3.5. Laccase 2, apparently homogeneous by SDS-PAGE, consisted of five isoforms identified by isoelectric focusing with pIs of 5, 6, 6.2, 6.5, and 6.8. Laccase 3, apparently homogeneous by SDS-PAGE, contained three isoforms with pIs of 6.2, 6.5, and 6.8. While forms 1 and 3 were typical of other blue oxidases, laccase 2 showed a reduced absorbance at 605 nm. Laccase 1 had a different N-terminal sequence from laccases 2 and 3, which had similar N-terminal sequences. All forms showed differences in substrate preference and pH stability characteristics.

Extracellular plant laccases have been isolated by concentrating the extracellular fluid followed by HIC on phenyl Sepharose (2.6 × 30 cm column; 2 M potassium phosphate buffer, pH 6.7). Enzymes are typically eluted from HIC columns with a decreasing salt gradient.

**Table 4** Purification of Laccases from *T. villosa* Culture Filtrates

Sample	Volume (mL)	Total protein (mg)	Total activity ( $\mu\text{mol min}^{-1}$ )	Specific activity ( $\mu\text{mol min}^{-1}/\text{mg protein}$ )	Purification (fold)	Yield (%)
Culture filtrate	1500	11,000	1800	0.16	1	100
conc. culture filtrate	280	460	1500	3.3	21	83
Q-Sepharose						
<i>neutral form</i>	0.40	5.1	270	53	330	15
<i>neutral-acidic form</i>	0.42	9.6	108	11	69	6

Because fungal and plant laccases are glycoproteins, some purification methods have employed lectin affinity chromatography on concanavalin A (Con A) Sepharose. Following is a summary of the purification used by Drouich et al. (21) to isolate laccase from sycamore cell cultures. Proteins in the extracellular fluid were precipitated with 5 M ammonium sulfate at 4°C. After centrifugation of the precipitated protein, the pellet was dissolved in 10 mM Tris buffer (pH 7.4) containing 1 mM MnCl<sub>2</sub> and 1 mM CaCl<sub>2</sub>. The sample was applied to a Con A Sepharose column (1.5 × 30 cm) equilibrated in the above buffer. Laccase was eluted from the column with buffer containing 50 mM methylmannoside. Laccase was precipitated from the solution with 5 M ammonium sulfate, washed with cold acetone, and dissolved in a small volume of 10 mM Tris buffer (pH 8.8), containing 10% glycerol. The sample was subjected to preparative native gel electrophoresis using the Laemmli system. After locating the laccase activity by staining the gel briefly with catechol, areas of active enzyme were excised from the gel and subjected to electroelution. Further purification of laccase for antibody production used preparative SDS-PAGE, followed by electroelution.

## B. Other Aspects of Purification

Laccases are generally expressed constitutively in cell culture, but higher levels can be produced using phenolic compounds as inducers. Some of these inducers include phenolic acids, anthroquinones, or 2,5-xylyidine. Chelators, such as EDTA and EGTA, in the culture medium have been found to repress laccase

activity and levels. The distribution of expressed laccase isoforms is often dependent on the type of culture conditions (shake vs. stationary), culture medium, and phenolic inducer used. Many of the purified laccases have small fold purification factors (based on the specific activity of starting material compared to purified samples), indicating the laccase is a major protein in the extracellular fluid or that there is a significant loss in activity during purification. Purified laccases are typically blue in color when concentrated, but the *Agaricus bisporus* laccase was reported to be yellow in color (34) and a “white laccase” (50) has also been reported. “Yellow” laccases, modified by reactive products of lignin degradation, may be generated from blue laccases during the isolation of laccases (35). Purified laccases are usually stable for several years when stored frozen. *Rhus vernicifera* laccase is commercially available from Sigma Chemical Co.; a *Coriolus versicolor* laccase is available from Mercian Corp., Tokyo.

## Mammalian Sulphydryl Oxidase

**Harold E. Swaisgood and Violeta G. Janolino**

*North Carolina State University, Raleigh, North Carolina, U.S.A.*

### I. INTRODUCTION

Most of the characteristics of sulphydryl oxidase (EC 1.8.3.) reported in this chapter are those of the enzyme isolated from the skim milk membrane vesicles obtained from bovine milk (1–3). The enzyme is an integral membrane iron-containing glycoprotein found in mammary tissue, kidney, and pancreas (4). Immunofluorescent staining also indicated its location in the endothelial cells lining the capillaries of the kidney, heart, and small intestine (4). The enzyme catalyzes oxidation of sulphydryl groups of cysteine, cysteine-containing peptides, and proteins to disulfides with molecular oxygen as the electron acceptor according to the stoichiometry given below (1, 5):

This enzyme differs from thiol oxidase (EC 1.8.3.2) not only by its substrate specificity and protein characteristics but also in the fact that water is a product of the thiol oxidase-catalyzed oxidation (6), whereas, hydrogen peroxide is the product of sulphydryl oxidase-catalyzed reactions. Also, sulphydryl oxidase differs from glutathione oxidase (EC 1.8.3.3) because of its broader substrate specificity and it does not contain FAD (6). Hence, the enzyme is a sulphydryl:oxygen oxidoreductase (EC 1.8.3.), but it has not been assigned a serial number as yet.

The mammalian enzyme is also distinct from microbial sulphydryl oxidase. The microbial enzyme from *Aspergillus niger* is a soluble flavoprotein that oxidizes small thiol compounds such as dithiothreitol (DTT)

but does not exhibit much activity with proteins such as reduced RNase, whereas the mammalian enzyme exhibits no activity with DTT, contains iron, and rapidly oxidizes reduced proteins (7). A mammalian flavoprotein sulphydryl oxidase that oxidizes DTT has been isolated from the male reproductive tract (8–10).

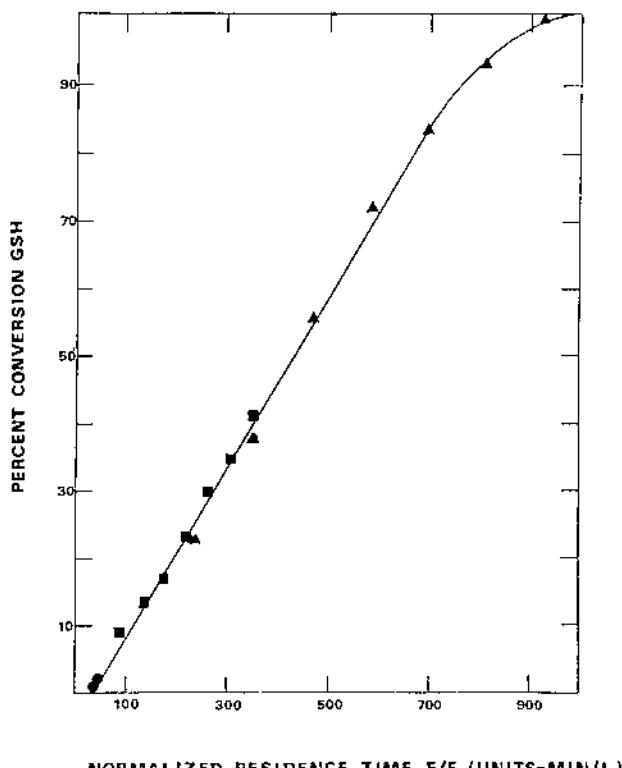

### II. IMPORTANCE TO FOOD QUALITY AND UTILIZATION IN FOOD PROCESSING

Heating of milk causes protein denaturation resulting in exposure of the sulphydryl group, Cys121, in  $\beta$ -lactoglobulin and other chemical reactions of the sulphydryl and disulfide residues of proteins yielding volatile sulfur compounds resulting in formation of a “cooked” flavor. Ultra-high-temperature (UHT) sterilized and aseptically packaged milk, typically processed at 140–150°C for 2–4 sec, initially has strong cooked flavor that slowly dissipates with storage (11). The intensity of the flavor is objectionable to most North Americans and northern Europeans who are accustomed to high-quality refrigerated pasteurized milk. UHT treatment causes extensive denaturation of the globular whey proteins and complete loss of sulphydryl oxidase activity. Dissipation of the cooked flavor occurs concomitantly with the oxidation of sulphydryl groups. Furthermore, sulphydryl oxidase-catalyzed oxidation of the exposed sulphydryls also results in elimination of cooked flavor (11–16).

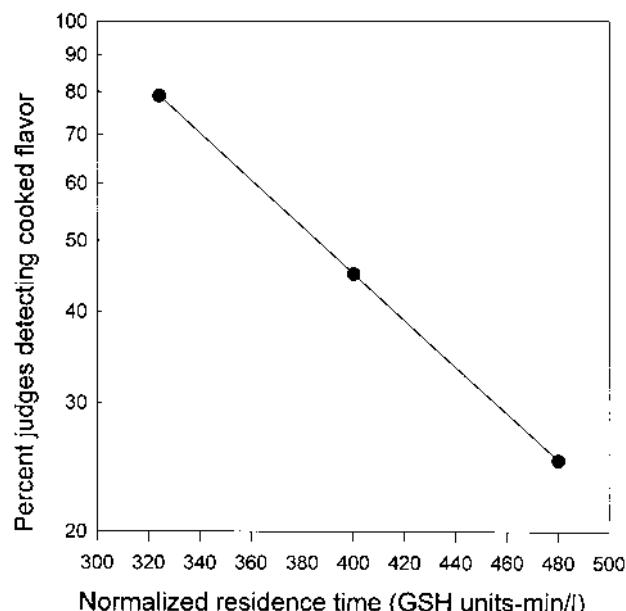

A number of studies using various preparations and forms of sulphydryl oxidase have shown that the cooked flavor of UHT milk can be immediately eliminated by treatment with the enzyme (12–16). For example, bioreactors for treatment of UHT milk have been prepared by covalent immobilization of the enzyme on succinimidopropyl porous glass beads (12–15) or by direct adsorption from whey on Spherosil QA (16). The concentration of free sulphydryl groups in freshly processed UHT milk was rapidly depleted by treatment with sulphydryl oxidase bioreactors operating in either a fixed-bed or a fluidized-bed configuration. Activities of the immobilized enzyme were routinely assayed using reduced glutathione (GSH) as the substrate. These data allowed a correlation to be established between the percent oxidation of GSH and the “normalized residence time” which is the ratio of units of activity/the flow rate through the bioreactor (Fig. 1) (12, 15, 16). The flavor of the enzyme-treated UHT milk was evaluated by a trained taste panel. Most significantly, a direct correlation was observed between the percent of the judges that

could detect the cooked flavor and the normalized residence time in the bioreactor (Fig. 2) (16). Two patents have been issued describing preparation of the enzyme and treatment of UHT milk with the enzyme for removal of cooked flavor (17, 18).

Some evidence suggests that enzymatic oxidation of heat-liberated sulphydryl groups may provide longer flavor stability. A major defect of UHT milk that develops during the long-term storage arises from flavors derived from oxidative reactions (19). Autoxidation of sulphydryls produce superoxide anion that can lead to other activated oxygen species that have a pro-oxidative effect on milk lipids (20). However, sulphydryl oxidase-catalyzed oxidation of sulphydryls does not produce superoxide anions (5). Comparison of untreated UHT milk with UHT milk treated with soluble filter-sterilized sulphydryl oxidase after a 10-month storage at ambient temperature indicated that the untreated milk had undergone extensive browning and was undrinkable because of its strong oxidized flavors, whereas the treated milk retained its original color and the flavor was acceptable (unpublished observations).

**Figure 1** Conversion of GSH to GSSG as a function of normalized residence time. Column assays (●); recirculation assays (■); batch assays (▲). (From Ref. 12.)

**Figure 2** Relationship between the degree of cooked flavor and the extent of enzyme treatment of UHT milk. The normalized residence time in a bioreactor represents the units of enzyme activity in the bioreactor divided by the flow rate through the bioreactor. The panel consisted of trained milk judges. (From Ref. 16.)

### III. PROPERTIES OF THE PROTEIN

The molecular weight of sulfhydryl oxidase determined with SDS-PAGE is 89 kDa (1). A similar value was obtained from light-scattering studies of a substantially purified preparation in 5 M guanidinium chloride (21, 22). Like other membrane proteins, preparations of the enzyme in the absence of dissociating agents are highly aggregated; thus, the size of the active protein as it exists in the membrane has not been established. The enzyme is present in skim milk in lipid vesicles  $> 0.3 \mu\text{m}$  in diameter as indicated by their exclusion from Nucleopore filters (21) and their limited penetration of  $0.3\text{-}\mu\text{m}$ -diameter controlled-pore glass (3, 23). Active enzyme can be solubilized with nonionic detergents. Polyoxyethylene-9-lauryl ether ( $\text{C}_{12}\text{E}_9$ ) and  $\beta$ -octyl-D-glucoside are best suited for this purpose (2). More than 80% of the activity is solubilized in 1%  $\text{C}_{12}\text{E}_9$ ; however, the complex is still quite large having limited ability to penetrate 7.5% polyacrylamide gels (2). Nevertheless, all of the solubilized enzyme was able to penetrate  $0.1\text{-}\mu\text{m}$ -diameter controlled-pore glass (3). Dissociation of the aggregated enzyme with either nonionic detergent or 1 M guanidinium chloride results in increased activity (3, 21).

Analysis of a substantially purified form of the enzyme indicated that it contains 11% carbohydrate and 0.5 g-atoms of Fe/89,000. Moreover, treatment with EDTA caused removal of the Fe and complete loss of activity (1). Subsequent dialysis of the apoprotein against dilute solutions of  $\text{Fe}^{2+}$  restored 70% of the original activity. However, treatment with other divalent metals did not restore any activity, with the exception of  $\text{Cu}^{2+}$  which yielded  $\sim 30\%$  of the original activity (1). The active enzyme contains two DTNB-reactive sulfhydryl groups/89,000, whereas the denatured protein contains three reactive groups (1, 24). Kinetics of activity loss due to carboxymethylation with iodoacetate indicated that modification of one sulfhydryl group/89,000 caused complete inactivation (24).

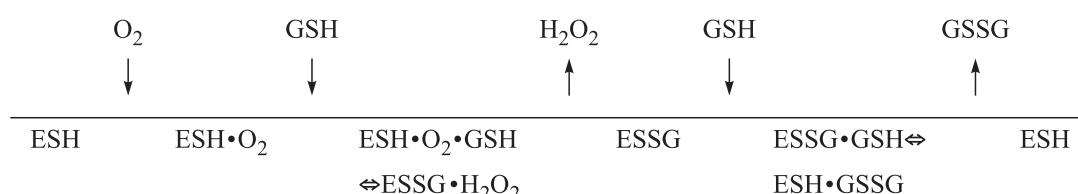

That sulfhydryl oxidase activity and  $\gamma$ -glutamyltransferase activity arise from distinct proteins was

shown by resolution of the proteins by transient covalent chromatography on cysteinylsuccinimidopropyl glass and by specific immunoprecipitation of sulfhydryl oxidase activity (25, 26). Furthermore, the activities of sulfhydryl oxidase,  $\gamma$ -glutamyltransferase, xanthine oxidase, and alkaline phosphatase in detergent-solubilized skim milk membranes were resolved by isoelectric focusing (3).

### IV. ENZYMATIC PROPERTIES

Cysteine, all peptides containing cysteine, and proteins with free sulfhydryl groups are all excellent substrates for mammalian membrane sulfhydryl oxidase (Table 1). Unlike the soluble flavoprotein microbial enzymes, this enzyme is not active with other simple thiol compounds such as DTT. Activity is completely lost upon treatment with EDTA (1) or reagents that react with sulfhydryl groups such as iodoacetate (24). Substrate inhibition is observed at concentrations  $> 5\text{--}10 K_m$  (1, 5, 28). With GSH as the substrate, a pH optimum of 6.8–7.0 and a temperature optimum of 35°C have been established (1). The stoichiometry of sulfhydryl oxidase-catalyzed oxidation of GSH has been confirmed by quantitation of the disappearance of GSH and  $\text{O}_2$  and the appearance of  $\text{H}_2\text{O}_2$  and GSSG (1, 5, 25). A number of observations, including kinetic studies (5), have indicated that catalysis follows a Bi Uni Uni Uni Ping-Pong mechanism as shown by the Cleland diagram below.

In addition to analysis of initial rate data (5), a substituted enzyme mechanism is supported by the specific covalent interaction with cysteinylsuccinimidopropyl glass and its release by reducing agents such as GSH or DTT (25). Binding of GSH prior to release of  $\text{H}_2\text{O}_2$  is supported by the requirement of a sulfhydryl oxidase substrate for the observed oxidation of horseradish peroxidase (HRP) in the presence of the enzyme (29). Enhancement of sulfhydryl oxidase-catalyzed oxidation of GSH in the presence of HRP is thought to occur by direct transfer of peroxide from sulfhydryl oxidase to HRP, thus speeding up the rate-limiting dissociation of peroxide from the enzyme (29).

**Table 1** Kinetic Characteristics of Several Sulfhydryl Oxidase Substrates

Substrates	$K_m$ (mM)	Relative pseudo-first-order rate constant ( $V_{max}/K_M$ )
Reduced glutathione	0.1 <sup>a</sup> , 0.3 <sup>b</sup> , 0.6 <sup>c</sup>	1.0
Gly-Gly-L-Cys	2.4 <sup>d</sup>	~1 <sup>d</sup>

5-Nitro-5-thiobenzoic acid	100 <sup>b</sup>	—
Reduced ribonuclease	0.14 <sup>c</sup>	—
No activity with (5, 22):		
Dithiothreitol	Mercaptoethanol	Mercaptopropionic acid
Dithioerythritol	Mercaptoacetic acid	Lipoic acid

<sup>a</sup> Janolino and Swaisgood (1).

<sup>b</sup> Swaisgood and Horton (22).

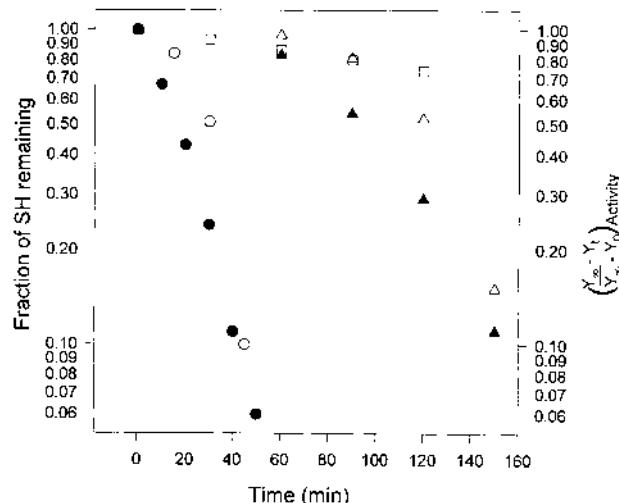

<sup>c</sup> Slivskowski et al. (5).

<sup>d</sup> Schmelzer et al. (27).

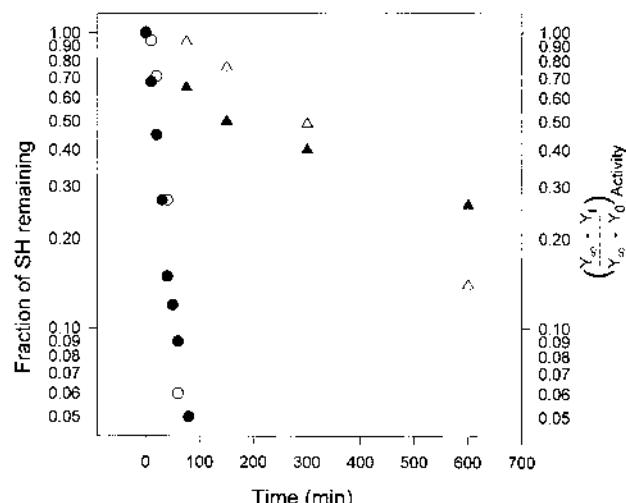

<sup>e</sup> Janolino and Swaisgood (28). This value was calculated on the basis of the sulfhydryl group concentration.

As indicated by the kinetic parameters in Table 1, reduced proteins are excellent substrates. Fully unfolded and reduced RNase A (1, 28, 30) and chymotrypsinogen A (31) are rapidly oxidized with nearly complete restoration of biological activity (Figs. 3, 4). Thus, sulfhydryl groups are oxidized and biological

activity is restored within minutes in the presence of sulfhydryl oxidase, whereas > 15 h is required in its absence. Restoration of biological activity proves that native disulfide bonds are formed. Comparison of the intermediates formed during enzyme-catalyzed oxidation and air or GSH/GSSG-catalyzed oxidation

**Figure 3** Comparison of the rates of sulfhydryl oxidase-catalyzed oxidation (●) and activity regeneration (○) with that observed in air (▲, △) for reduced ribonuclease. Also included are the data (□) obtained with the microbial enzyme from *A. niger* (7). Activity data are plotted as  $(Y_\infty - Y)/(Y_\infty - Y_0)$  where  $Y_\infty$  and  $Y_0$  are the activities at infinite and 0 time, respectively. Nearly 100% of the activity was restored. (From Refs. 1 and 7.)

**Figure 4** Comparison of the rates of sulfhydryl oxidase-catalyzed oxidation (●) and restoration of trypsin-activatable chymotryptic activity (○) with that observed in air (▲, △) for immobilized reduced chymotrypsinogen A. Activity data are plotted as  $(Y_\infty - Y)/(Y_\infty - Y_0)$  where  $Y_\infty$  and  $Y_0$  are the activities at infinite and 0 time, respectively. Nearly 50% of the original biological activity was restored. (From Ref. 31.)

of reduced RNase A (28) and bovine pancreatic trypsin inhibitor (32) suggests that the same disulfide bond formation pathway is followed in all cases. Consequently, the folding pathway of the reduced protein is determined by its structure, with the enzyme acting as a true catalyst affecting only the rate of the reaction and not the pathway.

Another reaction observed to be catalyzed in vitro by sulfhydryl oxidase that may have biological significance is the conversion of xanthine dehydrogenase to xanthine oxidase (33). The sulfhydryl groups of xanthine dehydrogenase are rapidly oxidized in the presence of the enzyme with the concomitant appearance of xanthine oxidase activity. Sulfhydryl oxidase is absent in liver where xanthine dehydrogenase is found, whereas in bovine milk xanthine oxidase is present.

## V. MEASUREMENT OF SULFHYDRYL OXIDASE ACTIVITY

Typically, the enzyme is assayed with 0.8 mM GSH in 0.047 M sodium phosphate buffer, pH 7.0, at 35°C (1, 5, 25, 34). To 1.0 mL of the 0.8 mM GSH solution equilibrated at 35°C, 0.1 mL of enzyme solution is added. A blank solution is prepared using 0.1 mL of boiled enzyme solution. At 1-min intervals, 0.1 mL is removed and added to 5.0 mL of 0.1 mM DTNB solution in 0.1 M sodium phosphate buffer at pH 8.0, containing 10 mM EDTA. The absorbance of each of these solutions is read at 412 nm after a 2-min reaction. Sufficient enzyme activity must be added to complete the assay within 10 min to avoid effects of autoxidation. The initial slope of the absorbance change versus time is used to calculate the activity. Enzyme activity per milliliter of enzyme solution is calculated from the relationship

$$\mu\text{mol SH}/\text{min/mL} = 561 (\text{A}_{412}/\text{min})/ \\ 13.6 (\text{mM}^{-1}\text{cm}^{-1})$$

where 1 μmol SH oxidized/min is defined as 1 unit of activity.

## VI. PURIFICATION PROCEDURES

The procedures described have been used to obtain the enzyme from bovine milk. Because more of the enzyme exists in skim milk membranes than in the milkfat globule membranes, initially fresh raw skim milk is prepared (1). It is very important to remove all of the milkfat globules because they apparently interfere with later isolation procedures (unpublished observations). Fresh milk is centrifuged at 4100 g for 30 min at 30°C and the skim milk is carefully removed from under the fat layer. Caseins are then coagulated by addition of four units of chymosin (one unit will coagulate 10 mL of skim milk in 1 min at 30°C)/100 mL skim milk, followed by incubation at 30°C for 30 min (34). Whey is prepared by centrifugal removal of the clotted caseins at 16,300 g for 45 min at 4°C. The next step is to prepare the skim milk membrane vesicles. Several procedures have been developed for this isolation (1, 25, 35) as described in Table 2. Preparations of the membrane vesicles by chromatography on 300 nm pore diameter controlled-pore glass (CPG-3000) or by membrane fractionation using a 100,000-dalton exclusion limit membrane are more homogeneous than that obtained by ammonium sulfate fractionation. Typically, purified vesicles represent a 200- to 300-fold increase in specific activity compared to whey (35, 36).

Three procedures have been developed for purification of the enzyme from membrane vesicles. The initial procedure developed involved a differential centrifugation taking advantage of the concentration-dependent aggregation of the enzyme (1). Thus, the ammonium sulfate precipitate is made to 0.15% protein in 0.047 mM phosphate buffer, pH 7.0, and centrifuged at 2000 g for 30 min at 4°C. The supernatant is concentrated to 3% protein and re-centrifuged under the same

<sup>a</sup> Biotin-HPDP is N-[6-(biotinamido)hexyl]-3'(2'-pyridyldithio)propionamide.

conditions, yielding sulphydryl oxidase activity in the pellet. Finally, the pellet is solubilized in twice the volume of the previous solution and again centrifuged under the same conditions, yielding the purified enzyme in the pellet.

The other two methods of purification are based on the catalytic mechanism or the active-site sulphydryl group (Table 3). First, the membrane vesicles are solubilized by adjustment to 1% C<sub>12</sub>E<sub>9</sub> in phosphate buffer, pH 7, and centrifuged at 100,000g to remove any insoluble material. Transient covalent chromatography on cysteinylsuccinamidopropyl glass based on the fact that sulphydryl oxidase follows a substituted enzyme mechanism. Thus, a mixed disulfide is formed between the enzyme and the immobilized cysteinyl residue which cannot be reduced without the addition of free thiols (34). Cysteinylsuccinamidopropyl glass is

prepared by reaction of cysteine with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide-activated succinamidopropyl glass as described by Sliwkowski *et al.* (25). A typical purification using this procedure results in a 4800-fold increase in the specific activity compared to that in whey (Table 4).

Bioselective adsorption on monomeric avidin is based on selective biotinylation of the active site sulphydryl group of the enzyme with N-[6-(biotinamido)hexyl]-3'(2'-pyridyldithio)propionamide (biotin-HPDP) (35). The resulting mixed disulfide, containing a biotinyl residue, strongly binds to avidin but can be released by reduction of the disulfide bond (35). The purified enzyme obtained by this procedure exhibits a 3100-fold increase in specific activity compared to that of whey (Table 5).

**Table 4** Data from a Typical Purification Using Cysteinylsuccinamidopropyl Glass

Fraction	Volume (mL)	Total protein (mg)	Total units of activity <sup>a</sup>	Specific activity (units/mg)	Yield (%)	Purification (fold)
Whey	910	8190	40	0.005	100	1

## Xanthine Oxidase

**John R. Whitaker**

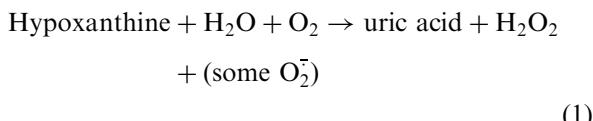

*University of California, Davis, Davis, California, U.S.A.*

### I. INTRODUCTION

The enzyme described in this chapter is called “xanthine oxidase,” “xanthine dehydrogenase,” or “xanthine oxidoreductase” by various authors. Except for the oxidation state of two sulphydryl groups in the active site of the protein, they are the same. When the two sulphydryl groups are present, the enzyme performs primarily as a dehydrogenase but still has some oxidase activity. When the two sulphydryl groups ( $-SH$ ) are oxidized to give a disulfide group ( $-S-S-$ ), or two sulfonic acid groups ( $-SO_3^{2-}$ ), the enzyme functions as an oxidase (1–5). Reduction of the  $-S-S-$  bond converts the oxidase back to a dehydrogenase, with a significant conformational transition in the flavin binding site (3).

#### A. Reactions Catalyzed

Xanthine oxidase (XO; EC 1.1.3.22) catalyzes the oxidation of hypoxanthine and xanthine to uric acid (Structure 1),

with  $\text{O}_2$  being the second substrate (oxidant). The heavy arrows in Structure 1 show the reactions catalyzed by XO; the dashed arrows show the net result of the reactions. Note that oxidation of hypoxanthine gives the enol form of xanthine, which then sponta-

neously isomerizes to some keto form of xanthine that can be catalyzed by XO to the enol form of uric acid, which then spontaneously isomerizes to some keto form of uric acid. The isomeric forms of the substrates make interpretation of the kinetic results difficult, as the enol form of xanthine and the keto form of uric acid may be competitive inhibitors of XO. Other purines and adenine are oxidized more slowly (Table 1). A number of aldehydes (Table 1) are oxidized also to the corresponding carboxylic acids by XO.

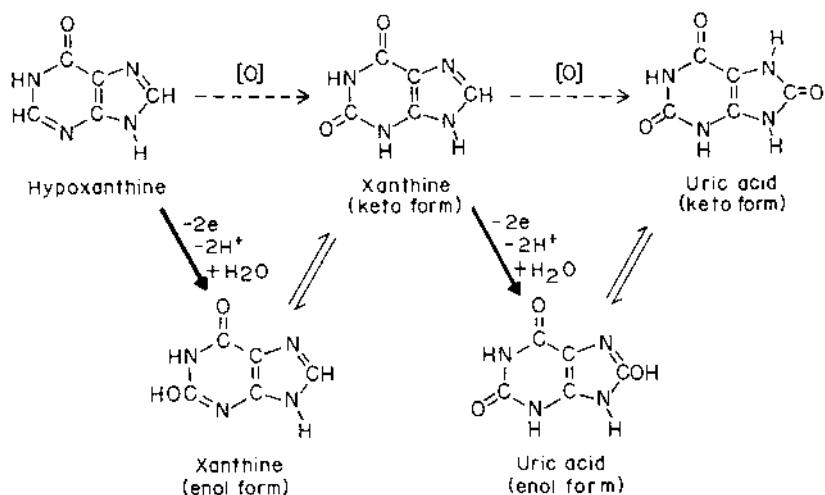

Xanthine dehydrogenase (XDH; EC 1.1.1.204) reduces  $\text{NAD}^+$  to  $\text{NADH}$  (7), as well as  $\text{O}_2$  to  $\text{H}_2\text{O}_2$  (8) with xanthine as the second substrate [Eqs. (2) and (3)].

Steady-state kinetic rate constants of xanthine/ $\text{O}_2$  and xanthine/ $\text{NAD}^+$  reactions catalyzed by XDH are  $2.1 \pm 0.1 \text{ sec}^{-1}$  (7) and  $6.3 \text{ sec}^{-1}$  (8) at  $25^\circ\text{C}$  and pH 7.5, respectively. For comparison, the oxidation of  $\text{NADH}/\text{O}_2$  is  $2.5 \pm 0.9 \text{ sec}^{-1}$  under the same conditions. Therefore, XDH has a significant and intrinsic xanthine oxidase activity on some substrates (7, 8).

Xanthine dehydrogenase has an  $\text{NAD}^+$  binding site and a substantially lower reduction potential for the  $\text{FADH}\cdot/\text{FADH}_2$  couple relative to XO (9, 10). In the case of the milk enzyme, the difference is 180 mV.

Xanthine oxidase has low specificity for both the substrates and the electron acceptor. More than 100 compounds are known to serve as substrates, and a

**Structure 1**

large number of electron acceptors are known, including  $O_2$ ,  $NAD^+$ , methylene blue, 2,6-dichlorophenol-indophenol, triphenyltetrazolium chloride, phenazine methosulfate, cytochrome c, and ferricyanide.

## B. Historical Aspects

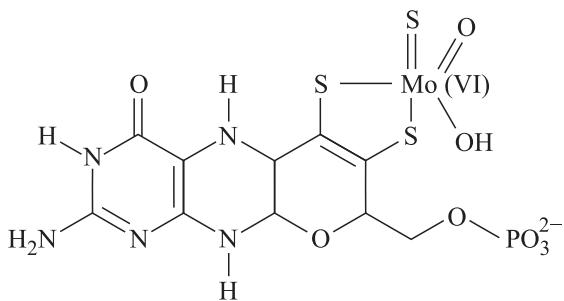

In 1902, Schardinger (11) determined that fresh milk decolorized Methylene Blue. In 1922, Morgan et al. (12) reported that bovine milk converted hypoxanthine and xanthine into uric acid under both aerobic and anaerobic (when Methylene Blue was included) conditions. They found the same activity in liver, spleen, and lungs of rats and cows. The activity, which they named "xanthine oxidase," was destroyed by boiling. In 1924, Dixon and Thurlow (13) partially purified XO and did

kinetic studies on the rate of reduction of Methylene Blue. Dixon (14) showed that aldehydes are substrates for XO. In 1939, Ball (15) and Corran et al. (16) obtained nearly pure XO, with a golden brown color due to intrinsic flavin (FAD), plus another unknown chromophore (now known to be molybdenum) (17, 18). In 1954, Richert and Westerfeld (19) reported that addition of ferric chloride in the diet of rats substantially increased the activity of XO in rat liver; they found iron, FAD, and molybdenum to be present in the ratio of 8:2:1 in XO. In 1955, Avis et al. (20) developed an isolation procedure for XO from cow's milk which gave crystalline XO with  $A_{280}/A_{450}$  of 5.0–5.2, a level of purity that has not been increased to the current time. The ratio of iron, molybdenum, and FAD was 8.1:1.4:2.0. Later, the iron, labile sulfide, molybdenum, and FAD were found to be in the ratio

**Table 1** Substrate Specificity of Xanthine Oxidase from Milk

Substrate	Relative rates	Substrate	Relative rates
Xanthine	140	Acetaldehyde	0.72
Hypoxanthine	100	Cinnamaldehyde	0.41
8-Hydroxypurine	6	Vanillin	0.01
6-Amino-2-hydroxypurine	4.5	Glyceraldehyde	0.014
6-Amino-8-hydroxypurine	7	p-Phthalaldehyde	0.013
Adenine	6	Decanaldehyde	0.0080
2,8-Dihydroxypurine	0.6	n-butyraldehyde	0.0060
p-Hydroxybenzaldehyde	1.3	Octaldehyde	0.0002
Benzaldehyde	0.8		

Source: Ref. 6.

**Structure 2**

of 2:2:1:1 per subunit (21). The molecular weight of XO was determined by ultracentrifugal sedimentation and diffusion data to be 290 kDa (22), with two identical subunits.

The mechanistic aspects will be presented in Section II.

### C. Importance of Xanthine Oxidase to Food Science, Nutrition, and Medicine

During metabolism of nucleic acids, animals convert the purine bases adenine and guanine to uric acid. Uric acid then forms calcium urate which is deposited in joints. As a result, XO has been implicated in a number of diseases ranging from rheumatoid pathology, ischemia-reperfusion injury, and in reactive oxidant-mediated signal transduction. The bases for these implications are due to known metabolic free radical generation by XO and correlation of XO concentrations with certain diseases. As pointed out in Section I.A, the oxidation of hypoxanthine and xanthine and of NADH/O<sub>2</sub> by XO leads to the formation of H<sub>2</sub>O<sub>2</sub> and O<sub>2</sub><sup>-</sup> (superoxide ion). In experimental animals, primarily rats and mice, there are good relationships between XO activity and the development of the pathological problems listed above. Evidence for this is well presented by the recent reviews of Nishino et al. (5), Wright and Repine (23), Bulkley (24), Harrison (25), and Blake et al. (26). In particular, the review by Blake et al. (26) details the current experimental evidence for the possible role of XO in rheumatoid pathology.

In 1977, major consumer concerns arose as to how milk was processed, in particular raw milk and lightly pasteurized milk. There was concern that active XO might pass through the small intestinal wall into the blood and lead to major problems in tissues. Special

attention was given to this concern by several researchers. In particular, Dr. Clifford at U.C. Davis carefully researched this area and determined that no intact XO (active or inactive) was found in the blood of rabbits (27). His results are not surprising when one considers the size of the XO (290 kDa).

Harrison (25) reported that purified human breast milk XO has only 2–3% the specific activity of cow's milk. His data indicate that XO activity is very low in most human tissues, except for liver and intestinal tissues.

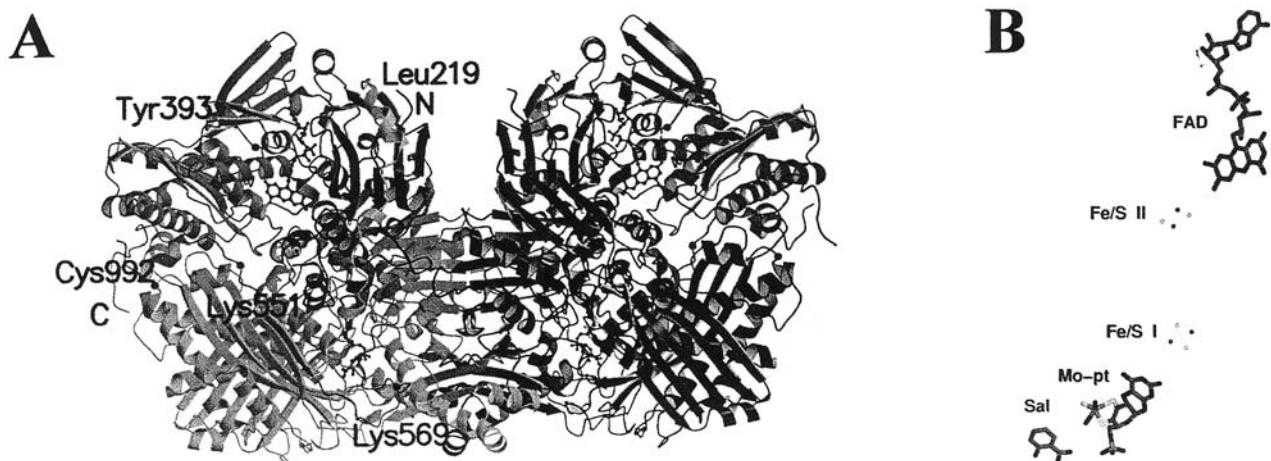

## II. MECHANISM OF XANTHINE OXIDASE CATALYSIS

### A. Protein Nature of Xanthine Oxidase

The complete amino acid sequences of XOs from various sources have been deduced by sequencing the respective cDNAs (genes). They are highly homologous consisting of, for example, 1332 amino acid residues for bovine milk XO and 1333 residues for human liver XO, with 90% sequence identity (28–30).

The x-ray crystallographic structure of bovine milk XO has been published (9). As reported by other methods, XO has a molecular weight of 290 kDa. It is composed of two identical subunits, each containing an active site. In addition to the several amino acid residues in the active sites there are two molecules of iron [Fe(III)], two molecules of labile sulfide, one molecule of molybdenum, one molecule of FAD per subunit (21), and one molecule of molybdopterin, a cofactor that binds the molybdenum (31) (see Structure I). In XO/XDH from prokaryotes, the dinucleotides of guanine, cytosine, adenine, or hydroxyxanthine are found. For example, in the gram-positive bacterium *Desulfouibrio gigas*, the cofactor is a molybdenum molybdopterin cytosine dinucleotide.

The dimensions of the active dimeric (two subunits) enzyme are 155 Å × 90 Å × 70 Å (Fig. 1) (9). It is butterfly shaped with the dimer interface on the smaller side of the vertically elongated subunits. Each subunit consists of three domains. The small N-terminal domain (residues 1–165) contains the two iron/sulfur cofactors. It is connected to the FAD-binding domain (residues 226–531) by a long segment of amino acid residues (166–225). The FAD domain is connected to the third domain (residues 590–1332) by the amino acid residues 532–589. This large third domain contains the Mo-pterin cofactor (Structure 2). The three domains are folded in proximity to each other so as to form the active site of the enzyme containing the

**Figure 1** (A) Molecular structure of xanthine dehydrogenase (XDH) as determined by x-ray crystallography. (B) For clarity, the cofactors and salicylate (added to stabilize XDH) are shown in the same positions as found in the protein molecule. (From Ref. 9.)

two iron/sulfur cofactors, the FAD cofactor and the Mo-pterin cofactor. Each subunit functions independently of the other. The reader is referred to the publication by Enroth et al. (9) for a color-coded diagram of the XO molecule.

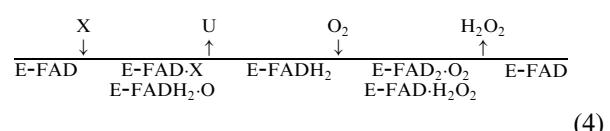

The tertiary structure of aldehyde oxidoreductase, a member of the xanthine oxidase family, is also known for *Desulfovibrio gigas* (32, 33); it is very similar to that of XO.

## B. Mechanism of Action of Xanthine Oxidase

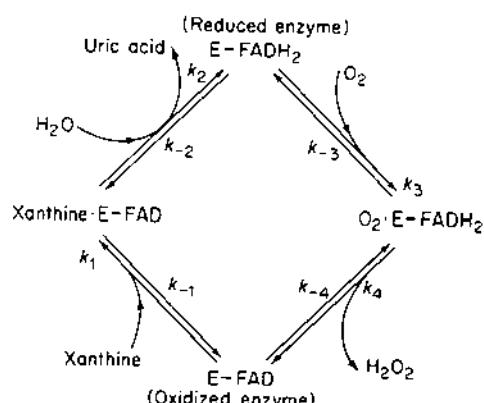

When xanthine and O<sub>2</sub> are added to XO, the reaction pathway was shown by Gutfreund and Sturtevant (34) to be that described by Fig. 2. The rate constants k<sub>1</sub>, k<sub>2</sub>, k<sub>3</sub>, and k<sub>4</sub> for the reactions were determined by rapid reaction techniques to be  $\sim 5.0 \times 10^5 \text{ M}^{-1} \text{ sec}^{-1}$ ,  $10.5 \text{ sec}^{-1}$ ,  $> 4.0 \times 10^5 \text{ M}^{-1} \text{ sec}^{-1}$ , and  $21.5 \text{ sec}^{-1}$ , respectively. The rate constants k<sub>1</sub> and k<sub>3</sub> are for formation of the Michaelis-Menten complexes of xanthine · E · FAD and O<sub>2</sub> · E-FADH<sub>2</sub>, respectively, while k<sub>2</sub> and k<sub>4</sub> are the rate constants for oxidation of xanthine to uric acid and reduction of O<sub>2</sub> to H<sub>2</sub>O<sub>2</sub>, respectively.

When the 1/(turnover numbers) are plotted versus 1/[xanthine] at three different concentrations of O<sub>2</sub>: air saturated (0.24 mM), 60% O<sub>2</sub> saturated enzyme and the results of the two are extrapolated to  $\infty \text{O}_2$  concentration, all three lines are parallel (Fig. 3) (21), indicating that the reaction follows a Ping-Pong Bi-Bi mechanism. This is diagrammed according to the

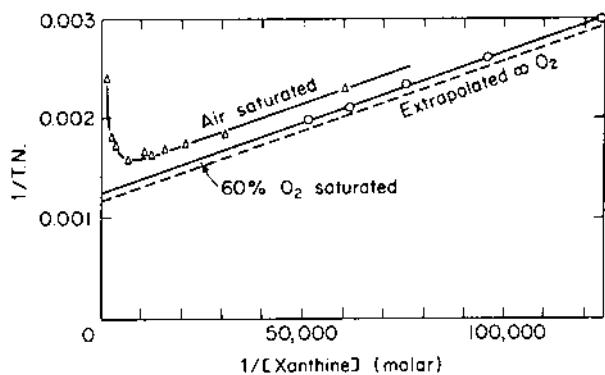

Cleland Nomenclature (35) in Eq. (4) where X is xanthine and U is uric acid.

In 1964, Bray et al.(36) used electron paramagnetic resonance spectroscopy to investigate the rates of electron transfer to and decay from the several cofactors of the enzyme-substrate system. The XO and xanthine were mixed very rapidly (< 1 msec) and frozen very rapidly (< 1 msec) in liquid N<sub>2</sub>. The Mo- $\delta$  signal,

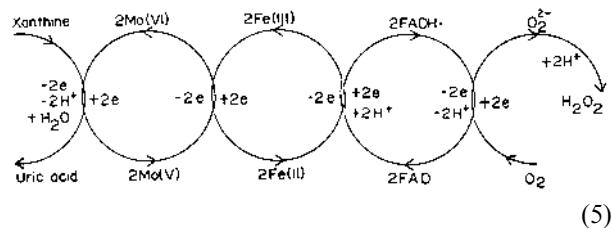

**Figure 2** Mechanism of action of xanthine oxidase as determined by fast reaction kinetics. (From Ref. 34.)

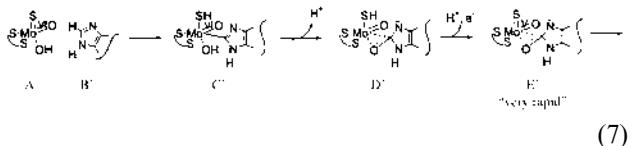

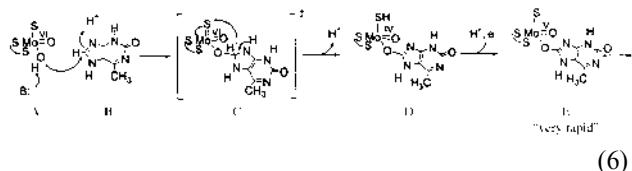

**Figure 3** Effect of xanthine and  $O_2$  concentrations on the rate of xanthine oxidation by xanthine oxidase. T.N. is the turnover number measured at pH 8.3 and 25°C. (From Ref. 21.)

believed to be conversion of Mo(VI) to Mo(V), reached a maximum in  $\sim 15$  msec. The Mo- $\beta$ , FADH $\cdot$  (FAD  $\rightarrow$  FADH $\cdot$ ), and Fe(II) [Fe(III)  $\rightarrow$  Fe(II)] signals were maximum at 40, 45, and 100 msec, respectively (Fig. 4). Therefore, Bray et al. (36) suggested that the sequential steps in the reductive reaction are: xanthine  $\rightarrow$  Mo  $\rightarrow$  FAD  $\rightarrow$  Fe  $\rightarrow$   $O_2$ . More recently, the reaction order has been shown to be: xanthine  $\rightarrow$  Mo  $\rightarrow$  2Fe/2S  $\rightarrow$  FAD  $\rightarrow$   $O_2$  (21). Therefore, the overall reaction involving the flow of electrons is best described by Eq. (5).

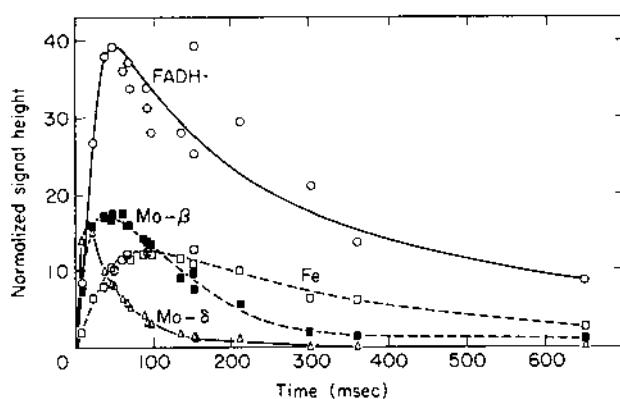

The order in which electrons and water are transferred from xanthine and oxygen to produce uric acid and hydrogen peroxide ( $H_2O_2$ ) is generally agreed to be that shown in Eq. (5). However, the mechanistic pathway of the Mo-pterin cofactor and substrate in the first step is still in dispute. The key difference among scientists in the field is primarily whether the first chemical event following formation of the noncovalent enzyme-substrate complex involves an Mo-C or a Mo-O-C covalent linkage between the Mo-cofactor and substrate as shown in Eqs. (6) and (7) (37).

While Eqs. (6) and (7) give the same final products, the mechanisms of the reactions are fundamentally different.

In the first proposed mechanism [Eq. (6)], the product of hydroxylation of the substrate 2-hydroxy-6-methylpurine (B; in the enolate tautomeric form) is suggested to be coordinated to the molybdenum via the induced oxygen atom from the -OH group of the molybdenum cofactor (A) of the enzyme to form the bracketed intermediate/transition state compound (C). The intermediate/transition state compound is proposed to be formed in a base-assisted (B: group in the active site of the enzyme) nucleophilic attack of the Mo<sup>VI</sup>-OH group on the C-8 of the substrate with a concomitant hydride transfer to the Mo=S group (bracketed structure) to give Mo<sup>IV</sup>-SH (D). The "very rapid" species is formed by a one-electron oxidation and deprotonation to give the EPR-detectable Mo<sup>V</sup>OS(OSR) species (D).

In the second proposed mechanism [Eq. (7)], the purine substrate (B') is complexed (noncovalently) to the molybdenum cofactor (A') of the enzyme as the keto tautomer permitting insertion of the C8-H-bond

**Figure 4** Electron paramagnetic resonance signals generated by xanthine oxidase in a "single turnover" experiment with xanthine as substrate. (From Ref. 36.)

across the  $\text{Mo}^{\text{VI}}=\text{S}$  bond to give a species with a Mo–C(SH) bond (C'). D' is formed by removal of a proton from the MoOH group to provide an O-bridge between the Mo and C-8 of the purine. Subsequent proton ( $\text{H}^+$ ) and electron ( $e^-$ ) transfers lead to the “very rapid” species (E'), with some resemblance to E in Eq. (6) (both have  $\text{Mo}^{\text{V}}-\text{OS(OR)}$  structure) which is EPR detectable.

### III. DETERMINATION OF XANTHINE OXIDASE ACTIVITIES

#### A. Xanthine Oxidase Activity

A number of methods are available to determine XO activity. Using xanthine as the substrate, the rate of oxidation of xanthine to uric acid can be followed by the rate of Methylene Blue reduction (under anaerobic conditions), by cytochrome c reduction (aerobically), by oxygen uptake (oxygen electrode use), or by the rate of uric acid formation (increase in absorbance at 290 nm).

The easiest, and perhaps best assay is to follow the rate of uric acid formation from xanthine, in the presence of  $\text{O}_2$ , in a recording spectrophotometer at 290 nm, pH 8.3, 25°C (8). The molar extinction coefficient,  $\epsilon_m = 9.6 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ .

Only initial rates should be used (< 5% conversion of xanthine to uric acid) in analyses, as  $\text{H}_2\text{O}_2$  slowly inactivates the enzyme. Catalase can be added to remove the  $\text{H}_2\text{O}_2$  when reaction times need to be extended (when low concentrations of XO are present).

The rate of reaction [Eq. (8)] can also be followed with cytochrome c under aerobic conditions. The rate of reduction of cytochrome c is determined by increase in absorbance at 550 nm (reduced band of cytochrome c).

#### B. Xanthine Dehydrogenase Activity

See Section IV.B.1.

### IV. PURIFICATION OF XANTHINE OXIDASE

#### A. Xanthine Oxidase from Cow's Milk

An abbreviated description of the method of Avis et al. (20) for the purification of xanthine oxidase from cow's milk, published in 1955, is given below. This method is chosen for several reasons:

1. Although XO had been partially purified by other researchers, Avis et al. (20) were the first to obtain a homogeneous XO preparation *and* to crystallize it.

2. Researchers have shown this method to be the best one, even after 45 years. Some modifications of the method have been published, but all report the same maximum specific activities as Avis et al. (20).

3. Fraction M7 contained FAD, iron, and molybdenum in the ratio of 2.0:8.1:1.4 per unit of protein; recent methods give nearly the same values.

4.  $Q_{\text{O}_2}$  is 2300 units activity using xanthine as substrate at 23.5°C, indicating purity. The steps involved in purification are described below.

#### 1. M1

Cream separated from fresh milk. The milk was cooled to 5°C overnight, skimmed, churned, and passed through a cream separator to remove additional fat. Approximately 50% of the original activity was retained; volume was 25.1 L. The buttermilk was warmed to 34°C in a pressure controlled cast-iron vessel. Calcium chloride (0.5 M: 250 mL) and pancreatin (40 g) were added. After 15 min a dense precipitate of casein formed and was removed by straining through nylon net to give 25 L of M2.

#### 2. M2

Filtration was performed on type PF 40 filters and 13 sterimats precoated with Hyflo Super Cel (650 g) at ~5 lb/in.<sup>2</sup> Hyflo Super Cel (325 g) was mixed with M1. Starting pressure was 7 lb/in.<sup>2</sup> using a nitrogen cylinder. The first 3 L of colorless filtrate was discarded. Filtration rate decreased after ~10 L was collected and a final pressure of 28 lb/in.<sup>2</sup> was required. Total volume of M3 was 21 L.

#### 3. M3

The cloudy filtrate was stored for 16 h at 5°C, then refiltered through PF 40 and 11 sterimats of grade GS to give 20 L of clear yellowish brown liquid (M4).

#### 4. M4

M4 was chromatographed on a 6 in.×12 in. Pyrex column packed with calcium phosphate gel/Celite 545 (1:1) (see Ref. 38 for preparation). M4 was cooled to 5°C, adjusted to pH 6.2 with 0.1 N acetic acid, and passed through the column at 4 lb/in.<sup>2</sup> pressure. The

brown enzyme bound to the calcium phosphate gel column. The column was washed with 0.02 M phosphate buffer, pH 6.2, until the washes gave a negative protein test by trichloroacetic acid addition (ppt.). The enzyme was eluted with 1 M phosphate buffer, pH 5.8, to give M5.

## 5. M5

M5 was precipitated with an equal volume of 4 M phosphate buffer (pH ~ 9) and the precipitate collected on a sintered-glass funnel with aid of 10 g Hyflo Super Cel. The precipitate was dissolved in a minimum amount of water and filtered using Hyflo Super Cel, which was washed with small amounts of water to give 400 mL enzyme solution. The solution was then dialyzed in a Visking cellulose casing (size 32/32) against 40 L of 0.01 M acetate buffer, pH 5.1, at 5°C. This treatment gave a copious, colored precipitate which was removed by centrifugation and discarded. The 450 mL of supernatant is M6.

## 6. M6

M6 was concentrated from 450 to 320 mL by pervaporation (air current produced by fan) in a Visking cellulose casing for 16 h at 5°C. The protein concentration was 1% as measured by absorbance at 280 nm. The solution was cooled to 0°C; 160 mL of 70% (v/v) ethanol, precooled in a carbon dioxide-acetone bath, was added to the solution from a burette fitted with a fine capillary, with sufficient stirring to ensure rapid mixing but without frothing. The solution, which began to form a small amount of precipitate, was held for 16 h at -6°C. The precipitate was collected in a refrigerated (-6°C) centrifuge at 1300g for 40 min. The precipitate was dissolved in water (88 mL), giving a total volume of 100 mL. Phosphate buffer (1 M; 1 mL; pH 5.8) and 10 mL of 50% (v/v) ethanol were added slowly to give a final ethanol concentration of ~ 8%. The solution was held at -1°C for 0.5 h and centrifuged. The precipitate was discarded. The supernatant liquid was seeded with crystals from a previous batch and held at -1°C. Crystals appeared after ~ 12 h. In other preparations crystals appeared within 36 h without seeding.

After 4 days at -1°C, the crystals were collected by centrifugation at -1°C and washed twice with phosphate buffer containing 7% ethanol (0.01 M phosphate, pH 6.2, -1°C), using 70 mL of the ethanolic buffer each time. The crystals were dissolved in aqueous 0.2 M sodium chloride (~ 45 mL) and the solution was dialyzed for 16 h against 1 L of 0.2 M sodium

chloride at 5°C. The solution was diluted to 50 mL (M7).

A second crop of crystals was obtained from centrifugation of the mother liquor after 28 days at -1°C. The crystals were collected by centrifugation and dissolved in 0.2 M sodium chloride (15 mL) (M7a).

Part of the M7 solution (10 mL), after storage at 2°C for 28 days, was recrystallized by the following method to give M8. The enzyme was precipitated by adding 70% (v/v) ethanol (5 mL), then centrifuged, and the precipitate dissolved in water to give 10 mL of solution. Phosphate buffer (1 M; 0.7 mL; pH 5.8) and 50% ethanol (1.5 mL) were added. The immediate precipitate formed at 10 min was removed by centrifugation at -1°C and the supernatant liquid was seeded and left at -1°C for 16 h. The crystals formed were collected by centrifugation and dissolved in 0.2 M aqueous sodium chloride (final volume of 10 mL) (M8). Results of the purification are summarized in [Table 2](#).

## B. Xanthine Dehydrogenase from Cow's Milk

Hunt and Massey (8) purified cow's milk XO in a dehydrogenase form (XDH) in the presence of 2.5 mM dithiolthreitol. While XO reacts rapidly only with O<sub>2</sub> (and xanthine) and not with NAD<sup>+</sup>, the XDH form of the enzyme reacts rapidly with NAD<sup>+</sup>. XDH has a turnover number for the NAD<sup>+</sup>-dependent conversion of xanthine to urate of 380 mol/NAD<sup>+</sup>/min/mol of XDH at pH 7.5 and 25°C, with a K<sub>m</sub> < 1 μM for xanthine and a K<sub>m</sub> of 7 μM for NAD<sup>+</sup>, but very little O<sub>2</sub>-dependent activity. XDH can be converted to the XO form by addition of three to four equivalents of the disulfide-forming reagent 4, 4'-dithiodipyridine, suggesting that in the XDH form of the enzyme disulfide bonds are reduced to -SH groups. This may create a binding site for NAD<sup>+</sup> that changes the protein structure near the flavin (8).

### 1. Enzyme Assays

Xanthine oxidase activity was measured using 165 μM xanthine in 0.1 M sodium pyrophosphate buffer containing 0.3 mM EDTA, pH 8.5, and 25°C in an air-equilibrated solution, by monitoring production of urate at 295 nm ( $\epsilon_M = 9,500 \text{ M}^{-1} \text{ cm}^{-1}$ ) (8).

Xanthine dehydrogenase activity was measured using the same assay mixture as above, plus 530 μM NAD<sup>+</sup> and determining the NADH production at 340 nm ( $\epsilon_M = 6.22 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ ) (39). Activities are expressed in turnover numbers, as moles of substrate catalyzed to product/min/mol enzyme-bound flavin.

**Table 2** Summary of Purification of Xanthine Oxidase

Fraction No.	Volume (L)	Total units (XO)	Spec. Act. <sup>a</sup> (units/L/E <sub>280</sub> )	Spec. Act. <sup>b</sup> (units/L/E <sub>450</sub> )	E <sub>280</sub> /E <sub>450</sub> <sup>c</sup>	Step

Source: Ref. 20.

Since XO/XDH have two flavins per mol, the turnover number is per active site. The XDH/XO ratio is calculated on the basis of these specific assays.

## 2. Enzyme Purification

### Purification of XO in the reduced XDH form (8).

1. To 15 L fresh unpasteurized cow's milk, add 50 mL of 0.75 M dithiothreitol (DTT), 15 mL of 0.1 M phenylmethanesulfonyl fluoride (to inhibit serine proteases), 15 mL of 1.0 M sodium salicylate, 240 g of sodium bicarbonate, and 2840 g of ammonium sulfate. Stir rapidly for 1 h at 4°C (all steps below are done at 4°C).

2. Add 2.5 L chilled 1-butanol and stir for 30 min.

3. Centrifuge the suspension in 800-mL aliquots for 15 min at 4000g. Remove the top butanol layer by suction. Remove the solid lipid layer. Discard both.

4. To the 15 L of liquid, add 160 g/L of ammonium sulfate and stir for 30 min. Then let stand for 2 h to permit the precipitate to rise to the top. Skim off the brown precipitate (in ~ 1.7 L); centrifuge for 1 h at 16,000g. Remove the liquid and discard.

5. Resuspend the solid precipitate in 500 mL of 0.05 M potassium phosphate buffer containing 0.3 mM EDTA, 1 mM salicylate, 2.5 mM DTT, pH 6.0. Dialyze twice, using 6 L of the same buffer solution each time. Centrifuge the dialysate (~ 470 mL) at 16,000g for 1 h. Decant the liquid portion and save. Discard precipitate.

6. Titrate the liquid portion from above using 30 mL enzyme preparation/mL calcium phosphate gel (38). Typically, 1 L of calcium phosphate gel is stirred well with 470 mL of enzyme solution. Centrifuge for 10 min at 4,000g. Discard supernatant.

7. Resuspend the precipitate in phosphate buffer (see 5 above) and centrifuge to collect insoluble material.

8. Resuspend the precipitate in 500 mL of 10% ammonium sulfate. Centrifuge. Repeat the washing of the precipitate three more times, saving the washes.

9. To the combined washes, add ammonium sulfate to increase its concentration to 50%. Centrifuge at 16,000g for 30 min. Save the precipitate.

10. Resuspend the precipitate in a mixture of 80% of 0.05 M Tris, 0.3 mM EDTA, pH 7.8, buffer and 20% of 0.1 M sodium pyrophosphate, 0.3 mM EDTA, pH 8.5, with 2.5 mM DTT (Buffer A). Dialyze against 2 L of the same buffer overnight.

11. A 100-mL portion is removed from the dialysate and loaded onto a folate affinity column, prepared according to Nishino et al. (40), and equilibrated in Buffer A. The column is washed with ~ 500 mL of Buffer A until the 280 nm absorbance reaches a minimum, then elution is begun with Buffer A containing 10 mM salicylate. XDH moves gradually down the column and elutes as a single dark band.

12. The dark band fractions from step 11 above are pooled, concentrated, and dialyzed in 0.1 M sodium pyrophosphate, 0.3 mM EDTA, pH 7.5, buffer. The

**Table 3** Purification of Milk Xanthine Dehydrogenase

Purification step	Volume (mL)	XDH/XO (total units)	Protein (mg/mL)	XDH/XO specific activity (units/mg)	XDH/XO purification (fold)	Dehydrogenase: oxidase activity (ratio)
Fresh milk	15,000	747/870	8	0.0062/0.0072	1/1	1.3
After $(\text{NH}_4)_2\text{SO}_4$ /butanol fractionation and dialysis	470	800/260	7	0.24/0.79	38/11	3.1
After calcium phosphate gel	2,000	810/250	0.4	1.0/0.31	161/43	3.2

liquid fractions from step 1 are stored at 4°C in the buffer above with 1 mM salicylate and 2.5 mM DDT added. During storage there is some conversion of XDH to XO. XO can be converted back to XDH by adding fresh DTT-containing buffer.

Table 3 summarizes the results of the purification of milk XDH.

## Lipoxygenase and Associated Enzymes

**Harold W. Gardner\***

*U.S. Department of Agriculture, Peoria, Illinois, U.S.A.*

### I. INTRODUCTION

#### A. Reactions Catalyzed

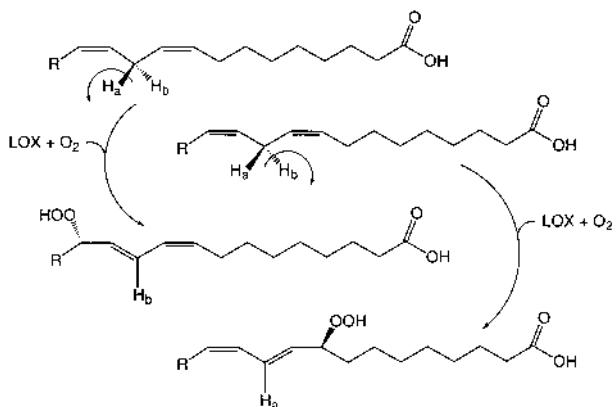

Lipoxygenase (LOX), a nonheme iron protein, is undoubtedly universally distributed in plants and animals. Fungal LOXs are known that give unique products and some of these LOXs apparently operate by different mechanisms (1), including a LOX with a manganese active site (2). A number of recent publications review various aspects of LOX (3–15). Although many LOXs have been thoroughly characterized, much of the literature focuses on one soybean seed isozyme, LOX-1. In this review a detailed account of soybean LOX-1 is unavoidable because the literature is too extensive to realistically review the field in its entirety.

LOXs catalyze the dioxygenation of methylene-interrupted pentadiene fatty acids to afford conjugated hydroperoxydiene fatty acids. With few exceptions, plant LOXs oxidize linoleic and linolenic acids regiospecifically at either the  $\omega_6$  (C-13) or  $\omega_{10}$  (C-9) position with (*S*)-stereospecificity (Fig. 1). In the animal kingdom LOXs oxidize linoleic and linolenic acids by mechanisms similar to those in the plant kingdom, but many of the important oxidations of physiological significance utilize arachidonic acid and other C:20 polyenoic acids as substrates. Although plant LOXs are capable of oxidizing C:20 polyenoic acids, these substrates are unnatural in plants. With some excep-

tions, oxidations of C:20 fatty acids occur either at  $\omega_6$  (C-15),  $\omega_9$  (C-12), or  $\omega_{16}$  (C-5) position with (*S*)-stereospecificity (7). As discussed below, the list of substrates include additional natural and synthetic substrates; many of the latter give reduced activity. Generally, plant LOXs having high pH optima oxidize at the  $\omega_6$  position if incubated at high pH, and those with optima at neutral or low pH mainly afford  $\omega_{10}$  oxidation or both types of oxidation. The spatial relationship of removal of the *bis*-allylic hydrogen, and an (*S*)-oxidation at  $\omega_6$  versus  $\omega_{10}$  requires an alignment of the substrate into the active site of LOX in reverse orientations—that is, “head first” or “tail first.” This can be deduced by reference to Figure 1. Since reducing the pH of the incubation has been observed to lower the ratio of  $\omega_6$  to  $\omega_{10}$  oxidation of linoleic acid by soybean LOX-1 (16) and also lowers the ratio of  $\omega_6$  to  $\omega_{16}$  oxidation of arachidonic acid by rice LOX-2 (17), this suggested that either a head-first or tail-first alignment at the active site was dependent on the charge of the carboxylate/carboxylic acid group. It is probably because of reverse orientation phenomenon that arachidonic acid is all-(*S*) doubly dioxygenated at both ends of the polyene structure (17, 18).

The rate-limiting step is an H removal from the *bis*-allylic methylene of the pentadiene on the opposite side of O<sub>2</sub> insertion (19, 20). The immense size of an observed kinetic isotope effect with deuterated linoleic acid indicates that hydrogen tunneling occurs in the LOX reaction (21). As shown in Figure 2, the iron

\*Retired.

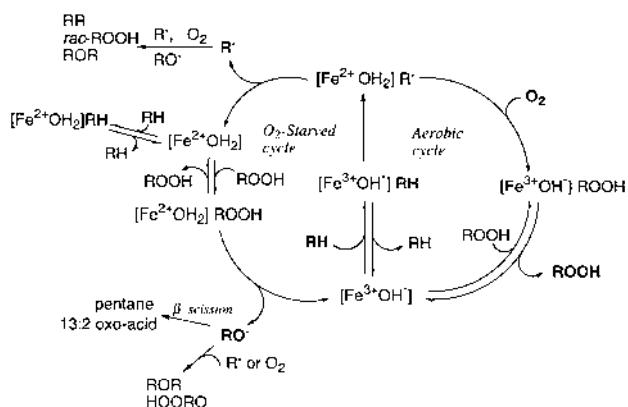

$R = \text{CH}_3\text{-(CH}_2)_4\cdot$  or  $\text{CH}_3\text{-CH}_2\text{-CH=CH-CH}_2\cdot$

**Figure 1** Oxidation of either linoleic (18:2) or linolenic (18:3) acid by plant LOXs is preceded by stereospecific removal of hydrogen followed by placement of oxygen on the opposite side of the molecule from hydrogen removal. Plant LOXs usually produce the 13(S)- and/or 9(S)-hydroperoxides of linoleic or linolenic acid as shown.

active site cycles electrons by a redox mechanism from H removal ( $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  transition) to conversion of the fatty acid peroxy radical to the hydroperoxide anion ( $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  transition) (15, 22, 23). Also shown in Figure 2 is an “ $\text{O}_2$ -starved cycle” of LOX (22, 23). When LOXs become deficient in  $\text{O}_2$  the enzyme undergoes an aberrant reaction whereby the product hydroperoxide fatty acid (ROOH) replaces RO $\cdot$  as an oxidant of the active site. This results in formation of a fatty acid alkoxy radical (RO $\cdot$ ) from the hydroperoxide, as well as unoxidized pentadienyl radicals from substrate. From linoleic acid and its 13-hydroperoxide, a number of compounds are formed by free radical chemistry, among which are pentane, 13-oxo-9,11-octadecadienoic acid, 13-oxo-9,11-tridecadienoic acid (24), dimers (25), and racemic fatty acid hydroperoxides (26). Similarly, from linolenic acid and its 13-hydroperoxide, one obtains isomeric pentenols, 13-oxo-9,11-tridecadienoic acid, and dimers (27). It is relatively easy to obtain  $\text{O}_2$ -starved conditions, such as by using excess concentrations of LOX and substrate, and by low  $\text{O}_2$  solubility due to increased temperatures of incubation. For good yields of hydroperoxides, one should optimize  $\text{O}_2$  dispersal/solubility, and use optimal enzyme concentrations (6).

## B. Structure of Substrates

“Natural” fatty acid substrates were discussed above. Other “natural” substrates, such as glycerides (28, 29)

**Figure 2** The iron redox cycle of the LOX active site shows the reaction of linoleic acid with  $\text{O}_2$  under conditions of adequate aeration, as well as an aberrant reaction with linoleic acid hydroperoxide under  $\text{O}_2$ -starved conditions. Shown in bold are the entry of linoleic acid (RH) and  $\text{O}_2$  into the cycle and products initially released from the active site—that is, linoleic acid hydroperoxide (ROOH), the alkoxy radical of linoleic acid hydroperoxide (RO $\cdot$ ), and the linoleic acid pentadienyl radical (R $\cdot$ ). The alkoxy radical (RO $\cdot$ ) often rearranges into an epoxyallylic carbon radical which reacts with  $\text{O}_2$  to form epoxyhydroperoxyoctadecenoic acid (HOORO), leading to epoxyhydroperoxyoctadecenoic acid. ROR represents dimers of epoxyoctadecenoic acid with the conjugated diene of linoleic acid. RR represents conjugated linoleic acid dimers, and *rac*-ROOH signifies racemic hydroperoxides formed by nonenzymic reaction of  $\text{O}_2$  with the pentadienyl radical of linoleic acid. Refs. 15, 22, and 23.

and phosphoglycerides (29, 30) have been described, but the activity is often reduced compared to free polyunsaturated fatty acids. Recently, it has been found that one of the olefinic double bonds can be replaced by a carbonyl double bond, such as a ketone (31) or aldehyde moiety (32). Many unnatural substrates have been synthesized to study enzyme mechanisms, among which two detailed studies are cited here as examples of the substrate structural requirements other than those found in usual substrate fatty acids (33, 34).

## C. Classification According to Enzyme Commission

According to the IUBMB (35), LOX is classified as a linoleate:oxygen 13-oxidoreductase (EC 1.13.11.12). However, many LOX isozymes that have been thoroughly characterized by sequence have been shown to catalyze other oxidations, such as linoleate:oxygen 9-oxidoreductase; thus, it would appear that classification of LOX should be amended.

## **II. IMPORTANCE TO QUALITY OF FOOD**

LOX is known to have several detrimental effects in foods (see reviews: 36, 37), and these effects can be controlled by various methods of enzyme denaturation. By the process of cooxidation by free radicals, LOX activity is known to cause bleaching of carotenoids, chlorophyll (38, 39, and Refs. therein), and oxidation of ascorbic acid (40). LOX probably accounts for a large portion of pigment bleaching and loss of quality observed in unblanched frozen vegetables. In addition, products of LOX action, fatty acid hydroperoxides, are cleaved both enzymically and nonenzymically into odorous shorter-chain aldehydes, alcohols, and alkanes. The nonenzymic formation of odors is very detrimental leading to complex free radical products broadly defined as "rancidity" (see review: 41). LOX reactions can even occur in "dry" substrates at the lowest relative humidities examined (52%) (42). It was also demonstrated that LOX action in dry substrates initiated free radical autoxidation of polyunsaturated fatty acids.

Although LOX is often considered to be detrimental to foods, there are examples of positive uses. LOX has been used in replacing bromates to improve dough elasticity for bread making presumably by increasing disulfide bonds through oxidation (see review: 43). In addition, LOX bleaches carotenoid through cooxidation in doughs increasing the whiteness of bread. As discussed below, the LOX/hydroperoxide lyase sequence, also involving other enzymes such as alcohol dehydrogenase and double-bond isomerase, is important in imparting odors and flavors to fresh fruit and vegetables. These flavors are important enough to persuade Firmenich to develop an enzymic procedure for their biosynthesis (44).

## **III. ENZYMES FOUND IN RAW FOODS**

### **A. Enzymes Acting on Hydroperoxide Products of LOX**

Generally, in raw foods LOX often operates in concert with other enzymes by sequential reactions. In plants, some of the cytochrome P450 enzymes, usually membrane bound, are of considerable importance to food quality. Each raw food has its unique blend of hydroperoxide-utilizing enzymes. One of the most important of these enzymes is hydroperoxide lyase, which has been cloned, sequenced, and identified as a cytochrome P450 (CYP74B) (45). Hydroperoxide lyase cleaves 13-hydroperoxides of 18:2 and 18:3 fatty acids into C-6

aldehydes and a C-12 oxoacid, the former giving rancid-green (hexanal) and grassy (3Z-hexenal) odors. 9-Hydroperoxides cleaves into C-9 aldehydes (cucumber-like odors) and C-9 oxoacid (see review: 46). The aldehydes are then subject to further transformation by enzymes, such as reduction to alcohols. The alcohols, which generally have similar odor profiles as the aldehydes, can also be transformed into other flavor volatiles, such as the intense apple flavor hexyl acetate. The 3(Z)-alkenals produced by hydroperoxide lyase are susceptible to transformation by isomerase into 2(E)-alkenals (47) or oxidation to 4-hydroperoxy-2(E)-alkenals by LOX itself and possibly other enzymes (32). Most of the volatile aldehydes and alcohols are considered very desirable fresh vegetable odors, and contrast with the complex mixture of odors obtained by the free radical process of rancidity development. However, in soybean hexanal is considered to be an off-flavor, and, as described below, mutants have been developed to eliminate LOX isozymes from the seed. Also, it has been reported that a LOX/hydroperoxide lyase sequence is responsible for the odor of fresh fish (48).

In the multistep biosynthesis of an important jasmine odor, methyl 7-iso-jasmonate (49), the enzyme allene oxide synthase catalyzes the inaugural step of 12-oxo-10,15-phytodienoic acid formation from 13-hydroperoxide of linolenic acid. It is of interest to note that methyl jasmonate, the racemate of methyl 7-iso-jasmonate, is odorless (49). Allene oxide synthase, a cytochrome P450 designated as CYP74A (50), has been cloned and sequenced from a number of sources (e.g., 50). When allene oxide synthase is active, it also has the practical function of removing rancidity-causing hydroperoxide fatty acids from foods.

Another plant hemoprotein, hydroperoxide peroxygenase (not yet sequenced), utilizes one of the hydroperoxide oxygens to epoxidize a double bond intra- or intermolecularly, and in the process the hydroperoxide itself is reduced to a hydroxide (51). Hydrolysis of the epoxide by epoxide hydrolase furnishes the corresponding diol. The resulting hydroxyl/dihydroxy/trihydroxy fatty acids have been implicated in imparting bitter tastes to certain foods (52). Other hydroperoxide-metabolizing enzymes, like divinyl ether synthase (53 and Refs. therein), have little known effects on foods.

### **B. Location of LOXs**

In plants LOXs are found in all tissues with a few exceptions. For example, soybean mutants have been

found devoid of all three LOX isozymes normally found in the seed (54), but it is likely that the absence of LOX in these mutants is only seed specific.

LOX is generally regarded as a soluble enzyme located in the cytoplasm, but recent research demonstrated a far more complex organization. Using techniques such as immunolocalization, LOX isozymes in soybean seed are generally found in the cytoplasm around the protein bodies of storage parenchyma, but LOX is also associated with aberrant protein bodies in the hypodermis and vascular bundle sheaths (55, 56). In soybean leaves, LOX isozymes also function as vegetative storage proteins being regulated by source-sink status. These isozymes differentially locate in vacuoles, in the cytosol of paravienal mesophyll and in the bundle sheath along with other storage proteins (57). Also, organ-specific expression of LOX isozymes has been observed, such as that found in potato (58).

It seems certain that membrane-associated LOXs are important. Although there are a number of reports showing LOX to be associated with microsomes and plasma membranes, there is little evidence to show specific targeting to these membranes; that is, such associations may be nonspecific binding. Numerous reports of the localization of LOXs in chloroplasts of a variety of plants (e.g., 59) have been authenticated in some cases by showing the presence of a chloroplast transit peptide (60, 61). Chloroplast LOXs have been reported to be induced by wounding, pathogenesis, and methyl jasmonate. LOX's presence in chloroplasts presumably functions to initiate a cascade of reactions through chloroplast-bound hydroperoxide-utilizing enzymes (62). There are several reports of a specific LOX being localized in lipid bodies (e.g., 63), and this type of LOX has been reported to preferentially metabolize esterified fatty acids (64).

## IV. PROPERTIES AS PROTEIN

### A. Protein Structure

Except for some LOXs from fungi, all are nonheme iron enzymes ranging in size from ~90 to 100 kDa. Soybean seed LOX-1, with a molecular weight of 94 kDa, serves as a model for several reasons, not the least of which are its abundance and priority of isolation in crystalline form (65). LOX-1 has been cloned and sequenced (66). As shown in Figure 3, the three-dimensional structure has been determined by x-ray crystallography (67). Numerous LOXs from plants and animals have now been cloned and sequenced, affording a pairwise sequence identity between plant

and mammalian LOXs of 21–27%, among plants of 43–86%, and among mammals of 39–93% (68).

Coral LOX, which catalyzes an unusual 8R-specific oxidation of arachidonic acid, warrants special mention as it exists as a fusion protein with allene oxide synthase (69). The allene oxide synthase portion of the protein is not a cytochrome P450, like that found in plants, but it shares homology with catalase.

### B. Isozymes

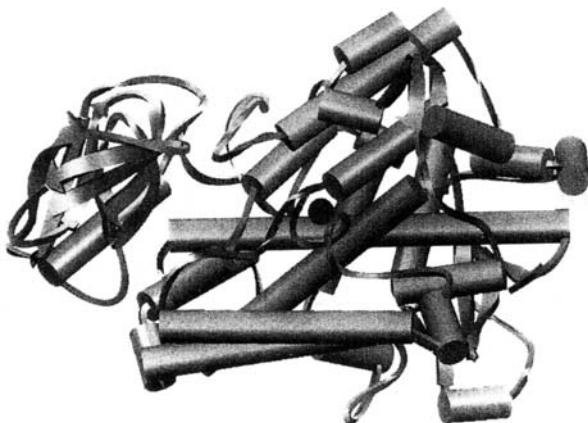

Known LOX isozymes are too numerous to review here. However, soybean can serve as an example. As discussed above, soybean seeds normally have three isozymes—LOX-1, -2, and -3 (54, 70). The process of germination gave expression of an additional three isozymes in seedlings, LOX-4, -5, and -6 (70). Multiple nonseed LOX isozymes have been identified in the soybean leaves (71). Ten isozymes of the soybean plant have now been identified (see review: 4).

Posttranslational modification of soybean seed isozymes has been studied. It has been shown that LOX-1 underwent transformation with incubation at room temperature to furnish five separable forms with different specific activity (72). Cleavage of LOX-1 and -3 by trypsin or chymotrypsin afforded two domains ~60 and 40 kDa without inactivation (73 and Refs. therein). The two domains were tightly associated, because the separated fragments did not possess activity (74).

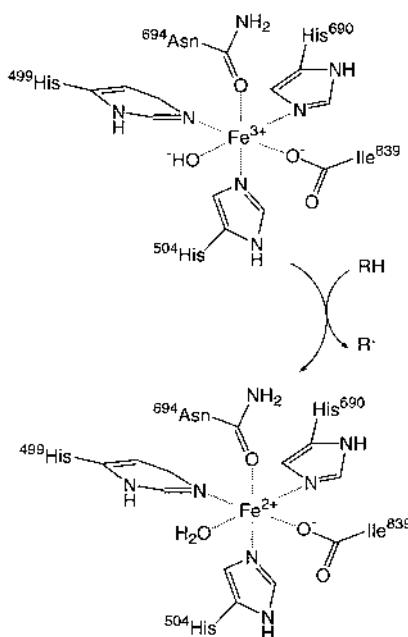

## V. PROPERTIES AS ENZYME

### A. Specific Mechanism of Action

As shown by Figure 2, the mechanism of action is an iron-catalyzed one-electron redox cycle that causes free radical oxidation of polyunsaturated fatty acids. X-ray crystallography revealed many clues of the details of catalysis. Not obvious in the structural depiction of the LOX protein shown in Figure 3 is a conical hydrophobic cavity, or tunnel, that connects the bottom of the enzyme with the iron active site, which is believed to be a path for O<sub>2</sub>. A substrate channel was identified by a long, narrow hydrophobic cavity with two bends lying to the right of the iron (75). As discussed above, the iron active site serves to cycle electrons. Iron is complexed by three histidines and one isoleucine. Higher-resolution x-ray crystallographic analysis showed that iron was additionally liganded with one water and weakly with asparagine<sup>694</sup> (76), making a total of six coordinates (Fig. 4). It has been proposed that the

**Figure 3** The three-dimensional structure of soybean lipoxigenase-1 determined by x-ray crystallography. The iron active site is shown as a sphere,  $\alpha$ -helices by cylinders, strands in  $\beta$ -sheets by arrows, and coils by narrow rods. (From Ref. 75.)

**Figure 4** The six-coordinate ligands of the iron active site of soybean LOX-1 showing five amino acids with their numbered positions in the sequence; the sixth ligand ( $\text{H}_2\text{O}$ ) is thought to abstract hydrogen from substrate ( $\text{OH}^-$  to  $\text{H}_2\text{O}$  transition) as shown. The position of the three histidines and isoleucine was determined by x-ray crystallography (67), and high-resolution x-ray analysis showed the presence of  $\text{H}_2\text{O}$  and asparagine as ligands (76). The  $\text{OH}^-$  to  $\text{H}_2\text{O}$  transition has been proposed by a number of investigators (e.g., see 15).

water ligand exists as a hydroxyl anion/water transition that accepts hydrogen from the substrate (see review: 15). Asparagine<sup>694</sup> (or its equivalent in sequential position) is mostly conserved in various LOXs, but not completely (15); replacement by histidine, as observed in certain LOXs of mammalian origin, reduced  $k_{\text{cat}}$  significantly (77).

### B. Kinetics, $K_m$ , $k_{\text{cat}}$ , Activation Energy

A number of factors must be considered prior to determining LOX kinetics. Kinetics should be determined below the critical micelle concentration (CMC), which is dependent principally on the pH, and the presence of other hydrophobic substances, including surfactants. The CMC for linoleic acid has been reported for Na borate buffer (0.1 M) at 167, 60, and 21  $\mu\text{M}$  at pH 10, 9, and 8, respectively (78).  $\text{Ca}^{2+}$  has been reported as a cofactor of LOX, but this ion is ineffective below the CMC, indicating that it affects CMC by calcium salt formation (79). However,  $\text{Ca}^{2+}$  may not be completely without effect in vivo. It has been recently reported that  $\text{Ca}^{2+}$  stimulated the membrane binding of soybean LOX-1, implying a regulatory mechanism for  $\text{Ca}^{2+}$  (80).

An initial lag in the kinetics of LOX must also be considered. The lag can be overcome simply by adding a small quantity of product hydroperoxide (81). This can be interpreted as an initial oxidation of native  $\text{Fe}^{2+}$ -LOX by hydroperoxide product to give  $\text{Fe}^{3+}$ -LOX to prime the catalytic cycle, but detailed kinetic analysis suggested a somewhat more complex interpretation (23).

The turnover rate,  $k_{\text{cat}}$ , and  $K_m$  for soybean LOX-1 with linoleic acid substrate has been variously reported at  $280\text{--}350 \text{ sec}^{-1}$  and  $12\text{--}25 \mu\text{M}$ , respectively (15, 81, and Refs. therein).

The activation energy ( $E_a$ ) for soybean LOX-1 and linoleic acid was determined to be 22 kcal/mol, and  $\Delta H^\ddagger = 21 \text{ kcal/mol}$ ,  $\Delta S^\ddagger = 20 \text{ e.u.}$ , and  $\Delta G^\ddagger \simeq 15 \text{ kcal/mol}$  (82, 83).

A kinetic scheme has been developed (23 and Refs. therein) and was recently modified by Solomon et al. (15) to account for recent findings of the active site. Figure 2 essentially illustrates this scheme modified to clearly show the aerobic and  $\text{O}_2$ -starved aspects of the active site redox cycle, as well as the products obtained.

### C. Effect of pH, Inhibitors, and Surfactants

Soybean LOX-1 is generally stable over a wide range of pHs. Its activity is optimum between pH 9 and 10.

Activity is negligible at pH 6.5, but it is stable at pHs as low as 4.5. Adjustment to pH 4.5 has been used with crude preparations to remove unwanted protein in LOX purification (84). However, pH 3.0 and below causes irreversible inactivation of soybean LOX activity (85).

Although many inhibitors of LOX have been investigated, only representative examples can be cited here. First, it should be emphasized that soybean LOX catalyzes its own destruction during oxidation of substrate. The destruction is greater with substrates of a higher degree of unsaturation (86). Several types of inhibitors mainly can be categorized as follows (for citations also see 86 and Refs. therein): (a) substrate suicide inhibitors, such as acetylenic fatty acids (irreversible) (87); (b) chain-breaking antioxidants (usually competitive and reversible) (88); (c) iron chelators (often reversible) (89); (d) disrupters of the active site (90); (e) reductants of the active-site iron (91); (f) free radical reactions with LOX, such as with hydroxyl radicals produced from H<sub>2</sub>O<sub>2</sub> (presumably irreversible) (92); and (g) substrate mimics (usually competitive) (93). In regard to substrate mimics, such as various fatty acids, potential errors are possible because of their disruption of CMC stability (94). That is, some fatty acids actually may not be inhibitors, and exert their effect by changing the CMC of the substrate.

Nonionic surfactants, such as Tween 20 and Triton X-100, are often used by researchers to clarify substrate solutions. However, it has been found that surfactants actually decrease activity, except when concentrations of substrate and surfactant are high and low, respectively (95). Kinetic data suggested that surfactant sequestered substrate in micelles, whereas the actual substrate was indicated to be solvated monomers. That is, substrate could be oxidized only after escaping micelles in equilibrium with the aqueous phase. The rate increase at high substrate and low surfactant concentrations was interpreted as alleviating substrate inhibition by sequestering substrate in micelles. Besides surfactants, ethanol or methanol is often used to conveniently disperse fatty acid substrates, but alcohols also inhibited the activity of LOX, increased the K<sub>m</sub> and decreased the V<sub>max</sub> (96). The alcohol effect was found to be reversible.

#### D. Control Methods in Foods

Heat is a simple, commonly used method to inactivate enzymes, including LOX. The inactivation rate constant of soybean LOX activity at 65°C was found to be  $8 \times 10^{-4} \text{ sec}^{-1}$  at pH 5–7 (97). Greater inactivation

efficiencies are obtained with combinations of heat and other treatments, such as ionizing irradiation (97), alcohol (96), sonication (98), and pressure (99). As discussed above, low pH alone inactivates LOX (85), but pH also plays a role in inactivation by heat (97) and combined treatments (98, 99).

### VI. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

#### A. Class Action with Assay Conditions

Axelrod et al. (84) outlined spectrophotometric methods for assaying all three soybean seed isozymes. For assay of LOX-1, the cuvette contains 2.975 mL of 0.2 M Na borate buffer, pH 9, containing LOX-1, and then 25 μL substrate solution is added, stirred and monitored at 234 nm at 25°C. The substrate solution was Na linoleate (10 mM) containing a weight of Tween 20 equal to the weight of linoleic acid used; final concentration of Na linoleate in the reaction was 0.083 mM. The rate is the straight-line portion observed after the initial lag period. Activity is defined in units ( $\mu\text{mol}$  of product formed/min). Specific activity is defined as units/mg or  $\mu\text{g}$  protein. The  $\mu\text{mol}$  of product is calculated from the molar extinction coefficient of the conjugated hydroperoxydiene measured at 234 nm. Like most investigators, Axelrod et al. (84) used a molar extinction coefficient of 25,000 M<sup>-1</sup> cm<sup>-1</sup>, but this value is probably too low. Our lab uses a higher value of 26,800 M<sup>-1</sup> cm<sup>-1</sup> (6).

Several comments should be made regarding the spectrophotometric method. The method is very satisfactory for highly purified LOXs with high pH optima. However, assay of crude enzyme preparations by this method is hazardous because protein and other UV-absorbing materials may absorb all or most of the light at 234 nm, and hydroperoxide-utilizing enzymes, if present, generally destroy the conjugated diene chromophore as it is being formed. Also, when LOX concentrations are extremely high, the absorbance could increase to a maximum before the assay could be started; this could mislead the investigator to the false conclusion that no LOX activity is present. Third, inhibitory surfactants are included to clarify the solutions to avoid scatter of UV light. In our laboratory we have found that pHs below 7.5 result in artifactual absorbance changes due to imperceptible changes in micelles, even in the presence of surfactant. For these reasons, the use of O<sub>2</sub>-electrode measurement of O<sub>2</sub> uptake can be a reliable and sensitive method to assay LOX activity. The method described

**Table 1** Purification of LOX-1 from 200 g Defatted Soybean Meal

Purification step	Volume (mL)	Protein (mg)	Total activity (units) <sup>a</sup>	Specific activity (units/mg)	Fold purification
Crude extract (0.2 M Na acetate, pH 4.5)	1,160	20,800	95,900	4.72	1 <sup>b</sup>
(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> (0.3–0.6 saturation, pH 6.8)	170	3,424	73,400	21.4	4.5
DEAE-Sephadex chromatography	172	229	24,900	101	21
Rechromatography on DEAE-Sephadex	106	81	14,600	180	38

<sup>a</sup> A unit is defined as 1 μmol product formed/min.

<sup>b</sup> The first step of extraction at pH 4.5 gave some purification from unwanted protein that would normally be extracted at higher pH. This inherent purification is not reflected in the fold purification of "1."

Source: Ref. 84.

above can be utilized, except the substrate is linoleic acid dissolved in a minimum of methanol to aid dispersal. This avoids the use of inhibitory surfactants, but alcohols are also inhibitory at high concentrations (96). Methanol can be kept to a minimum to give negligible inhibition (e.g., 2–5 μL substrate dissolved in methanol injected into 2.5 mL buffered enzyme solution).

### B. Assays for Screening Purposes

In instances where seed or other material is being screened for absence or presence of LOX activity, there is need for rapid assay methods. A number of colorimetric tests have been developed that rely on the detection of either hydroperoxides or free radical cooxidation reactions (100–103). Researchers have also developed a continuous-flow amperometric detection of hydroperoxides to assay LOX activity (104).

## VII. PURIFICATION

The method of Axelrod et al. (84) has been used successfully by our laboratory to isolate large quantities of soybean LOX-1. The method employs preparation of a crude extract from hexane-defatted soybean flour with 0.2 M Na acetate buffer (pH 4.5), followed by (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> fractionation and then two sequential chromatographic separations on DEAE-Sephadex (Table 1). The isolate can be stored as a concentrated suspension in 2.3 M (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> at 4°C (refrigerator) for many years. The authors (84) also outlined procedures for the isolation of LOX-2 and LOX-3.

A more recent method chromatographically separated all six isozymes found in soybean seedlings (70). Seedlings were homogenized in 50 mM Na phosphate (pH 6.8) containing 1.5% Triton X-100. The

Triton X-100 was removed from the supernatant after centrifugation with Amberlite XDA-2. An initial purification was achieved by a DEAE-Toyopearl column, and final separation was accomplished with Mono Q. One isozyme that did not bind to DEAE-Toyopearl required a different purification with CM-Toyopearl and Mono S columns.

With the advent of cDNA technology, LOX is increasingly purified from *E. coli*; however, it has been found necessary to cultivate *E. coli* at low temperatures in order to obtain active LOX (105, 106).

## Sorbitol Oxidase

Kohei Oda and Kazumi Hiraga

*Kyoto Institute of Technology, Kyoto, Japan*

### I. INTRODUCTION

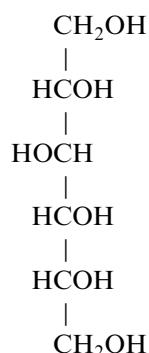

Various pathways for the use of sorbitol have been described. Sorbitol dehydrogenase (SDH; EC 1.1.1.14) is an enzyme of the polyol pathway in a wide variety of species (Fig. 1) (1-3). SDH acts on polyols such as D-sorbitol and D-xylitol but has no activity toward primary alcohols. SDH catalyzes the oxidation of D-sorbitol to form D-fructose with NAD<sup>+</sup> as a cofactor.

In the course of screening for glycerol oxidase-producing microorganisms, we found an enzyme that oxidized D-sorbitol in the cell-free extract of a strain isolated from soil. The enzyme is capable of oxidizing D-sorbitol to produce hydrogen peroxide and glucose without the requirement of exogenous cofactors such as NAD<sup>+</sup>, NADP<sup>+</sup>, and FAD. Apparently, this type of sorbitol-oxidizing enzyme has a different reaction mechanism from the SDHs described above. Hence, according to the reaction mechanism, we named the enzyme "sorbitol oxidase" (EC 1.1.3.-) (SOX). This enzyme contains covalently bound FAD. Moreover, when D-sorbitol is used as a substrate, the SOX does not act on the reaction product, glucose. These properties of the SOX will provide a precise and routine determination of D-sorbitol concentration even in a crude sample and may be suitable for technical applications (4).

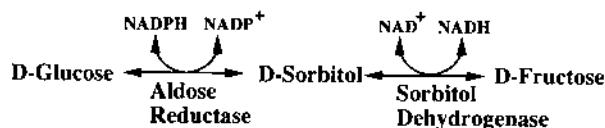

The expression level of SOX in *Streptomyces* sp. H-7775 was very low (10 units/L culture). To obtain a large amount of SOX from H-7775, we cloned the

SOX gene and succeeded in expression of the recombinant SOX with covalently bound FAD in *E. coli* with total activity about 240-fold higher than that of *Streptomyces* sp. H-7775 (5).

Sorbitol oxidase (SOX) from *Streptomyces* sp. H-7775 converts D-sorbitol to glucose in the absence of exogenous cofactors, and the other reaction product is hydrogen peroxide. SOX catalyzes the following reaction (4).

Based on the chemical reaction catalyzed by SOX as described above, SOX is classified in a subclass of oxidoreductases (subclass 1), within six main types of enzymes. SOX can act on the CH-OH group of donors (subclass 1.1). This can be further classified in a subclass according to the acceptor, which is an

**Figure 1** The polyol pathway.

oxygen. According to "Enzyme Nomenclature" (6), SOX from *Streptomyces* sp. H-7775 is classified as EC 1.1.3-.

## II. IMPORTANCE TO QUALITY OF FOOD DURING GROWTH, MATURATION, STORAGE, AND PROCESSING

Applications of SOX from *Streptomyces* sp. H-7775 to quality of food during growth, maturation, storage, and processing have not been investigated. The regulation of the metabolism and transport of sorbitol in fruit may have an important influence on the accumulation of photosynthates in fruit, and consequently on their yield and quality (7–9). Sorbitol-oxidizing activity was detected in apple leaves (10).

## III. RAW FOODS IN WHICH ENZYMES ARE FOUND

SOX from *Streptomyces* sp. H-7775 is localized in mycelia. The subcellular location of SOX was determined semiquantitatively in the cell-free extract, cell debris, and culture supernatant after disruption of the mycelia by ultrasonication using the method described in Section VIII. SOX activity was detected only in the cell-free extract.

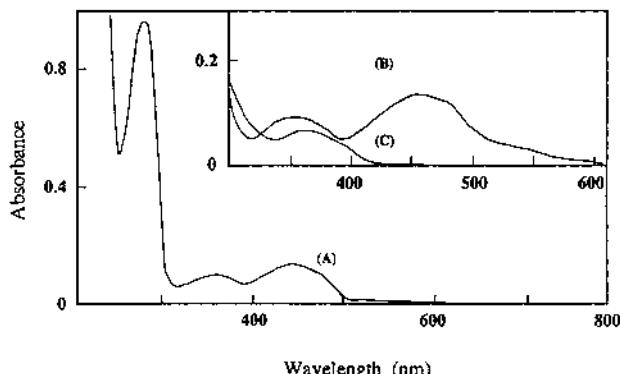

## IV. UTILITY/UTILIZATION OF ENZYMES IN FOODS (INCLUDING EXOGENOUS APPLICATION)

SOX from *Streptomyces* sp. H-7775 may be used for determination of D-sorbitol and D-xylitol concentration added as additives in foods. As SOX contains covalently bound FAD, the enzyme activity is not influenced by exogenous cofactors such as NAD<sup>+</sup>, NADP<sup>+</sup>, or FAD<sup>+</sup> in food.

## V. PROPERTIES AS PROTEIN

The molecular weight of SOX purified from the cell-free extract is 45,000 daltons. The prosthetic group is a covalently bound FAD. The absorption spectrum of SOX purified from *Streptomyces* sp. H-7775 has a typical flavoprotein spectrum with the absorption maxima at 276, 358, and 455 nm and a shoulder at ~480 nm (Fig. 2A,B). A hypsochromic shift of the second absorption band to 358 nm relative to that of riboflavin at 372 nm has also been observed. The spectrum is similar to those of flavoproteins with covalently bound flavin (11–14). With the addition of D-sorbitol, the peaks at 358 nm and 455 nm decrease owing to the reduction of flavin (Fig. 2C). This indicates that the flavin component is functionally involved in the oxidation of D-sorbitol. The fluorescence intensity of the purified SOX is pH dependent and is similar to that of FAD as in the case for choline oxidase, but different from that of FMN and riboflavin (14). The flavin prosthetic group could not be liberated from the purified SOX protein by (a) acidification with 5% trichloroacetic acid, (b) boiling for 5 min, (c) treatment with 1% SDS, or (d) dialysis against 3 M KBr in 1 mM EDTA for 2 days at 4°C (15). It was calculated that 0.9 mol of FAD is bound to 1 mol of SOX, assuming the molecular absorption coefficient for FAD at 460 nm to be 11,300 M<sup>-1</sup>cm<sup>-1</sup> (16).

Recombinant SOX has been expressed in *E. coli* and purified. The SOX was homogeneous by SDS-PAGE showing a strong yellowish fluorescence under UV light ( $\lambda = 265$  nm) and acidic condition. The failure

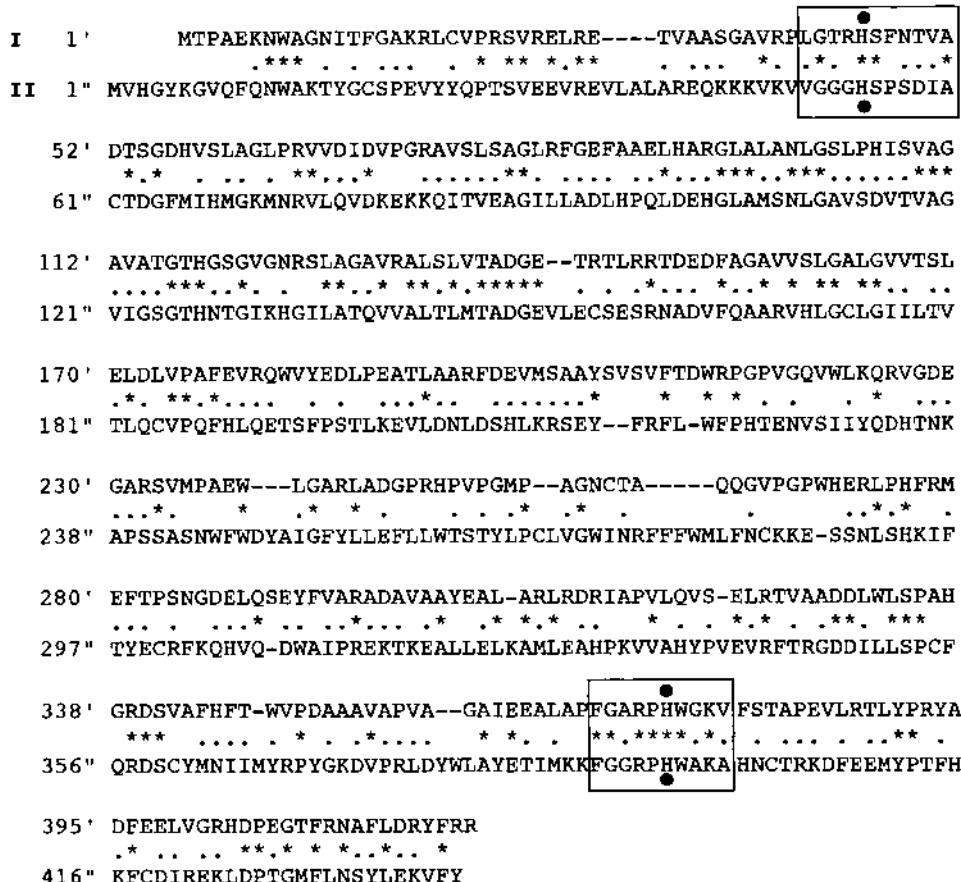

**Figure 2** Absorption spectra of purified SOX. Absorption spectrum of purified SOX (A) in 20 mM potassium phosphate buffer, pH 6.0, at the final concentration of 0.64 mg/mL. The insert shows the enlarged spectrum before (B) and after (C) addition of 50 mM D-sorbitol.

to dissociate the cofactor by the same methods described above has led to the conclusion that FAD is covalently bound to the SOX even when it is expressed in *E. coli* (5).

The molecular weight of SOX from *Streptomyces* sp. H-7775 was estimated to be 45,000 daltons by both SDS-PAGE and Sephadex G-75 column chromatography. This has the same value of the molecular weight of the purified recombinant SOX expressed in *E. coli*.

The SOX gene from *Streptomyces* sp. H-7775 was cloned and sequenced (accession number for GenBank, EMBL, and DDBJ Nucleotide Sequence Database is AB000519). It consists of an open reading frame of 1260 bp encoding a protein of 420 amino acids with a molecular weight of 45,148 daltons (5). This value is in good agreement with that of an authentic SOX purified from *Streptomyces* sp. H-7775.

The deduced amino acid sequence of the SOX gene has 25.3% identity and 68.1% similarity to that of rat L-gulonolactone oxidase (EC 1.1.3.8) (10) (Fig. 3). SOX does not oxidize L-gulonolactone. One of the features of rat L-gulonolactone oxidase is that the enzyme contains a FAD covalently bound to histidine (18, 19) and has no nucleotide-binding motif (-G-x-G-x-x-G-) often found at the amino terminal region in a number of dehydrogenases (20-26). *Streptomyces* SOX also contains no nucleotide-binding motif. The cofactor that may be involved in the SOX is covalently bound FAD. Until now, five types of covalently bound flavins are known: 8- $\alpha$ -[N(1)-histidyl]-FAD, 8- $\alpha$ -[N(3)-histidyl]-FAD, 8- $\alpha$ -S-cysteinyl-FAD, 6-S-cysteinyl-FMN, and 8- $\alpha$ -O-tyrosyl-FAD (27). Thus, His, Cys, and Tyr residues are suggested to constitute the site for the covalently bound FAD. The SOX molecule

**Figure 3** Comparison of the deduced amino acid sequence of SOX with that of the rat L-gulonolactone oxidase. The deduced amino acid sequence of the SOX gene (upper, I) is compared with that of rat L-gulonolactone oxidase (lower, II). Asterisks and dots indicate identical and related amino acids, respectively. Closed circles indicate the histidine residue that is possible for covalent attachment of FAD.

has 12 His, two Cys, and seven Tyr residues. The similarity between the SOX and rat L-gulonolactone oxidase shows that the similarities are mainly found around His residues (His45 and -374). These His residues occupy similar positions in the alignment as marked by a closed circle in Fig. 3. The His residue that has been suggested to be responsible for covalent attachment of FAD of the rat L-gulonolactone oxidase and mitomycin C resistance protein is located at the N-terminal region according to the sequence similarity (28). However, in the case of SOX, amino acid residues around His374 located at the C-terminal showed higher similarity than those of His45 located at the N terminal. Comparison of the amino acid sequences around Cys and Tyr residues between SOX and rat L-gulonolactone oxidase shows no possible site contributing to the binding of flavin. Moreover, Cys- and Tyr-binding regions of other flavoproteins have no sequence similarity to SOX (29, 30). From these results, it is suggested that the His374 is responsible for the binding of FAD.

There are no isoforms of SOX from different genes. There are no data about the possible formation of isozymes from posttranslational modification.

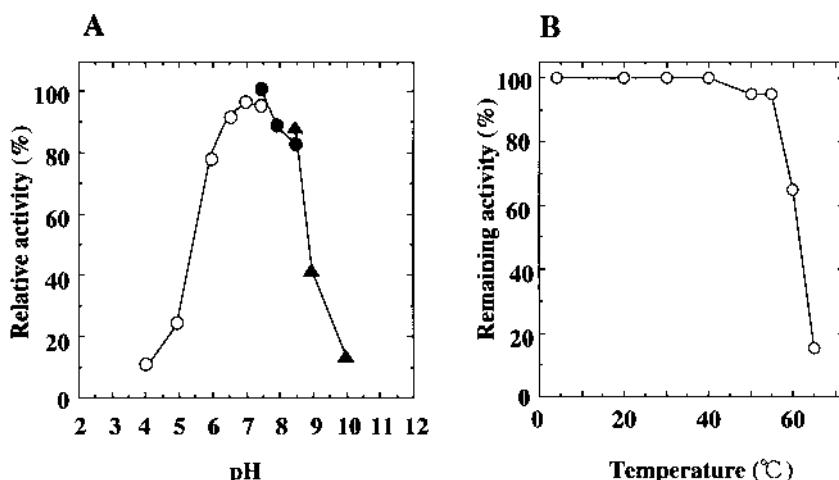

## VI. PROPERTIES AS ENZYME

Substrate specificity of SOX from *Streptomyces* sp. H-7775 is summarized in Table 1. D-Sorbitol and D-xylitol

were oxidized most rapidly. D-Xylitol, D-mannitol, and D-arabitol were oxidized at a rate of 93.5%, 55%, and 39%, respectively, of that for D-sorbitol. Glycerol, 1,3-propanediol, 1,3-butanediol, and 1,4-butanediol were oxidized at low rates, while D-glyceraldehyde, the dihydroxyacetone, methanol, ethanol, 1-propanol, and 1-butanol were not attacked at all at various substrate concentrations from 1 to 100 mM (Table 1). SOX did not react with glucose, a reaction product of D-sorbitol.

Enzyme characteristics of SOX are summarized in Table 2. Optimum pH is between 6.5 and 7.5 (Fig. 4A) Optimum temperature is 50°C in 10 min incubation at pH 7.5. SOX is stable below 55°C in 15 min incubation at pH 7.5 (Fig. 4B). The enzyme activity is completely lost after incubation for 15 min at pH 7.5 at 80°C. SOX is stable between pH 7.5 and 10.0 after 24 h incubation at 30°C. The enzyme activity is inhibited by 1 mM moniodoacetate (IAA) and 1 mM *N*-ethylmaleimide (NEM) by 53.8% and 54.8%, respectively. The enzyme activity is inhibited by 1 mM of Zn<sup>2+</sup> and Hg<sup>2+</sup> by 96.8 and 90.7%, respectively (Table 2).

Sugar alcohols that have the *R* configuration on C3, such as D-sorbitol, D-xylitol, D-mannitol (C2 epimer of D-sorbitol), and D-arabitol (C4 epimer of D-xylitol), are good substrates of SOX. However, ribitol (C3 epimer of D-xylitol) and D-threitol, which have *S* configuration at C3 are poor substrates of SOX. The results suggest that the stereochemical requirement at position C3 of sugar alcohol is important for SOX activity.

**Figure 4** Optimum pH (A) and heat stability (B) of SOX. (A) SOX activity was measured at various pHs for 10 min at 37°C. Buffers used were 40 mM citrate-Na<sub>2</sub>HPO<sub>4</sub> (pH 4.0–7.5, open circles), 40 mM Tris-HCl (pH 7.5–8.5, closed circles), 40 mM glycine-NaOH (pH 8.5–10.0, open triangles). (B) SOX was incubated at various temperatures for 15 min in 40 mM Tris-HCl buffer, pH 7.5, and the remaining activity was measured at 37°C.

**Table 1** Substrate Specificity of Sorbitol Oxidase<sup>a</sup>

Compound	Relative activity (%)		Compound	Relative activity (%)
D-Sorbitol	100	( $K_m$ 0.26 mM)	D-Fructose	0

<sup>a</sup> Relative activity, %.<sup>b</sup> Inhibition, %.<sup>c</sup> Substrate; D-sorbitol.

SOX has a  $K_m$  value of 0.26 mM for D-sorbitol, 0.38 mM for D-xylitol, 7.38 mM for D-mannitol, and 7.73 mM for D-arabitol.

A SOX-like activity that converts sorbitol to glucose was reported in an apple leaf (10). The partially purified enzyme converts sorbitol to glucose in the absence of NAD<sup>+</sup> or NADP<sup>+</sup>. This enzyme is reported to catalyze the following reaction:

One of the reaction products of this enzyme is not H<sub>2</sub>O<sub>2</sub> but H<sub>2</sub>O.

## VII. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

The standard enzyme assay is based on the measurement of hydrogen peroxide generated during the oxidation of D-sorbitol. The hydrogen peroxide oxidatively couples with 4-aminoantipyrine and *N*-ethyl-*N*-(2-hydroxy-3-sulfopropyl)-3-methylaniline (TOOS) in the presence of peroxidase to form a quinoneimine dye, by the method of Allain et al. (31). The concentration of quinoneimine dye is measured spectrophotometrically at 555 nm. The reaction mixture in a final volume of 950 μL contains 150 mM KH<sub>2</sub>PO<sub>4</sub>-KOH (pH 7.0), 47.3 mM D-sorbitol, 614 μM TOOS, 158 μM 4-aminoantipyrine, 1.9 units/mL horseradish peroxidase, and a suitable amount of sorbitol oxidase. The incubation is done at 37°C for 10 min. The reaction is stopped by the addition of 2 mL of 0.5% SDS. Sorbitol oxidase activity has a linear function of both incubation time and protein concentration. One unit of the enzyme activity is defined as the amount of enzyme that catalyzes the formation of 1 μmol of H<sub>2</sub>O<sub>2</sub> per min.

SOX is useful for the determination of D-sorbitol and D-xylitol concentrations in food. D-sorbitol and

D-xylitol are used as sweetening agents. SOX may be used to quantitatively determine these sugar alcohols in foods. A histochemical approach elucidates the location of accumulated D-sorbitol (or D-xylitol) in vivo.

A microtiter plate assay is an easy and fast way for detection of D-sorbitol and D-xylitol in a large number of samples. At first, purple color is detected visually by the microtiter plate assay; a precise concentration of the sugar alcohols is determined spectrophotometrically.

In order to detect a reaction product directly, analysis by thin-layer chromatography is recommended. A silica gel plate is soaked in 30 mM borate buffer (pH 9.0) and dried at 110°C for 1 h. Then samples are spotted on the plate. The developing system consists of: first dimension with ethyl acetate-pyridine-H<sub>2</sub>O (3:3:2); and second dimension with 1-butanol-methanol-H<sub>2</sub>O (5:3:2). The chromatogram is sprayed with a color reagent, 2% (w/v) diphenyl amine:2% (v/v) aniline:15% (v/v) phosphoric acid in acetone. The plate is heated at 100°C for 10 min. Reducing sugars, such as D-glucose, are detected as a dark spot.

One millimolar Zn<sup>2+</sup> and Hg<sup>2+</sup> strongly inhibit SOX activity. One millimolar monooiodoacetate (IAA) and *N*-ethylmaleimide (NEM) also inhibit SOX activity (Table 2).

## VIII. PURIFICATION

The expression level of SOX in *Streptomyces* sp. H-7775 is very low. In contrast, we succeeded in expressing about 236-fold higher total enzyme activity in *E. coli* (production of 2360 units/L culture) (5) than that of *Streptomyces* sp. H-7775 (production of 10 units/L culture) (4). The recombinant SOX was purified as shown in Table 3; 384 mg of SOX was purified from 20 L of culture broth of *E. coli* with a yield of 37.1%. The recombinant SOX showed almost the same char-

**Table 3** Purification of Recombinant Sorbitol Oxidase from *E. coli* Harboring pUCSOX

Purification step	Total activity (units)	Total protein (mg)	Specific activity (units/mg)	Yield (%)
Cell-free extract	47,200	42,000	1.1	100
Heat treatment	42,500	8,400	5.1	90.0
Q-Sepharose Big Beads	40,000	3,000	13.3	84.7
Phenyl Sepharose Fast Flow	22,000	1,200	18.3	46.6
Sephadex G-25	21,500	1,100	19.5	45.6
Q-Sepharose HP	18,000	400	45.0	38.1
Sephadex G-25	17,500	384	45.6	37.1

acteristics as those of the authentic SOX from *Streptomyces* sp. H-7775 (5). We describe below a method for the purification of recombinant SOX from *E. coli*. A method for purification of SOX from *Streptomyces* sp. H-7775 is also described in Hiraga et al. (4).

#### A. A Proven Method Leading to Purity

When SOX was expressed in *E. coli*, SOX activity was detected in the supernatant of a bacterial sonicate, but not in the insoluble fraction or in the culture supernatant. This suggests that SOX is localized in the cytosol or periplasmic space. In the case of *Streptomyces* sp. H-7775, SOX is localized in mycelia.

##### Step 1. Preparation of Cell-Free Extract

*E. coli* [pUCSOX] cells from 20 L of culture broth are washed with distilled water and resuspended in 4 L of 10 mM Tris-HCl, pH 7.0 (Buffer A). After the addition of 0.1% lysozyme and 20 mM EDTA, the cell suspension is incubated at 37°C for 30 min. The cell debris is removed by centrifugation at 15,000g for 15 min at 4°C.

##### Step 2. Heat Treatment

The cell-free extract from Step 1 is heated at 50°C for 1 h, and centrifuged at 15,000g for 15 min at 4°C.

##### Step 3. Q-Sepharose Big Beads Column Chromatography

The heated cell-free extract is applied onto a Q-Sepharose CL-6B Big Beads column (10 × 20 cm) equilibrated with Buffer A. The column is washed with the same buffer. The sorbitol oxidase is eluted with a linear 0–0.5 M NaCl gradient in buffer A. SOX fractions are pooled and dialyzed against Buffer A at 4°C.

##### Step 4. Phenyl Sepharose FF Column Chromatography

The SOX fraction obtained from Step 3 was put on a Phenyl Sepharose FF column (5 × 20 cm) equilibrated with Buffer A. The column was washed with the same buffer. SOX was eluted with a linear 0–1.0 M NaCl gradient in Buffer A and eluate was collected in fractions.

#### Step 5. Sephadex G-25 Column Chromatography

SOX fractions obtained at Step 4 are applied onto a Sepharose G-25 column (2 × 20 cm) equilibrated with Buffer A and eluted with the same buffer. SOX fractions are pooled and dialyzed against Buffer A overnight at 4°C.

#### Step 6. Q-Sepharose HP Column Chromatography

The enzyme solution is then loaded on a Q-Sepharose HP column (2.6 × 30 cm) equilibrated with Buffer A and eluted with a linear 0–1.0 M NaCl gradient. Active fractions are pooled.

#### Step 7. Sephadex G-25 column Chromatography

The enzyme solution is then put on a Sepharose G-25 column (2 × 20 cm) equilibrated with Buffer A and eluted with the same buffer. SOX fractions were pooled and stored at 4°C.

#### B. Stability

SOX is stable from pH 7.5 to 10.0 after 24 h incubation at 30°C. SOX is stable below 55°C after 10 min incubation at pH 7.5.

## Starch Phosphorylases

**Ying Yu**

Rutgers University, New Brunswick, New Jersey, U.S.A.

### I. INTRODUCTION

Alpha-1,4-glucan phosphorylases (EC 2.4.1.1) are widely distributed in plants and animals. Starch phosphorylase may catalyze its reversible enzymatic reaction in either a synthetic or degradative mode.

In the synthetic reaction, a glucose unit is transferred from Glc-1-P to a growing oligoglucan chain, with release of inorganic phosphate. In the degradative mode, addition of inorganic phosphate liberates a molecule of Glc-1-P. With respect to the direction of the starch phosphorylase reaction, the precise physiological function of starch phosphorylase in higher plants remains unclear, though the predominating belief is that this enzyme catalyzes the stepwise disassembly of starches and oligoglucans. Evidence for a biosynthetic role for starch phosphorylases, within the starch biosynthetic pathway, has by no means been discounted and has been the subject of much discussion (1).

The earliest studies on starch phosphorylase focused mainly on the interconversion between starch and sugars during fruit ripening and cold-sweetening phe-

This chapter is dedicated to the memory of my mentor, Professor Bruce P. Wasserman, who passed away Aug. 26, 1998.

\* Abbreviations: ADP-Glc, adenosine diphosphoglucose; AGP, adenosine diphosphoglucose pyrophosphorylase; Glc-1-P, glucose-1-phosphate; Glc-6-P, glucose-6-phosphate; *sh4*, *shunken4* mutant; *sh2*, *shunken2* mutant.

nomenon observed in stored potatoes. More recently, there has been increasing interest in the function of starch phosphorylase in plant growth and development, particularly with respect to starch deposition and degradation within a range of higher plants.

The objective of this chapter is to provide an overview of the biochemistry, molecular biology, and putative functions of starch phosphorylases in plant tissue. The first part of this chapter focuses on the importance of starch phosphorylase to cold storage of food, specifically potato, and the putative functions of this enzyme in plant growth and starch deposition. The second part will discuss the biochemical properties of starch phosphorylases and the recent information classifying the various isoforms of starch phosphorylase present in higher plants. This information is based largely on biochemical characterization studies and the analysis of the genes and gene families encoding a range of starch phosphorylase isoforms.

### II. IMPORTANCE OF STARCH PHOSPHORYLASE TO COLD STORAGE OF POTATO AND PLANT STARCH DEPOSITION

#### A. Starch Phosphorylase and the Cold-Induced Sweetening Phenomenon in Potato

Interconversions between starch and sucrose are of great interest, particularly with respect to a phenomenon referred to as cold-induced sweetening in potato.

Cold-induced sweetening generally occurs when storage temperatures are reduced from 10°C to 2°C over the course of several days. Since starch phosphorylase acts upon oligoglucans to form hexose phosphates, which are presumed precursors to sucrose, starch phosphorylase activity has been proposed as a logical catalyst for the initial process of cold-induced sweetening of potato during storage (2). However, despite numerous efforts, a direct role for starch phosphorylase in cold-induced sweetening has yet to be demonstrated. Temperature shift experiments, either from 10°C to 2°C or vice versa, were accompanied by negligible changes in starch phosphorylase activity (3). A follow-up study (2) on the dual role of glycolytic intermediates and amyloplast envelope integrity showed that visible deterioration to the double envelope was not evident until 38 days of storage at 2°C. While these studies cannot exclude a role for starch phosphorylase in the cold-induced sweetening phenomenon, the precise function of starch phosphorylase in this process remains speculative.

#### B. Putative Function in the Starch Deposition of Higher Plants

Starch phosphorylases from higher plants were initially suggested to be the primary catalysts for starch chain elongation since in the synthetic direction they catalyze the incorporation of Glc-1-P into (1,4)- $\alpha$ -glucan chains. This assumption began to be questioned when AGP was discovered and the starch-deficient maize mutant, *sh2*, was characterized (4). *Sh2* lacks the AGP large subunit and is thus unable to convert Glc-1-P into ADP-Glc. The deficient starch levels of this mutant implied that AGP was the enzyme regulating the flow of carbon into starch. This finding indicates that starch synthesis is predominantly controlled by transglucosylases rather than phosphorylases. Antisense inhibition of cytosolic starch phosphorylase in potato plants did not cause any significant changes of starch levels in leaves or tubers of the transgenic plants (5). In addition, no observable alterations of starch structure or tuber formation were found in the transgenic plants. This evidence suggested that cytosolic starch phosphorylase did not play an essential role in starch metabolism. Another antisense study was conducted on the potato leaf Pho 1-type starch phosphorylase. Determination of the leaf starch content revealed that the antisense inhibition of the leaf starch phosphorylase activity had no significant influence on starch accumulation in leaves (6). The effects of antisense suppression of Pho1-type starch

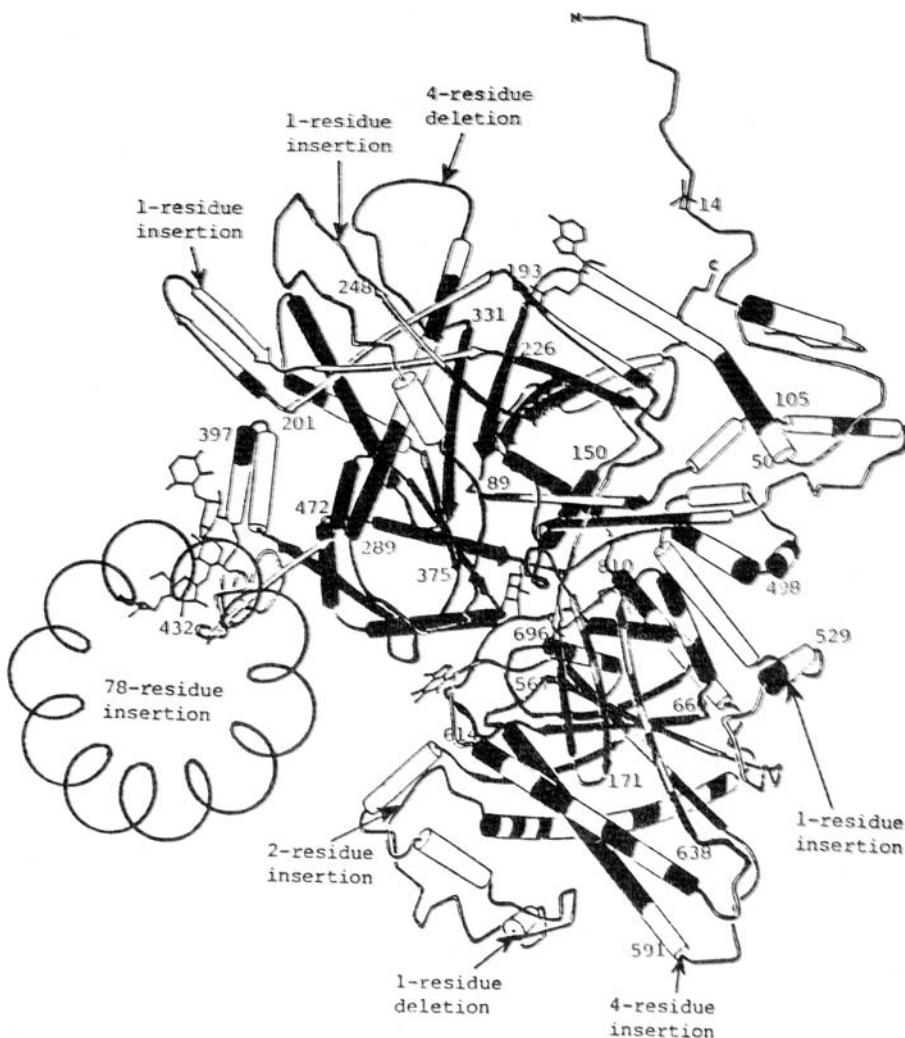

phosphorylase genes in potato tubers or maize endosperm have not yet been reported.

In chloroplasts, starch phosphorylase is regarded as a starch degradative enzyme in the diurnal starch accumulation cycle (7). However, whether starch phosphorylase plays a similar role in the amyloplasts of storage tissues has not been determined. Since amyloplasts are actively involved in starch biosynthesis, it is conceivable that Pho 1-type starch phosphorylases could play a synthetic role using Glc-1-P as substrate. This is supported by the observation that high levels of the plastidic starch phosphorylase transcript levels as well as starch phosphorylase enzyme activity present in sink tissues of spinach. Source leaves, however, contained low amounts of plastidic starch phosphorylase transcripts. In addition, the induction of starch phosphorylase expression was observed when the leaf disks were supplied with carbohydrates (8). Some primer-independent starch phosphorylase isoforms could also be involved in the initiation of starch biosynthesis by synthesis of glucan primers. Another alternative role of starch phosphorylases suggested by some scientists is the degradation of starch-derived malto-oligosaccharides (5).

### III. BIOCHEMICAL PROPERTIES OF STARCH PHOSPHORYLASE

#### A. Protein Structure

Phosphorylases from plants, animals, and prokaryotes exist as dimers or tetramers containing identical sets of subunits (9). It is generally accepted that glycogen phosphorylase from mammalian tissue participates in glycogen degradation and is subject to both allosteric regulation, and covalent modifications such as phosphorylation (10). Three-dimensional crystal structures of mammalian glycogen synthases, illustrating the coordinated interaction of subunits, have shed a great deal of light on the mechanism of action of glycogen phosphorylase with respect to glycogen mobilization in mammalian systems (11). X-ray crystallographic studies have revealed the three-dimensional crystal structures of mammalian glycogen synthases. For example, the subunit of rabbit muscle phosphorylase is composed of two domains. Each domain consists of a central  $\beta$ -sheet core surrounded by one or more layers of  $\alpha$ -helices (Fig. 1) (11, 12).

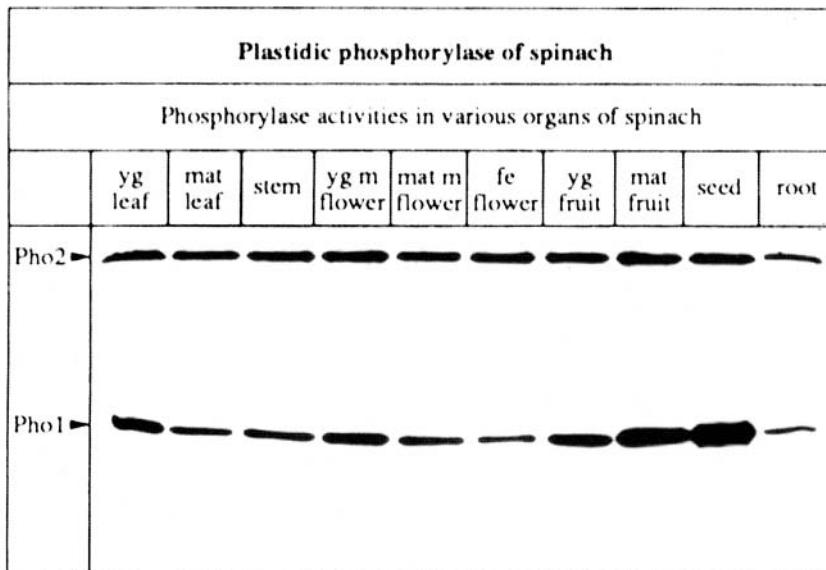

**Figure 1** X-ray crystallographic model of a mammalian glycogen synthase. The “barrel-and-arrow” schematic of rabbit muscle phosphorylase *a* was compared with potato phosphorylase. The dark areas represent the regions of strong similarity. (From Refs. 11, 12.)

## B. Starch Phosphorylase Isoforms

Higher-plant starch phosphorylases are classified into two groups based on their subcellular localization and affinity for various glucans (13). Members of each group can be readily distinguished by the use of zymograms (Fig. 2). The cytosolic class of starch phosphorylases has frequently been referred to as H-type starch phosphorylases, but more recently the term Pho2-type starch phosphorylase, based primarily upon the migration behavior on zymograms, has replaced the earlier nomenclature. In addition to their cytosolic localization, Pho2-type phosphorylases

tend to exhibit high affinity for large-highly branched glucans, such as glycogen. Pho2-type starch phosphorylases have an apparent monomer size of 90 kDa (13, 14). The second distinct starch phosphorylase group, originally classified as the L-type, but now known as the Pho1-type group represents starch phosphorylases localized in plastids such as chloroplasts and amyloplasts, and are generally characterized by a monomer size of 100 kDa. Pho1-type starch phosphorylases prefer oligoglucans such as maltodextrins.

In spinach leaf or pea seed, one form of each starch phosphorylase type is present. However, the relative

**Figure 2** Classic zymogram illustrating starch phosphorylase activities in various organs of spinach. (From Ref. 8.)

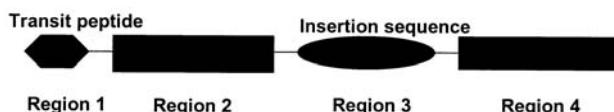

ratio of the two starch phosphorylase types varies during plant development (15, 16). During seed germination, the amount of Pho2-type starch phosphorylase is increased while Pho1-type starch phosphorylase remains at a constant, lower level. The developing seeds, however, contain much higher amounts of Pho1-type starch phosphorylase than Pho2-type starch phosphorylase.

In maize, characterization of four starch phosphorylase isoforms has been reported (17, 18). The maize endosperm is rich in starch phosphorylase activity, and starch phosphorylase expression patterns correlate closely with starch deposition (19, 20). The four isoforms differ in their pH optima, primer dependence, chromatographic properties, development expression patterns, and their localization. Isoforms I, II, and III occur mainly in the endosperm, while isoform IV is localized in the embryo. The activities of isoforms I, II, and III were each reduced in the mutant *sh4*, and their enzymatic properties such as pH optima and sensitivity to activators and inhibitors were altered (18). However, the properties of isoform IV did not seem to be affected by the *sh4* mutation (21). These studies were mainly based upon separation of isoforms by ion exchange chromatography. At that time, it was not possible to prepare antibodies or to clone cDNAs. Therefore, it is not known if these starch phosphorylase isoforms represent distinct gene products.

### C. Starch Phosphorylase Gene Classifications: Significance of the Species Specific Pho 1 Insertion Sequences

cDNA clones representing both Pho1- and Pho2-type isoforms of starch phosphorylase have been obtained from potato and several other plant species. In potato tuber, cDNA clones for one cytosolic (Pho2-type) (22) isoform and two plastidial (Pho1-type) isoforms (6, 23, 24) have been characterized. cDNAs for Pho1-type starch phosphorylases have also been obtained from sweet potato (25), broad bean (26), and spinach leaf (8). Predicted amino acid sequences are well conserved. For example, spinach Pho1-type starch phosphorylase has an overall amino acid sequence identity of 75% with potato (6, 8) and sweet potato (27) Pho1-type starch phosphorylases. The sequence of spinach Pho1-type starch phosphorylase has 62% identity with Pho2-type starch phosphorylases from potato (22) and broad bean (26).

Starch phosphorylase cDNAs are typified by four distinct regions (Fig. 3). Region 1, the transit peptide, exhibits low homology among species. Regions 2 and 4, at the N- and C-termini of the mature protein, respectively, are highly conserved. Region 3, distinguished by a 50- to 80-residue stretch of additional amino acids, is commonly referred to as an "insertion sequence." Insertion sequences are present only in Pho1-type starch phosphorylases. As with the transit

**Figure 3** Schematic diagram of cDNAs encoding the four regions of a typical Pho1-type (plastidial) starch phosphorylase. Pho2-type starch phosphorylases lack the transit peptide and insertion sequence. The remaining regions of Pho1-type starch phosphorylases retain strong amino acid sequence similarity with the Pho2-type starch phosphorylases. (From Refs. 16, 17, 35.)

peptides, the insertion sequences are widely divergent from species to species; however, some common structural features are noted (28). Each insertion sequence is highly acidic, with a calculated isoelectric point of 4.0.

The presence of a transit peptide at the N-terminus of potato Pho1-type starch phosphorylase was confirmed by the sequence analysis of the cDNA clone (24). This 50 amino acid transit peptide sequence has several structural features common to transit peptides of chloroplast proteins. This sequence is rich in hydrophilic residues. It contains seven Ser and five Thr residues, representing 14% and 10% of the total amino acid content of the transit peptide. The transit sequence also contains 13 positively charged amino acids, but no acidic residues or large hydrophobic sequences. The transit peptides are required for translocation of plastidic Pho1-type starch phosphorylases from the cytosol into the plastid.

With respect to function, the insertion sequences are hypothesized to influence the affinity of starch phosphorylase for substrate. In a benchmark study designed to test the function of an insertion sequence, a chimeric potato starch phosphorylase, lacking the 78 amino acid insertion of the Pho1-type enzyme was constructed, and an extensive kinetic analysis was conducted (28). Removal of the insertion sequence resulted in a dramatic lowering of the Michaelis constant for glycogen. The authors concluded that the insertion sequence served to sterically hinder the interaction of starch phosphorylase with highly branched substrates such as glycogen. This region is therefore thought to reflect the affinity of starch phosphorylases for glucan substrate.

#### IV. PROPERTIES OF STARCH PHOSPHORYLASES

The enzymatic properties of several starch phosphorylases have been characterized. For example, the

major starch phosphorylase of maize kernels is a homodimer with an estimated molecular weight of  $223,000 \pm 10,000$  daltons (29). Pyridoxal phosphate is a cofactor of the enzyme. The estimated pyridoxal phosphate content of the purified enzyme was 112,000 g protein/mol pyridoxal phosphate (29). The purified enzyme had a  $K_m$  value of 1.0 mM for Glc-1-P when assayed in the synthetic direction at 37°C, pH 5.8. In the phosphorolytic direction, the purified enzyme had a  $K_m$  value of 4.2 mM for Pi when assayed at 25°C, pH 6.3 (29). Magnesium ion was shown to be an inhibitor of the enzyme (29). ADP-Glc was found to be an inhibitor with respect to Glc-1-P in the synthetic reaction (29). Both Pho1- and Pho2-types of starch phosphorylases have been purified and characterized from spinach leaves (13). The subunit molecular weights of Pho1- and Pho2-types spinach leaf starch phosphorylases were calculated to be 108,000 and 92,000 daltons, respectively. Based on their native molecular weights, it was suggested that both starch phosphorylases exist in dimeric form. The optimal pH values for Pho1- versus Pho2-type enzyme were shown to be 5.7 versus 6.1 in the synthetic direction, and 6.2 versus 6.5 in the phosphorolytic direction. At pH 6.6, the  $K_m$  values of Pho1-type enzyme were determined to be 3.1 mM for Glc-1-P in the presence of 10 mg/mL soluble starch in the synthetic direction and 2.2 mM for Pi in the presence of 2 mg/mL maltopentose in the phosphorolytic direction. Under the same conditions, the  $K_m$  values of Pho2-type enzyme were 6.2 mM for Glc-1-P in the synthetic direction and 6.9 mM for Pi in the phosphorolytic direction (13).

#### V. QUANTITATIVE DETERMINATION OF STARCH PHOSPHORYLASE ACTIVITY

The activity of starch phosphorylase can be measured either in the synthetic direction or in the phosphorolytic direction. In the synthetic direction, the amount of inorganic phosphate released from Glc-1-P can be determined by a molybdate-based colorimetric assay (30, 31). Alternatively, starch phosphorylase activity can be determined by measuring the incorporation of  $^{14}\text{C}$ -labeled Glc-1-P into glucan primer (17). In the phosphorolytic direction, a continuous assay system is used (13, 14). Glc-1-P is converted to Glc-6-P by phosphoglucomutase. NADP reduction by Glc-6-P dehydrogenase can then be followed spectrophotometrically at 340 or 265 nm.

## VI. PURIFICATION OF STARCH PHOSPHORYLASES

Starch phosphorylases have been purified from a number of sources, including spinach leaf (13), potato tuber (32), and maize kernels (29). The purification of the major starch phosphorylase of maize kernels is described below (29).

Protein extracts of maize kernels harvested at 22 days after pollination were prepared by homogenization and centrifugation. The extract was brought to 40% saturation with ammonium sulfate. Following centrifugation at 16,000g for 20 min, the supernatant was brought to 50% saturation with ammonium sulfate and centrifuged again at 16,000g for 10 min. The precipitate was resuspended and dialyzed overnight. The sample was then subjected to a step known as starch absorption. The starch absorption step was adapted from the method of Kamogawa et al. (33). Waxy maize starch was solubilized in 100 mL water by autoclaving for 1 h at 1 bar (100 kPa). The solution was chilled to -2°C and 15 mL of chilled 95% ethanol was added. The precipitate was washed once with 100 mL 11% ethanol at -15°C and resuspended in 100 mL 0.1 M EDTA, pH 7.2. The protein sample was also made 11% with ethanol and centrifuged. The chilled supernatant was then added to the starch preparation which had been chilled to incipient freezing. After mixing in an ice bath for 5 min, chilled 95% ethanol was added slowly to the mixture to a final concentration of 12.5%. The resulting precipitate was washed once with 100 mL of 11% ethanol at -15°C. The precipitate was then dissolved at room temperature with 100 mL 5 mM sodium citrate buffer, pH 6.3, and applied to a DEAE-cellulose column. The protein precipitate from the fractions constituting the peak of starch phosphorylase activity was dissolved in buffer and applied onto a Sephadex G-200 column. The fractions constituting the

peak of starch phosphorylase activity were pooled and stored (Table 1) (29).

## VII. CONCLUSIONS

Starch phosphorylases from higher plants possess unique features with regard to their structures, catalytic properties, and subcellular localization patterns. Structurally, the phosphorylases have been classified into distinct groups based on zymograms that accurately pinpoint subcellular localization of the major isoforms. Deduced amino acid sequences show sequence conservation among a host of species. Genes corresponding to cytosolic and plastidial phosphorylase isoforms have been appropriately classified, and expression levels for transcript levels and tissue distribution have been carefully quantified. A more precise role for the insertion sequences located in the Pho2-type phosphorylases remain to be determined.

Functionally, however, the various roles of starch phosphorylase have yet to be unequivocally sorted out. Roles for starch phosphorylases in providing carbon for seed germination and photosynthetic conversions seem clear, but other functions for this enzyme remain vague. For example, the precise role of starch phosphorylase in starch deposition or degradation has remained elusive. Transformed potatoes with various forms of starch phosphorylase inserted in the antisense orientation do not appear to exhibit visible effects on starch phenotype (5, 6). Such effects could be attributed to the presence of multiple starch phosphorylase isoforms, which could require co-suppression of several genes.

Moreover, for many years, it was believed that starch phosphorylase was the primary catalyst for chain elongation of amyloses and amylopectins in monocots such as corn. This idea quickly fell from the forefront when the existence of the AGP pathway

**Table 1** Purification of Maize Phosphorylase

Fraction	Volume (mL)	Activity (units/mL)	Protein (mg/mL)	Specific Activity (units/mg)	Recovery (%)
Crude homogenate	1427	0.56	5.0	0.047	100
40–50% ammonium sulfate precipitation	80	8.4	14.0	0.44	85
DEAE-cellulose peak	46	8.9	0.17	49	52
Sephadex G-200 peak	7	41	0.72	57	36

Source: Ref. 29.

for starch synthesis was finally characterized (34). Nonetheless, maize amyloplasts are rich in starch phosphorylase activity and starch phosphorylase expression patterns correlate closely with starch deposition (19, 20). Therefore, more recent thinking retains the possibility that starch phosphorylases may yet prove to be a key component of the amylose and amylopectin biosynthetic system of higher plants (1). Similar questions linger with respect to a precise biochemical function for starch phosphorylase in the cold sweetening process of potato. Continued generation of mutant cultivars deficient in the various isoforms of starch phosphorylase should play a major role toward further clarifying the potentially interesting and diverse functions of this enzyme.

## Amylosucrase

**Volker Büttcher**

*Aventis CropScience GmbH, Frankfurt, Germany*

### I. INTRODUCTION

The enzyme amylosucrase was discovered by Hehre and Hamilton (1). The reaction demonstrated an in vitro glycogen synthesis without any activated nucleotide sugars for the first time. The reaction of amylosucrase can be described as follows:

The amylosucrase splits off the glucosyl part from the substrate and links it covalently to an acceptor molecule. During this reaction fructose is released. The reaction mechanism is still not proven, but it is assumed that the glycosyl residue is transferred to the nonreducing end of an alpha-1,4-glucan. For the enzyme reaction no additional energy is needed but a primer seems to be necessary to trigger the reaction. The best primer is glycogen which shows enormous stimulation of the amylosucrase reaction (2).

#### A. Microbiology

Amylosucrase occurs only in prokaryotes and only in some genera of the genus *Neisseria* (Table 1). The amylosucrase is located in the cytoplasm of the cells, except in *N. polysaccharea*, which secretes the amylosucrase in the medium.

The genus *Neisseria* is the type genus of the family Neisseriaceae which contains 18 species that can be isolated from humans and animals. The Neisseriaceae are gram-negative bacteria. The morphology in this family can be diplococci, cocci, or rods. The *N. gonorrhoeae* and the *N. meningitidis* are the only two species that are pathogenic. All other *Neisseria* sp. are non-pathogenic and are known to be commensals.

*rhomphaea* and the *N. meningitidis* are the only two species that are pathogenic. All other *Neisseria* sp. are non-pathogenic and are known to be commensals.

#### B. Molecular Genetics

The GC content of *Neisseria* sp. ranges from 49.3 to 55.6 mol% (3). The size of the chromosome is  $\sim 1.5 \times 10^6$  bp (4). The gene for amylosucrase was cloned (5, 6) and sequenced. Up to now no sequences of other amylosucrases have been published, but it is assumed that the DNA sequences among the *Neisseria* spp. are very similar. The amylosucrase gene of *N. polysaccharea* could be strongly expressed in various *E. coli* strains (6). Because of its own secretion-signal-like leader sequence in recombinant *E. coli* the enzyme is secreted into the medium, but the bulk of the protein is retained in the cytosol.

### II. PROPERTIES OF THE AMYLOSUCRASE

#### A. Protein Data

The purified amylosucrase is a very stable enzyme. It remained active for several days in the reaction buffer (100 mM Na citrate, pH 6.7) at 37°C. The enzyme could be stored over 1 year at -20°C without significant loss of activity. The MW of the protein is around 72 kDa and the calculated isoelectric point is at pH 5.59.

**Table 1** Amylosucrases Are Found in the Following *Neisseria* Strains

<i>N. canis</i> ATCC 31005
<i>N. cinerea</i> ATCC 14685
<i>N. cuniculi</i> ATCC 14688
<i>N. denitrificans</i> ATCC 14686
<i>N. perflava</i>
<i>N. polysaccharea</i> ATCC 43768
<i>N. sicca</i>
<i>N. subflava</i> ATCC 19243

The amylosucrase appears to be tightly bound to its product/substrate, which is amylose (7).

### B. Detection of the Amylosucrase Activity

The simplest way to detect amylosucrase activity is in a small *in vitro* reaction assay. An aliquot of the enzyme sample is mixed with 100  $\mu$ L reaction buffer (5% (w/v) sucrose, 50 mM Na citrate pH 6.5) and incubated for some minutes up to several days at 37°C. Very high activity samples show a white precipitate, and samples with a lower activity are mixed with Lugols solutions (0.5 mM I<sub>2</sub>KI). This test can be used for relatively rough quantitative determination by comparing the color intensity with a calibration row.

A more accurate activity test can be done by measuring the real-time fructose release in an optically coupled enzymatic assay. The reaction cuvette contains 20% sucrose, Na citrate buffer (100 mM, pH 7), glycogen (0.05%), NAD (0.4 mM), ATP (1 mM), and the helper enzymes hexokinase (1.5 units/mL), phosphoglucose-isomerase (2  $\mu$ g/mL), and glucose-6-phosphate dehydrogenase (5  $\mu$ g/mL), which are added directly to the reaction mixture (200  $\mu$ L). The assay is started by addition of the enzyme sample and the OD 340 is monitored. The increase of absorption at 340 nm is equivalent to the production of fructose and can be transformed mathematically in  $\mu$ mol of fructose released per minute (units).

### C. Primer Dependence

The glucan synthesis by amylosucrase is strongly stimulated by primers. Glycogen was shown to be one of the best primers (2), but oligoglucans like maltoheptaose or branching enzymes can also trigger the glucan synthesis. From studies of MacKenzie et al. (8) it seems that the amylosucrase of *N. denitrificans* has an abso-

lute requirement for a primer. Up to now it is not absolutely clear if the sucrose itself or an oligoglucan of a certain length is required obligatorily, because traces of glucans are enough to trigger the reactions after a very long lag phase. The reaction kinetics depends not only on primer presence or concentration. The enzyme and substrate concentrations are very important factors in the beginning of the polymerization reaction.

### D. Substrate Specificity

Amylosucrase has a high substrate specificity. Several substrates like 6-desoxy-6-fluorosucrose, 6-desoxysucrose, 4,6-dideoxysucrose, 3-desoxysucrose, and  $\alpha$ -D-allopyranosyl- $\beta$ -D-fructofuranoside were used as substrates. None of the tested substrates were incorporated into a polymer, but 6-desoxy-6-fluorosucrose, 6-desoxysucrose, and 4,6-dideoxysucrose could inhibit the enzymatic reaction (9). Under optimal conditions the amylosucrase achieves nearly 100% conversion of its substrate sucrose to polymers (or oligomers) and fructose. Invertase activity (the splitting of sucrose into fructose and glucose without any glycosylation step) is negligible for the amylosucrase reaction under all reaction conditions tested. Remaud-Simeon et al. (5) showed that under special reaction conditions a transglycosylation reaction of oligomaltose may be possible. When the substrate sucrose was lacking, the amylosucrase could disproportionate oligoglucans. The glycosidic residues were mainly transferred such that the maltopentaose concentration decreased in favor of maltohexaose and maltoheptaose.

### III. THE PRODUCT OF THE AMYLOSUCRASE

The product of the amylosucrase reaction is characterized as an  $\alpha$ -1,4-glycosidic glucan (6). The molecular weight depends on substrate concentration and reaction time. The polymer molecular weights are in the range from several thousands ( $10^3$ ) up to several millions ( $10^6$ ) g/Mol. The molecular weights reported in the literature are often overestimated owing to the low solubility of the polymers and the preference of amylose to form strong aggregates.

Older references (10, 11) described the presence of  $\alpha$ -1,6 linkages, which were generated by very small impurities of branching activity. The recombinant enzyme, when produced in a branching enzyme-deficient strain (glgB $^{-}$ ), allowed the production of a pure

amylosucrase free from any branching activity. The product of the purified amylosucrase is an  $\alpha$ -1,4-glycosidic-linked glucose polymer and no  $\alpha$ -1,6-glycosidic (or other) linkages could be detected with NMR or methylation methods.

The naturally occurring amylose normally must contain some  $\alpha$ -1,6-glycosidic branches, because in vivo the amylose is synthesized in the presence of a glucan branching enzyme activity. Therefore the in vitro product of amylosucrase is different from the naturally found amylose, because of the homogeneity of its glycosidic linkages. This small but important difference implies different polymer properties distinct from naturally occurring "branched" amylose. For clear differentiation the product is called "Nepo-Amylose" (*Neisseria polysaccharea*-Amylose).

#### IV. APPLICATIONS

The enzyme amylosucrase is not yet used in industry, because the product (Nepo-Amylose) from the pure amylosucrase is not well characterized. The formerly used crude enzyme preparations synthesized different polymers compared to the very pure recombinant amylosucrase. The reason for that is small impurities, e.g., glucans and branching enzymes, which get carried over from the crude extract. Glucans have a very high binding affinity for the amylosucrase (7). The glucans act in an uncontrolled way as primers and serve as starter molecules for the polymerization. Branching enzymes enhance the polymerization reaction by providing non-reduced ends, at which the amylosucrase elongates the growing chain and accelerates the polymerization (12).

The amylosucrase could, for example, be used in pharmaceutical formulation processes. The microcrystalline amylose could be easily synthesized around a pharmaceutical compound to change the solubility of the substance. The wrapped pharmaceutical compound could be protected after application and would release the active substance in a controlled manner. A second example is the production of indigestible amylose, which can be used as a probiotic food ingredient to improve the healthy bacterial flora in the intestine in order to prevent colon cancer. With a controlled enzymatic process, tailor-made amylose with special properties could be produced for paper coating. The coating would improve the printing quality of recycled paper used by inkjet printers.

The investigation of amylosucrase demonstrates clearly the impact that the recombinant expression of industrial enzymes can have. Only when the recombi-

nant expression of the amylosucrase is an appropriate host strain became possible, the very pure enzyme, free of all disturbing molecules, became available. With this recombinant enzyme new products can be synthesized in a controlled method and with a reliable quality.

### I. INTRODUCTION

#### A. Chemical Reactions Catalyzed

In 1861, Louis Pasteur discovered the microbial origin of the gelification of cane sugar syrups (1). In 1874, the corresponding product was named "dextran" because of its positive rotatory power. The microorganism causing that gelification was isolated in 1878 by Van Tieghem and named *Leuconostoc mesenteroides* (2). Hehre demonstrated in 1941 that dextran could be synthesized from sucrose by a cell-free filtrate (3). The corresponding extracellular enzyme was named "dextransucrase" by Hestrin et al. (4).

Dextransucrase (DS) catalyzes the following reaction:

Sucrose is the only natural D-glucosyl unit donor used as substrate by the enzyme. The energy necessary for D-glucose polymerization simply comes from the cleavage of the high-energy glycosidic bond. No activated intermediate or cofactor is needed.

Dextran is a D-glucopyranosyl polymer containing more than 50%  $\alpha$ -1,6 glycosidic bonds, with a molecular weight ranging from 0.5 to  $6.10^6$  kDa (5, 6). Its type and degree of branching vary according to the origin of the dextransucrase (Table 1) (7, 8). Jeanes et al. (9) have purified and characterized the dextrans produced

by 96 strains of *L. mesenteroides*, in order to select the polymers most suitable for medical applications. The structural characteristics of dextrans from several *L. mesenteroides* strains are given in Table 1. Seymour and Knapp (10) suggested classifying dextrans into three groups, according to the main type of branching: Group A,  $\alpha$ -1,2 branching; Group B,  $\alpha$ -1,3 branching; Group C,  $\alpha$ -1,4 branching.

The most widely used dextran is produced by the dextransucrase of the strain *L. mesenteroides* NRRL B-512F, which synthesizes a very highly linear polysaccharide containing 95%  $\alpha$ -1,6 bonds. Besides *Leuconostoc*, dextransucrase is also obtained from two other types of lactic bacteria—*Streptococcus* and *Lactobacillus* (7). Streptococcal glucosyltransferases, particularly from *Streptococcus mutans*, are involved in cariogenesis phenomena. These enzymes synthesize from sucrose a glucan polymer which plays a key role in the adhesion mechanism of bacteria on the tooth surface to form the dental plaque (11–13).

#### B. Substrates and Acceptors

The only natural substrate of dextransucrase (DS) is sucrose, which serves as a high-energy glucosyl donor for polysaccharide and oligosaccharide synthesis; the main product is dextran. In addition to sucrose,  $\alpha$ -D-glucopyranosyl fluoride, *p*-nitrophenyl- $\alpha$ -D-gluco-

pyranoside,  $\alpha$ -D-glucopyranosyl- $\alpha$ -L-sorbofuranoside, and lactulosucrose serve as glucopyranosyl donors (14).

In a secondary reaction, the so called *acceptor reaction*, the glucosyl moiety is transferred from sucrose to the acceptor molecule instead of the growing dextran chain to produce the acceptor molecule elongated by one single glucosyl unit as the primary product. Usually the new bond formed is an  $\alpha$ -1,6-glucosidic bond. In most cases, the product can itself serve as an acceptor, so that a homologous series of glucosylated oligosaccharides is formed (15, 16).

Acceptor properties have been reported for a wide variety of mono-, di-, and oligosaccharides (e.g., glucose (17), fructose (18), maltose (19), and raffinose [for overview see 14, 20]), but also for some functionalized saccharide derivatives, as for example the sugar alcohols D-sorbitol and D-glycerol (17) or the 5-O- $\alpha$ -D-glucopyranosyl-arabonic acid (21, 36) or even glucal, an unsaturated sugar (22, 23). This secondary reaction is therefore of special technical interest. It offers perspectives for the synthesis of new oligosaccharides, which are not accessible otherwise by feasible technical routes.

Maltose and isomaltose are the most efficient acceptors. In most acceptors, the glucose from sucrose is transferred to the 6-hydroxyl group of the nonreducing end glucose residue to give a series of isomaltooligosaccharides of degree of polymerization of 2–7 (14). A detailed kinetic analysis revealed a nearly equally high acceptor activity for the di- to tetrasaccharides in the reaction mixture (23).

### C. Classification

Dextranucrase is a glucosyltransferase, and more precisely a transglucosidase, named sucrose:1,6  $\alpha$ -D-glucan 6- $\alpha$ -D-glucosyltransferase. Its Enzyme Commission nomenclature number is EC 2.4.1.5.

## II. UTILIZATION

### A. Synthesis of Nondigestible Oligosaccharides

The dextranucrase from the soil bacterium *Leuconostoc mesenteroides* NRRL B-1299 is known to catalyze the synthesis of dextran polymers containing  $\alpha$ -1,2-linked branched chains (Table 1). When this specific glucosyltransferase is used in the presence of maltose as acceptor and of sucrose as D-glucosyl donor,  $\alpha$ -gluco-oligosaccharides are obtained, which contain  $\alpha$ -1,2 glucosidic bonds (24, 25) at their nonreducing end and a maltose residue at the reducing end.

The presence of these  $\alpha$ -1,2 linkages results in a very high resistance of these oligosaccharides to attack by the digestive enzymes of humans and animals (26). Such  $\alpha$ -gluco-oligosaccharides cannot be metabolized, as demonstrated by using germ-free rats. That is why such  $\alpha$ -gluco-oligosaccharides were initially developed as low-calorie bulking agents, to be used in food formulations in complement of intense sweeteners (24).

But these  $\alpha$ -gluco-oligosaccharides are specifically metabolized by the positive intestinal bacterial flora.

In contrast to fructo-oligosaccharides and galacto-oligosaccharides, these  $\alpha$ -gluco-oligosaccharides are not bifidogenic, but they promote the growth of the cellulolytic intestinal flora. In addition, they induce a broader range of glycolytic enzymes than fructo-oligosaccharides and galacto-oligosaccharides, without any important side production of gases and thus any detrimental effect (27).

The prebiotic effect of  $\alpha$ -gluco-oligosaccharides has been demonstrated for piglets, broilers, and calves (28). The addition, for example, of 0.15% (w/w) of  $\alpha$ -gluco-oligosaccharides to young calves' feed results in a 20% decrease in veterinary costs (28). These oligosaccharides are currently marketed for human nutritional application as food complements, in combination with specific microbial flora and vitamins.

The prebiotic effect of such  $\alpha$ -gluco-oligosaccharides has also been demonstrated at the level of skin microbial flora (29), in which lactic bacteria also play a key protective role. This has resulted in the development of dermocosmetic applications for the  $\alpha$ -gluco-oligosaccharides, under the trade name BioEcola.

## B. Isomalto-oligosaccharides

A product manufactured in Japan as Alo mixture (Anomalously Linked Oligosaccharides) contains a range of isomalto-oligosaccharides to a major extent (glucose, isomaltose, and panose as major constituents) (30). However, it is produced from starch as substrate with  $\alpha$ -amylase,  $\beta$ -amylase and a transglucosidase. It is claimed to have favorable properties for application in the food industry.

Using glucose as an acceptor, a European patent (31) describes the formation of isomalto-oligosaccharides from sucrose with 10–20 anhydroglucose units; the average molar weight may be in the range of 2000–5000. The molar ratio of sucrose to glucose is in the range of 2–5. The sucrose is added to the reaction solution of 0.2–0.5 M glucose and 1000 units dextranase quasi-continuously. The sucrose concentration should not exceed 25% of the total dry substance; the reaction is conducted to high conversion. The product mixture contains fructose in a molar range corresponding to that of the sucrose added and may be used as a sweetener. Some further data are presented by Pereira et al. (32) with, however, limited yields of oligosaccharides of up to 45%. Systematic investigations concerning reaction engineering were undertaken by K. Demuth (23).

## C. Leucrose

Leucrose ( $\alpha$ -5-O-[ $\alpha$ -D-glycopyranosyl]- $\beta$ -D-fructopyranose) is an isomer of sucrose which is obtained via glucosyltransfer from sucrose to fructose as an acceptor. Since fructose is a reaction product, the net reaction is an isomerization of sucrose. Basic data are: spec. rotation  $[\alpha]_D^{20} - 7.5\%$ , melting point 156–158°C (33).

Pilot production was reported by Schwengers (33) using dextranase (DS) in a 65% aqueous solution with 1/3 sucrose and 2/3 fructose (w/w) at 25°C. When the reaction was complete, the leucrose formed was separated from fructose by chromatography with a cation exchange resin, followed by an evaporation step and crystallization (30, 33). The formation of leucrose and some reaction conditions, such as the effect of fructose concentration on the formation of leucrose and dextran, were investigated also by Itoh et al. (34).

## III. PROPERTIES AS PROTEIN; DS CHARACTERISTICS

### A. Molecular Weight

The size of dextranase from *L. mesenteroides* NRRL B-512F has been debated for some time. Molecular weights of 65 kDa (35) to 190 kDa (36) have been reported. Finally, the isolation of the gene coding for this enzyme (37) suggested a protein with a total of 1527 amino acids, which corresponds to a 170-kDa molecular weight. Lower values are due to proteolytic degradation, while higher values can be attributed to dextran contamination of the protein preparation. However, one has to be careful in concluding that the gene size represents the final MW of a mature protein, since there often is proteolytic processing (to remove signal peptide and to form subunits) as well as glycosylation, phosphorylation, and other posttranslational modifications.

### B. Gene Structure

The structure of the gene coding for dextranase from *L. mesenteroides* NRRL B-512F (37) is very similar to that of glucosyltransferases from streptococci (38–40). Starting from the N-terminal end, they consecutively contain: a signal peptide with 36 amino acids (37) allowing excretion; a variable region with 180–200 amino acids with unknown role (41); an N-terminal catalytic domain with 900 amino acids, highly conserved, which contains the catalytic groups, and parti-

cularly the Asp551 residue (41); and a C-terminal domain, with repeated units, involved in the glucan binding, but also in the dextran and oligosaccharide synthesis mechanism (42).

The site-directed mutagenesis of amino acid residues Asp511 and Asp513, which were replaced by Asn residues, completely suppresses dextran and oligosaccharide synthesis activity (43).

#### IV. PROPERTIES AS ENZYME

##### A. Mechanism

For dextran formation Ebert and Patat (45) and Ebert et al. (17, 44) were the first to propose an insertion mechanism. This concept was further developed by Kindler and Ludwig (46), who suggested the existence of a covalent intermediate glucosyl-enzyme complex. Several groups provided strong evidence for a covalent glucosyl enzyme intermediate for *S. sanguinis* and *S. sorbinus* dextranucrase (47–50; for overview see 14). Robyt et al. (51, 52) presented further evidence for both covalent glucosyl and glucanyl enzyme intermediates, suggesting two active centers involved in the growth of the polymer chain via an insertion mechanism, questioned however by recent gene sequence data showing one active center with two Asp (511 and 551) involved in glucosyl transfer (41, 43).

In a secondary reaction, the so-called acceptor reaction, the glucosyl moiety is transferred from sucrose to the acceptor molecule instead of the growing dextran chain to give the acceptor molecule elongated by one single glucosyl unit as the primary product. A specific acceptor binding site at the active center of the enzyme

has been proposed (53, 54). Usually the new bond formed is an  $\alpha$ -1,6-glucosidic bond. In most cases, the product can itself serve as an acceptor, so that a homologous series of glucosylated oligosaccharides is formed (15, 16).

##### B. Kinetic Characteristics

Sucrose is the only simple carbohydrate used by dextranucrase as a D-glucosyl donor. Initial reaction rates follow Michaelis-Menten kinetics up to 200 mM sucrose concentration, but the enzyme is inhibited by higher substrate concentrations (55). The inhibitor constant for sucrose is 730 mM (56). This inhibition can be removed by acceptor or dextran addition (6, 57, 58).

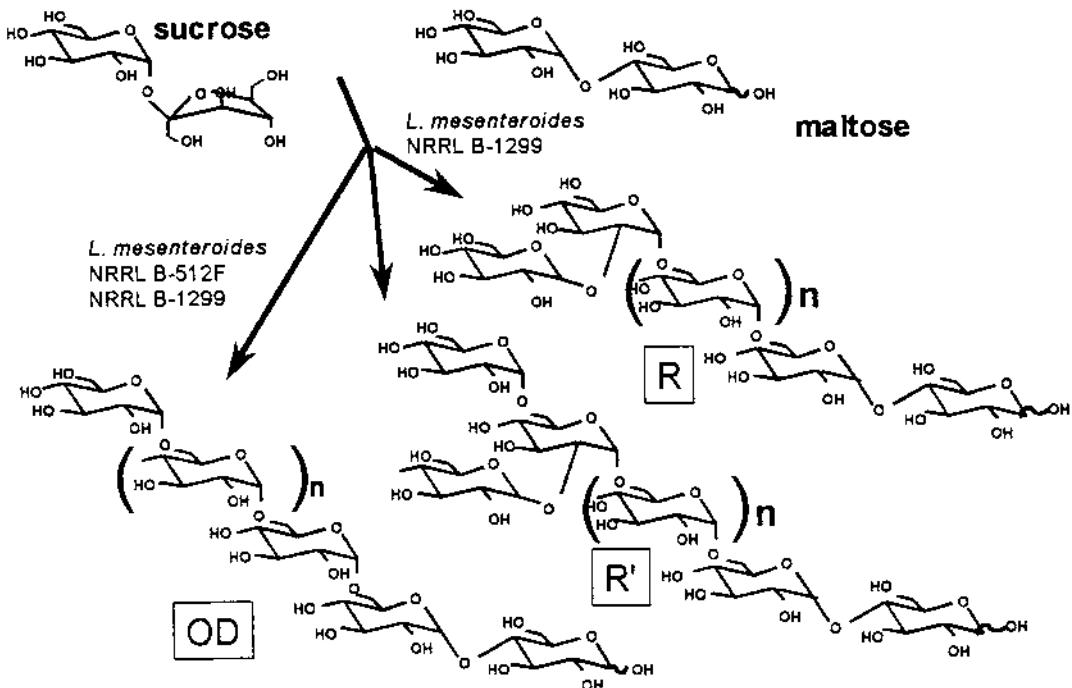

**Table 2** summarizes the Michaelis constant values reported in the literature for dextranucrase. Optimal pH and optimal temperature with the corresponding reaction activation energy are also given.

Dextranucrase is activated and stabilized by calcium ions (59), but they do not seem to be directly involved in the catalytic mechanism (60). The kinetic behavior of dextranucrase has been characterized and modeled to optimize the production of  $\alpha$ -gluco-oligosaccharides containing  $\alpha$ -1,2-glucosidic bonds. In fact, three families of oligosaccharides of increasing degree of polymerization are obtained (61), which respectively contain, besides a maltose residue at the reducing end (Fig. 1), only  $\alpha$ -1,6-glucosidic bonds;  $\alpha$ -1,6-glucosidic bonds and one  $\alpha$ -1,2-glucosidic bond at the nonreducing end;  $\alpha$ -1,6-glucosidic bonds and one  $\alpha$ -1,2-glucosidic bond on the penultimate D-glucosyl unit.

**Table 2** Parameter Value of *L. mesenteroides* NRRL B-512F Dextranucrase

(90) <sup>a</sup>				56

<sup>a</sup> Immobilized enzyme, apparent  $K_M$ .

**Figure 1** Types of oligosaccharides formed by dextranases.

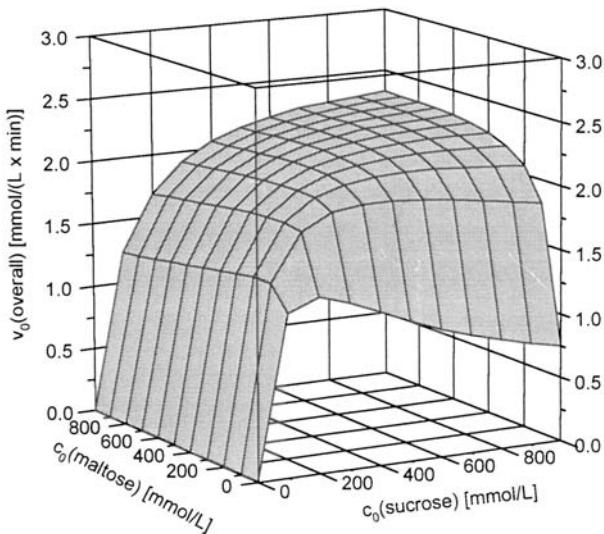

It must be pointed out that Michaelis kinetics only apply in the absence of acceptors. Constants like  $V_{max}$ ,  $K_M$ , and  $K_I$  are dependent on acceptor concentrations (cf. next paragraph). Thus with good acceptors, apparent  $V_{max}$  values increase with increasing acceptor concentration, from 5.8 (U/mL) with substrate only up to 19.1 (U/mL) at 600 mM maltose concentration (64). They decrease with increasing concentrations of weak acceptors like fructose, from 1.3 (U/mL) to 0.38 (U/mL) at 2.75 M fructose concentration (54). Apparent  $K_M$  values increase as well with increasing acceptor concentration, from 12 mM at zero to 163 mM at 600 mM maltose (64). A  $K_M$  value of 27 mM was obtained in the absence of an acceptor whereas this value was 40 mM at a fructose concentration of 1.39 M (54). It is obvious that in the presence of acceptors, kinetics are complex and Michaelis kinetics do not apply.

In the presence of strong acceptors, like maltose or isomaltose, several general effects may be summarized: initial overall reaction rates (sucrose consumption or sum of acceptor product and dextran formation) significantly increase both with substrate and acceptor concentration. Initial rates of acceptor

product formation follow the same scheme with an even more pronounced tendency; dextran formation may be nearly suppressed at high acceptor concentration (Fig. 2) (65).

The final product concentrations depend significantly on the ratio of substrate and acceptor. The first acceptor product (panose in the presence of maltose) is favored at high maltose excess, whereas tetra- and pentasaccharides are formed in comparable amounts, as well as some higher oligosaccharides, at about equimolar substrate and acceptor concentrations.

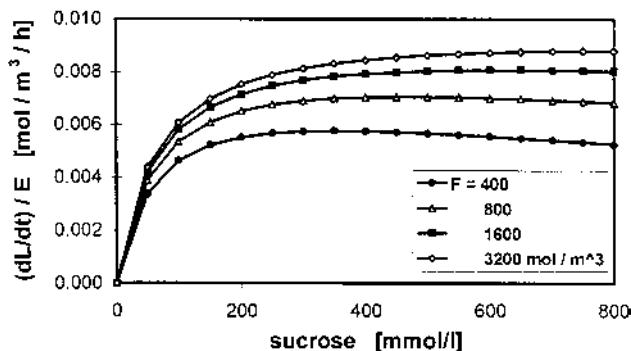

In the presence of weak acceptors, like fructose, initial overall reaction rates decrease significantly with increasing acceptor concentration, whereas they increase with the substrate concentration. Initial rates of acceptor product formation increase with both substrate and acceptor concentration, the dextran formation being suppressed to a major extent only at very high acceptor concentration (range of 10% at 3 M fructose concentration) (Fig. 3) (66). The acceptor product of fructose, leucrose, does not act as an acceptor, so high yields can be obtained (54).

**Figure 2** Overall initial reaction rates of acceptor product formation with maltose as an acceptor. (From Ref. 65.)

### C. Mathematical Modeling and Reaction Engineering Considerations

The synthesis of oligosaccharides by dextranase is a complex series of reactions. The quantitative description of it therefore requires a model which comprises all of the relevant parameters. Such a model has been developed to predict the optimal reaction conditions and reactor configurations for different acceptors, and notably for the production of leucrose and isomalto-oligosaccharides (54, 66). The kinetic parameters of the model identified are based on a wide range of experimental data (23, 54, 56, 65, 67, 68).

**Figure 3** Initial rates of leucrose formation. (From Ref. 66.)

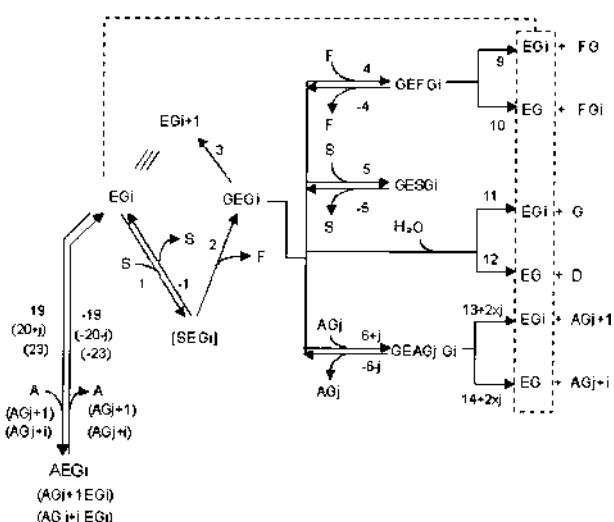

The acceptors considered, fructose, glucose, and maltose, represent different types; the first is a weak acceptor which slows down the overall reaction rate, the second is an acceptor of intermediate strength, and the third represents a strong acceptor which accelerates the overall reaction rate. These effects are included in the model. The scheme of reactions catalyzed by dextranase is shown in Figure 4 (66).

The enzyme is assumed to have three binding sites: one covalent glucosyl-, one dextran, and one acceptor (53, 54). Reactions 1, 2, and 3 represent the growth cycle of dextran formation. A sucrose molecule S is bound at the enzyme E, fructose F is released, and the glucosyl G is transferred to the dextran chain  $G_i$ , which is always linked to the enzyme. Fructose can be linked to the acceptor site, and react with G to form leucrose FG (reactions 4 and 9). The same reactions are possible with other acceptors A (reactions 6 and 13), and acceptor products (except leucrose) may again react as acceptors (reactions 6+j and 13+2xj). Sucrose is able to bind at the acceptor site (reaction 5) but does not react to an acceptor product, thus leading to inhibition at high concentrations. For approximate modeling, reactions 10–12 and 14 may be neglected.

The decrease of enzyme activity  $E$  with time is described by a first-order reaction (66):

$$E = E_0 \cdot \exp(-k_d \cdot t)$$

$E_0$  is the initial activity at the time  $t_0 = 0$ ;  $E$ , the remaining activity after time  $t$ ; and  $k_d$ , the inactivation

**Figure 4** Scheme of reactions catalyzed by dextranase (see text for details). (From Ref. 66.)

parameter. For two experiments, the inactivation parameters have been calculated for the immobilized enzyme (66, 67). In these experiments, different acceptors were used: fructose in the first, and maltose in the second. The bead diameters were 0.7 and 1 mm, which have been found to be optimal. The inactivation constants  $k_d$  were 0.029 ( $d^{-1}$ ) in the first and 0.0135 ( $d^{-1}$ ) in the second case, respectively.

#### D. Kinetics of Leucrose Formation

Böker et al. (54) presented approximate kinetic correlations as well as a rational model based on the reaction mechanism for different concentration ranges of sucrose and fructose with emphasis on leucrose formation. If only sucrose and fructose are present in the reaction mixture the model may be simplified, so that it comprises only six parameters (Table 3) (54, 66). These equations are similar to an extended Michaelis-Menten equation where two substrates (sucrose and fructose as an acceptor) as well as substrate inhibition are considered.

From the model, it follows that the fructose concentration should be as high as possible; for practical reasons, it is limited by solubility and viscosity of the solution considering the sum of substrate, acceptor and product. A sucrose concentration higher than

~ 100–200 mM has little effect on leucrose production. According to the model, the ratio sucrose/fructose has no effect on the ratio of dextran formation to leucrose formation. A tubular flow reactor with immobilized enzyme is the best choice for production in a continuous mode. So with initial concentrations of 0.6 M sucrose and 2.2 M fructose the leucrose yield was in the range of 64–72% depending on the sucrose conversion (95–55%) (69). The yield can further be improved to about 85% by increasing the fructose concentration up to 3 M, however, at the expense of enhanced separation efforts. Byproducts are isomaltulose and trehalulose in the range of 4–5% each. The leucrose yield can be further improved, for example, from 70% to 75%, and the byproduct concentrations reduced at lower temperature (5°C instead of 25°C) (54). The productivity of the immobilized enzyme in a continuous tubular reactor was found to be 1.5 g leucrose formed per unit dextran-sucrase (test at 25°C) (69). This type of reactor proved to be optimal in model calculations, as is shown in Figure 5, where the productivity is shown as a function of the initial fructose concentration with an optimum at ~ 1.6 M and 1% residual sucrose concentration (or ~ 2.4 M and 10% residual sucrose concentration) (66).

Formation of the series of oligosaccharides from isomaltose to isomaltodecaose is shown in Figure 6 (23). The first acceptor products are much stronger acceptors themselves than glucose; therefore isomaltose up to isomaltopentaose are formed with nearly equal concentrations in the range 35–45 mM by the end of the reaction.

An overview for the acceptor activity of a range of sugars and sugar derivatives for which kinetic

**Table 3** Parameters of Simplified Kinetics for Leucrose Formation<sup>a</sup>

Sucrose consumption rate:

$$ds = -E \cdot S \cdot (p24 + p70 \cdot F)/X$$

Leucrose formation rate:

$$dL/dt = E \cdot p70 \cdot S \cdot F/X$$

$$X = 1 + p42 \cdot S + p46 \cdot F + p47 \cdot F \cdot S + p68 \cdot S^2$$

The values of the parameter are<sup>b</sup>

$$p24 = 3.31 \cdot 10^{-8} \text{ m}^3 (\text{U} \cdot \text{min})$$

$$p42 = 1.45 \cdot 10^{-2} \text{ m}^3 / \text{mol}$$

$$p46 = 7.27 \cdot 10^{-3} \text{ m}^3 / \text{mol}$$

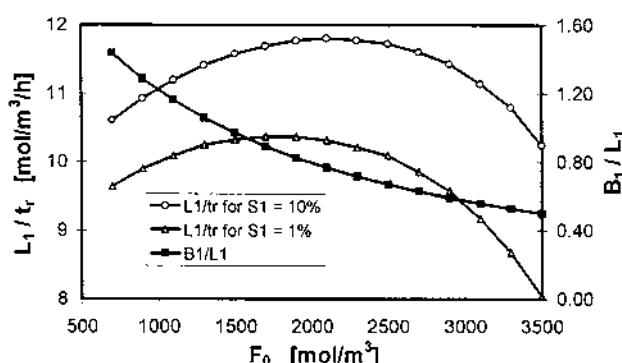

$$p47 = 1.11 \cdot 10^{-4} (\text{m}^3 / \text{mol})^2$$

$$p68 = 3.16 \cdot 10^{-5} (\text{m}^3 / \text{mol})^2$$

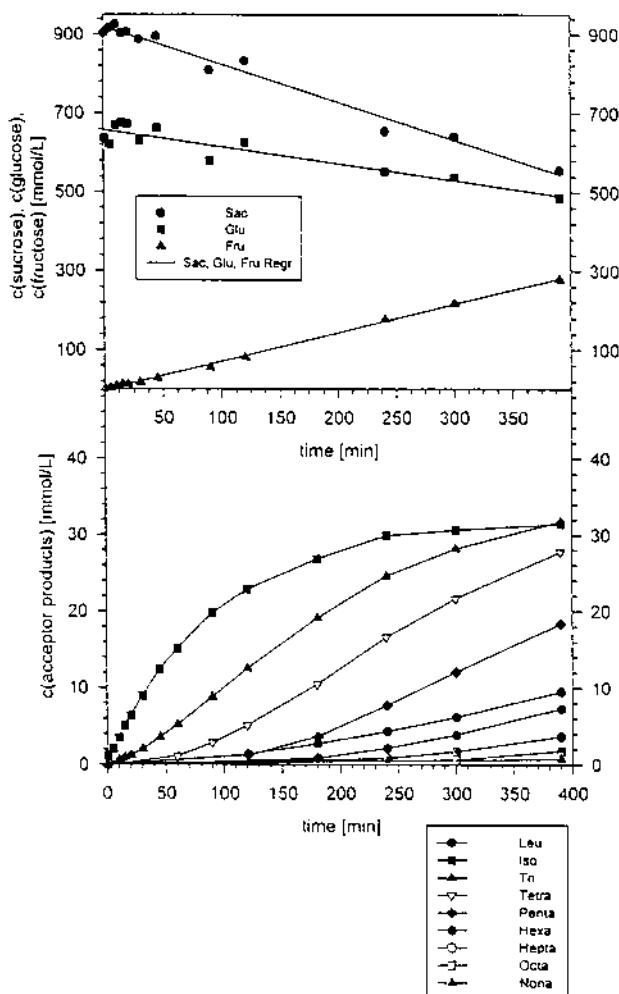

$$p70 = 1.95 \cdot 10^{-8} \text{ m}^6 / (\text{U} \cdot \text{min} \cdot \text{mol})$$

<sup>a</sup> Parameters pi refer to the model as developed in Ref. 66.

<sup>b</sup>  $\text{m}^3$  stands for cubic meters.

**Figure 5** Modeling of the tubular flow reactor—leucrose production rate and formation of byproducts. Kinetics of the formation of isomaltooligosaccharides and different acceptor products. (From Ref. 66.)

**Figure 6** Acceptor production formation with glucose as an acceptor. (From Ref. 23.)

investigations were performed are given in Figure 7 (23). The acceptor activity is based on modeling so that varying concentrations of substrate, acceptor, and acceptor products during the experiments are taken into account. It is obvious that monosaccharides and their derivatives like mannitol and sorbitol are rather weak acceptors. Disaccharides, including acceptor products like isomaltose, are much better acceptors, except singular molecules like leucrose, which is not an acceptor. Surprisingly, many tri- to pentasaccharides are equally good acceptors as the disaccharides, or much better ones in the case of the mannitol and sorbitol acceptor products. It should be noted that the latter ones are nonreducing oligosaccharides with presumably increased thermal stability.

## V. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

Dextranucrase catalyzes, using sucrose as substrate, both the synthesis of high-MW dextran polymers and the synthesis of low-MW oligosaccharides in the presence of efficient acceptors. Two different sets of reaction conditions are thus necessary to determine dextranucrase activity.

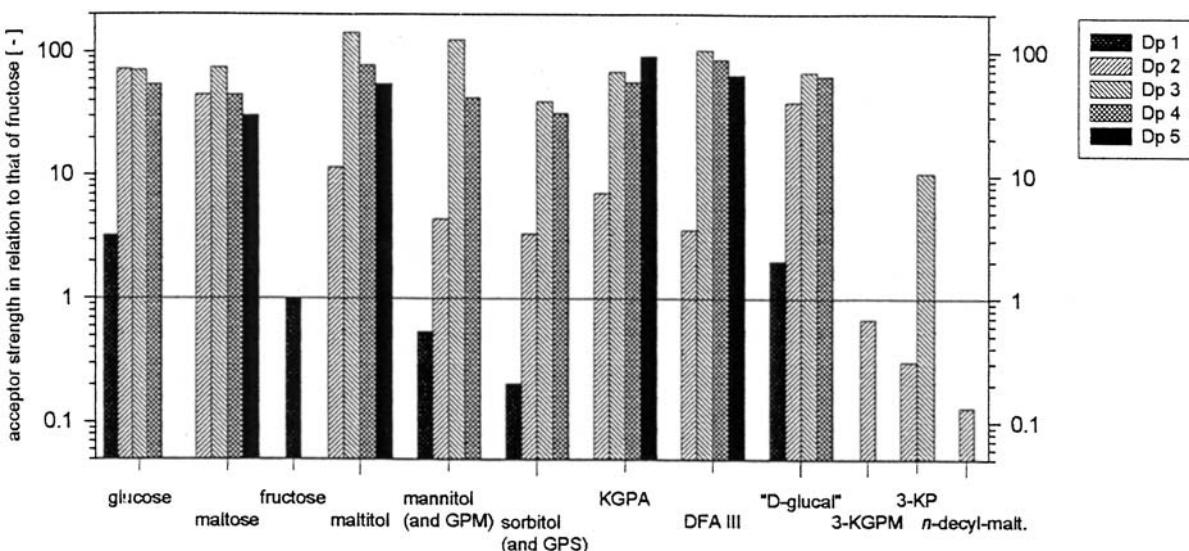

### A. High-MW Dextran Synthesis

Standard reaction conditions are: 20 mM acetate buffer, pH 5.4, containing 100 g/L sucrose, 0.05 g/L calcium chloride ( $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ ), 1 g/L sodium azide at 30°C. Dextranucrase activity must be in the range of 0.3–1.0 U/mL (1 unit corresponds to the amount of enzyme which catalyzes the production of 1  $\mu\text{mol}$  of fructose per min in the above reaction medium).

Dextranucrase activity is measured by determining the initial rate of production of reducing sugars followed by the 3,5-dinitrosalicylic acid (DNS) method (70). Reaction samples (0.1 mL) are withdrawn at various time intervals. Dextranucrase reaction is stopped by addition of 0.1 mL DNS solution (10 g/L DNS, 300 g/L sodium potassium tartarate, 16 g/L sodium hydroxide). After heating for 5 min at 95°C followed by ice cooling, 1 mL water is added and absorbance is read at 540 nm. A standard curve is prepared with standard fructose solutions ranging from 0 to 2 g/L in fructose concentration. Any catalytic activity producing reducing sugars will interfere with activity determination. HPLC for analysis of fructose can be applied as an alternative (see below).

### B. Low-MW Oligosaccharide Synthesis

Standard reaction conditions are: 20 mM acetate buffer, pH 5.4, containing 100 g/L sucrose, 20–100 g/L acceptor (maltose, isomaltose, ...), 0.05 g/L calcium chloride ( $\text{CaCl}_2 \cdot \text{H}_2\text{O}$ ), 1 g/L sodium azide at 30°C. Dextranucrase activity must be in the range of 0.3–1.0 U/mL. The key factor determining the molecular-weight distribution of the products is the sucrose donor/acceptor molecular ratio. Reaction samples (0.1 mL) are heated for 5 min at 95°C to stop the reaction. They are diluted with ultrapure water to reach a total carbohydrate concentration < 5 g/L and analyzed by HPLC using a C18 column and ultrapure water as eluent. Fructose, maltose, leucrose, sucrose, and gluco-oligosaccharides with a polymeriza-

**Figure 7** Acceptor strength of various mono- and disaccharides and their ensuing acceptor products in relation to the acceptor efficiency of fructose (DP1 signifies the monosaccharide, followed by the acceptor products, from di- (DP2) to pentasaccharide (DP5) (GPM: glucosylmannitol, GPS: glucosylsorbitol, KGPA: potassium glucosylarabonic acid, DFA III: difructoseanhydride III, 3-KGPM: 3-keto-glucosylmannitol, 3-KP: 3-keto-isomaltulose, n-decyl-malt: n-decyl-maltoside). (From Ref. 23.)

tion degree up to 6 are easily separated within 30 min elution time. Products are detected and quantified by measuring the refractive index of the eluent solution.

### C. Immobilized Dextranucrase

For immobilized dextranucrase it is obvious that systematic errors in the activity measurement can be avoided only when dextran formation is suppressed as far as possible. This can be achieved by adding an excess of good acceptor like maltose (71). A test in which maltose was applied in fivefold excess was developed for this purpose (56, 68). However, it must be taken into account that in the presence of excess maltose the maximal activity of dextranucrase is higher by a factor of 3 at low concentrations (sucrose 28, maltose 50 mmol/L) and a factor of 2 at high concentrations (sucrose 280, maltose 150 mmol/L) (65). The test solution was composed of 730 mM maltose and 146 mM sucrose in a 0.025 M calcium acetate buffer at pH 5.4. To avoid microbial growth the solution furthermore contained 200 mg/L sodium azide and a droplet of toluene.

With native dextranucrase, 4.8 mL of this solution was incubated with 0.2 mL dextranucrase solution (activity in the range of 5–15 U/mL) at 25°C. When dextranucrase–calcium alginate beads were tested, 20 mL of the maltose test solution and 1.0 g beads (activ-

ity in the range of 5–10 U/g wet weight) were used. Samples from the reaction digests were taken after 15, 30, 45, 60, and 90 min; diluted; and heated at 100°C for 5 min to inactivate the enzyme. After cooling to ambient temperature, the samples were membrane-filtered through a 0.2-μm cellulose nitrate filter and analyzed by HPLC. [Note that prolonged storage of frozen samples prior to analysis will give wrong results due to a slowly continuing reaction (72)]. The enzyme activity is calculated from the fructose concentrations by linear regression. In case of immobilized dextranucrase, corrections must be made for the decrease in reaction volume by sampling whereas the amount of immobilized enzyme remains constant.

### D. Analytical Methods: HPLC

Samples were analyzed by HPLC with the LiChrospher 100 NH<sub>2</sub> column (Merck, Darmstadt, Germany). Acetonitrile-water eluent mixtures from 80:20 to 70:30 (v/v) were used at 0.8 mL/min. A refractometer (Knauer, Berlin, Germany) served as detector, while data were acquired with Gynkosoft (Gynkotek, Munich, Germany). The analytical error is ±5% at low sugar concentration (< 8 g/L) and ±3% at higher concentrations. For complex mixtures of oligosaccharides high-performance anion chromatography is the optimal method (73).

## VI. PRODUCTION AND PURIFICATION

### A. Dextransucrase Production and Purification

Large-scale production of dextransucrase involves only *L. mesenteroides* strains. These gram-positive, nonsporulating bacteria are heterofermentative and produce equimolar amounts of D(–) lactate and acetate or ethanol (74). Their optimal growth temperature is 25–30°C, with an optimal pH of 6.5 (75). Dextransucrase production is specifically induced by sucrose (76), but the induction mechanism has not been elucidated. Several constitutive mutants have been described for *L. mesenteroides* NRRL B-512 F (77–79), B-1355 (80, 81), B-742 (82), and B-1299 (83).

Dextransucrase is directly connected with microbial growth (84, 85). Lopez (86) obtained a linear relationship between *L. mesenteroides* NRRL B-512F growth rate and dextransucrase specific production rate. The optimization of the culture medium of *L. mesenteroides* NRRL B-512F has been reported by several groups (63, 87, 88). A pH value of 6.7 results in an improved dextransucrase activity and stability (87). The higher pH value also limits dextran production in the culture medium and thus facilitates dextransucrase purification (89). Culture temperature is generally 26°C or 27°C, although higher enzyme activities have been reported at a slower culture growth at 23°C (63, 90), corresponding to 23 units/mL. Aeration conditions poorly affect cell growth, but carbon dioxide significantly increases dextransucrase production (90). Fed-batch sucrose addition results in a sixfold increase in enzyme activity (91). This can be coupled together with pH regulation by adding an alkaline sucrose solution (63, 85). As sucrose acts simultaneously as an inducer for the enzyme production, a carbon source for the bacterial growth and a substrate for dextransucrase, enzyme preparations contain a high concentration of dextran, tightly associated to the protein.

Dextransucrase from *L. mesenteroides* NRRL B-512F can be purified from the culture medium by ammonium sulfate or ethanol precipitation (92). It can also be concentrated by ultrafiltration and purified by Biogel A-5m chromatography after dextran hydrolysis by dextranase treatment (93). The dextran associated with the enzyme allows its very efficient concentration/purification by phase partition after polyethyleneglycol (PEG 1500) addition, resulting in a one-step 20-fold concentration from the culture supernatant and a 200-fold purification (63).

The production of  $\alpha$ -gluco-oligosaccharides at the industrial scale is achieved using immobilized dextran-

sucrase in a continuous packed-bed reactor. The enzyme is produced by fed-batch cultivation of *L. mesenteroides* NRRL B-1299 (94, 95). Sucrose plays the simultaneous role of growth substrate for the microbial strain, specific inducer for extracellular dextransucrase production, and substrate for this enzyme. The precise characterization of the physiology of *L. mesenteroides* NRRL B-1299 has shown that the enzyme production was repressed by D-fructose accumulation in the growth medium. But it is possible to remove this repression effect in the presence of D-glucose. For that reason, the simultaneous fed-batch addition of sucrose and D-glucose to the cultivation medium has allowed an increase of 100% in the amount of dextransucrase activity present in the culture medium (96).

More than 90% of the dextransucrase activity is linked to the microbial cells and/or to the dextran polysaccharide associated to the cells. This allows a very easy recovery of the enzyme from the cultivation medium by centrifugation, as well as a very simple immobilization process by entrapping the dextransucrase activity in calcium alginate beads. Immobilized dextransucrase is used in a 1 m<sup>3</sup> packed-bed reactor.

## VII. IMMOBILIZATION

High-MW dextran synthesis can be obtained using either crude *L. mesenteroides* culture medium after growth on sucrose as carbon source, or the culture supernatant after microbial cell removal. But in the case of oligosaccharide synthesis through the acceptor reaction, the continuous operation of dextransucrase involves its immobilization.

Several attempts have been made for immobilizing dextransucrase by covalent grafting onto a variety of supports, in order to study either the enzyme mechanism or the effect of diffusional limitations on enzyme kinetics. The efficiency of such methods is always relatively limited. Dextransucrase has been coupled onto BioGel activated with glutaraldehyde (51, 97). Covalent grafting onto DEAE-Sephadex or SP-Sephadex gives, under the best conditions, a 10% immobilization yield and a specific activity of 0.5 U/g support (98). Dextransucrase adsorption onto phenoxy acetylcellulose (99) or hydroxyapatite (50) results in improved immobilization yields, but the enzyme is rapidly desorbed from the support. Covalent coupling onto porous amino silica carrier activated with glutaraldehyde gives a specific activity of 40 U/g support, but with a 2% immobilization yield (100, 101).

The presence of high-MW dextran associated with the enzyme results in the possibility to very simply and efficiently immobilize dextranases preparations by inclusion into alginate gels. Immobilization yields >90% are obtained, with a specific activity of 1 up to 10 U/mL gel (69, 102, 103). The apparent volume of the dextranase enzyme complex, associated with dextran/alginate interactions, allows enzyme retention within such gels, while globular enzymes are easily washed out from the gel (68).

In the case of the production of the dextranase from *L. mesenteroides* NRRL B-1299, >90% of the activity is associated with the bacterial cells. For that reason, the continuous industrial production of gluco-oligosaccharides containing  $\alpha$ -1,2 linkages involves the use of the alginate-entrapped biomass (104). The immobilization yield is 93%, with a specific activity of 4.1 U/mL gel.

## VIII. CONCLUSIONS

Dextranase is one of the very few enzymes able to synthesize glucosidic bonds using a substrate as simple as sucrose. It has the capacity to catalyze both the production of high-MW dextran polymers, containing thousands of D-glucosyl units, and the production of low-MW oligosaccharides with <10 D-glucosyl units when efficient acceptors, like maltose for example, are added to the reaction medium.

A variety of dextranases have been characterized, presenting a wide range of selectivities and thus resulting in a large diversity of poly- and oligosaccharides. The main microbial sources of dextranases are lactic bacteria from soil (*L. mesenteroides*) and from the oral flora (*Streptococcus* sp.). It must be pointed out that *L. mesenteroides* strains can be isolated from several food products (dairy products, sauerkraut, alcoholic fermentation), and can thus be regarded as safe. In fact, dextran polysaccharides can be used as texturing agents, particularly for dairy products. In addition, dextran oligosaccharides containing  $\alpha$ -1,2 linkages have been proven to present original prebiotic properties and are of interest for nutritional application. The simplicity of production and operation of dextranases, either as free or immobilized enzyme preparations, makes such enzymes very good candidates for large-scale production of both poly- and oligosaccharides.

In the near future, the diversity of dextranases will be significantly increased owing to both the wider screening of microbial sources using classical microbio-

logical approaches as well as nucleic probes and genomic analysis, and the construction of modified enzymes by site-directed and random mutagenesis, combined with directed gene molecular evolution. This will result in the possibility to design improved dextranases with controlled selectivity in D-glucosyl residue transfer. This will allow the synthesis of a new range of poly- and oligosaccharides, and more broadly of glucosconjugates of nutritional and/or medical interest.

## Levansucrase

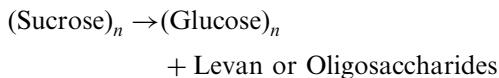

**Ki-Bang Song and Sang-Ki Rhee**

*Korea Research Institute of Bioscience and Biotechnology (KRIBB) and Real Biotech Co., Ltd., KRIBB, Daejeon, Korea*

### I. INTRODUCTION

Levansucrase is a kind of transferase which catalyzes a fructosyl transfer from sucrose to various acceptor molecules. The product, levan, consists of D-fructofuranosyl residues linked predominantly by  $\beta$ -(2,6) linkage as a main chain with some  $\beta$ -(2,1) branching points. Both linkage types are formed by the single enzyme levansucrase. The enzyme catalyzes the following reactions:

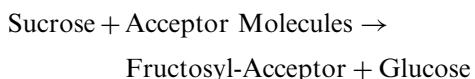

1. Polymerization reaction

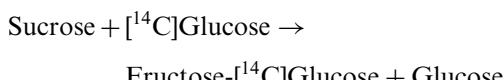

2. Hydrolysis reaction

3. Acceptor reaction

4. Exchange reaction

5. Disproportionation reaction

The enzyme catalyzes hydrolysis and polymerization reactions concomitantly (Reaction 1), resulting in fructose homopolymer (levan) and free glucose. This reaction occurs when sucrose exists as the sole fructosyl donor and acceptor, and involves three steps: initiation, propagation, and termination (1). Chains of levan grow in a stepwise fashion by repeated transfer of a hexosyl group from the donor to growing acceptor molecules. The enzyme primarily catalyzes a coupled reaction by a Ping-Pong mechanism, i.e., sucrose hydrolysis followed by transfructosylation involving a fructosyl-enzyme intermediate (2).

When water acts as an acceptor, a free fructose is generated from both sucrose and levan (Reaction 2). This reaction occurs in all the levansucrase-catalyzed reactions mentioned above, but the rate is much slower when compared to a sugar acceptor. Reaction 3 occurs in the presence of an acceptor in the environment. The enzyme transfers the fructosyl residue of sucrose specifically to the C-1 OH of aldose in the acceptor. Compounds containing hydroxyl groups, such as methanol, glycerol, and oligosaccharides, can act as fructosyl acceptors. The reaction mechanism yields a nonreducing sugar compound and a series of oligosaccharides, in which the sugar molecule with one more fructose moiety remains as a major reaction product. The reaction occurs predominantly in the presence of a high concentration of fructosyl donors, such as sucrose or raffinose. Reaction 4 might be considered analogous

to Reactions 2 and 3, but differs in the regeneration of sucrose, which has a high-energy bond. The enzyme also catalyzes Reaction 5, a disproportionation reaction, in which the degree of polydispersity of levan or oligomers is modified. The above five reactions compete with one another, yielding a specific major product with some minor products, but they are predominantly controlled by environmental factors.

The enzyme recognizes sugar compounds with a  $\beta$ -1,2 linkage between glucose and fructose residues. The most abundant substrate for the enzyme in nature is sucrose. Raffinose also serves as a substrate. Levan formed by levansucrase is hydrolyzed by the enzyme itself, and the hydrolysis ceases at the branching points. The degree of levan hydrolysis depends on the enzyme source. For example, *Rahnella aquatilis* levansucrase has strong activity, but *Zymomonas mobilis* levansucrase shows very little activity even at higher temperatures (3).

Levansucrase (sucrose:2,6- $\beta$ -D fructan:6-D-fructosyltransferase, sucrose 6-fructosyltransferase) is classified EC 2.4.1.10. There are several enzymes that relate to the hydrolysis of sucrose or sucrose-originated sugar compounds: sucrase ( $\beta$ -D-fructofuranosidase, invertase, EC 3.2.1.26), dextranucrase (EC 2.4.1.5), levanase (EC 3.2.1.65), inulinase (EC 3.2.1.7), and alternansucrase (EC 2.4.1.140). A new fructosyltransferase (aldose  $\beta$ -D-fructosyltransferase, EC 2.4.1.162), which has an exceptionally high propensity to form a wide range of  $\alpha$ -(1,2)-linked disaccharides, does not form appreciable amounts of levan (4). The enzymes involved in the biosynthesis of fructan (levan and inulin) in plants are as follows:

Sucrose:sucrose 1F-fructosyltransferase (1-SST,  
EC 2.4.1.99)

Fructan:fructan 1-fructosyltransferase (EC  
2.4.1.100)

Sucrose:fructan 6-fructosyltransferase (6-SFT)

The last one, which has similar enzymatic functions with microbial levansucrases, is responsible for the production of levan in plants (5).

## II. SOURCES AND FUNCTION OF LEVANSUCRASE

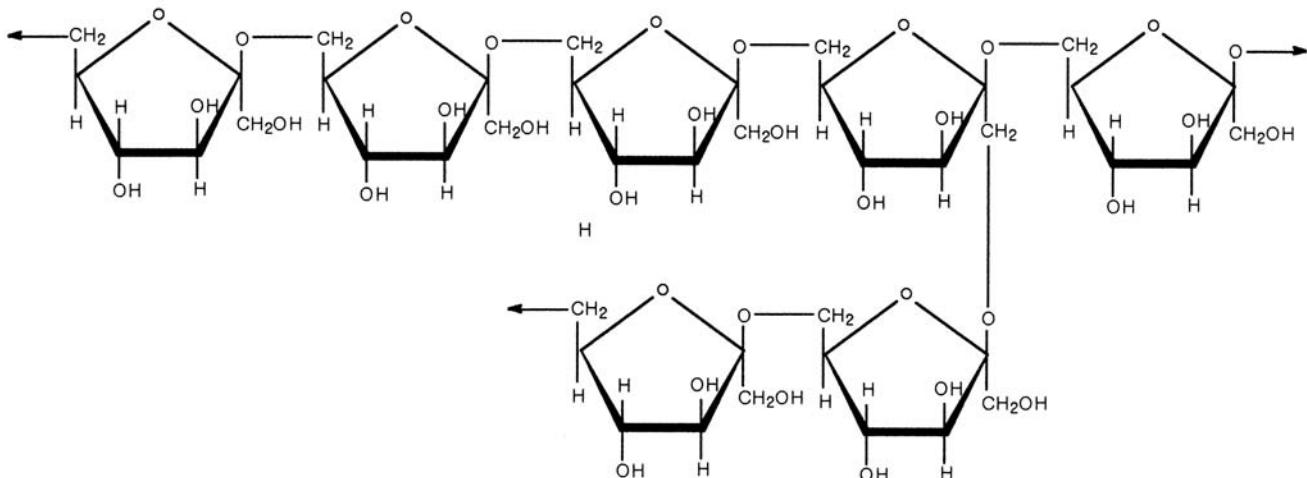

Levansucrase is found in various kinds of microorganisms and in higher plants. Levan as a product of levansucrase-type enzyme reactions is a major non-structural carbohydrate found in plants such as barley, wheat, onions, and grass. In plants, levan accumulates

in vacuoles and plays an important role in temporary storage and partitioning of assimilates and in osmoregulation. It also assists some plants in overcoming drought and cold stress (6). For example, improved drought resistance is shown upon transformation of tobacco, a species normally incapable of forming levan, with a gene encoding a bacterial levansucrase. The enzyme involved in levan biosynthesis in plants, which may be synthesized by the concerted action of a number of distinct fructosyltransferases, is not fully understood.

There are a number of microorganisms reported as levan producers beyond the genus (7). Levansucrases from some bacteria are inducible and exocellular, whereas some are constitutive and endocellular. The synthesis of levan by levansucrase in a sucrose-containing medium gives the microorganisms a mucoid morphology. Researchers have demonstrated that this mucoid structure of the microorganisms plays a role in the symbiosis (*Bacillus polymyxa*) or phytopathogenesis (*Erwinia amylovora*) of plant interactive bacteria. In addition, the enzyme also participates in the defense mechanism against environmental stress (*Bacillus subtilis*) (8). The function of levansucrase located intracellularly in some bacteria is not understood. The diversity of the enzymatic properties of levansucrase may be caused by the different biological function of each enzyme in each microorganism. Recently, the enzyme was overexpressed in *E. coli* for the mass production of levan with high yield and purity (9). An approach to produce levan in large quantity was achieved successfully in transgenic plants (10).

## III. UTILIZATION OF LEVANSUCRASE

Levan, produced by levansucrase from sucrose, consists entirely of fructose and glucose at one terminal in each molecule (Fig. 1). Many potential applications of levan in food and pharmaceutical industries exist, but the use of this polymer is not yet practical due to the lack of information about its polymeric properties needed in industrial fields. Novel applications of levan include such uses as emulsifier, formulation aid, stabilizer, thickener, surface-finishing agent, encapsulating agent, and carrier for colors or flavors and fragrances in the food industry (7). It has been reported that levan has certain biological activities, such as the promotion of infection and necrosis, tumor inhibition, and an increase in cell permeability to a cytotoxic agent (11). Calazans et al. (12) postulated that levan showed anti-tumor activity against sarcoma 180 and Ehrlich carci-

**Figure 1** Chemical structure of levan.

noma in Swiss albino mice, and hypothesized that the effect might be associated with the polymer of a specific molecular size.

In addition to the above, a novel aqueous two-phase system has been developed by mixing polyethylene glycol (PEG) and levan, which offers a potential application of levan in separation and purification of biological materials, as an alternative to PEG/dextran and PEG/salt two-phase systems (13). The enzymatic or chemical hydrolytic products of levan may be used in the food industry as sweeteners or dietary fiber: ultra-high-fructose syrups (UHFS) and  $\beta$ -(2,6)-linked fructofuranosyl oligosaccharides (7). Several microorganisms producing various levan-assimilating enzymes such as exo- or endo-type levanase, fructose dimer- or heptamer-producing levanase, and levan fructotransferase were isolated and characterized (14). Together with the difructose anhydride compounds (DFA I and III) from inulin, which are  $\beta$ -(2,1)-linked fructans found in plants, DFA IV from levan is an attractive material as low-calorie sugar, non- or anti-tooth-decaying sweetener, stabilizer, and antianemic agent in the food and pharmaceutical industries (15).

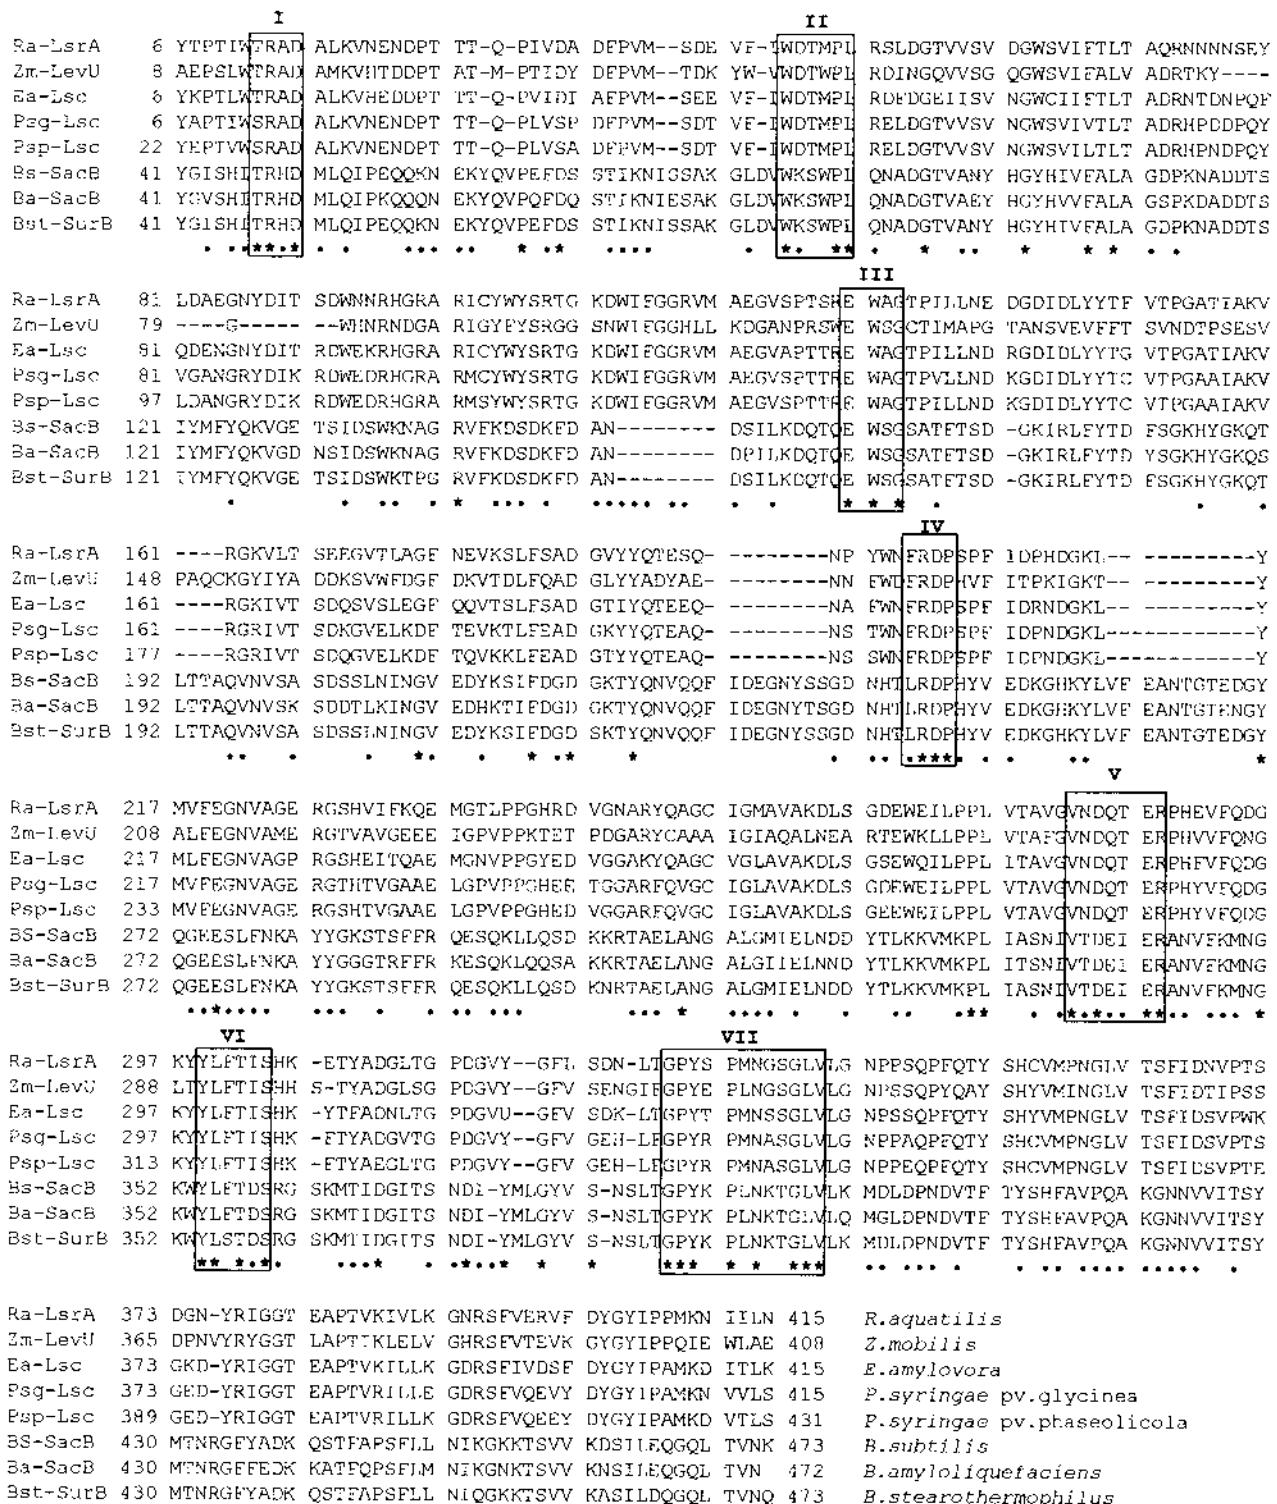

Another reason for the increasing interest in levansucrase is that the enzyme can catalyze the transfer of fructosyl residue to a variety of sugar molecules. Some of the resulting hetero-oligosaccharides have potential applications as sweeteners and probiotics (16). Currently fructo-oligosaccharides and lactosucrose, which are formed using a fungal fructosyltransferase, are available in the market as a “functional food.” Levansucrase enables the formation of a variety of

fructosyl derivatives, alkyl fructosides, which are expected to be applicable in similar or improved uses of alkyl glucoside and used as a nonionic surfactant and as raw materials for the production of sugar esters of fatty acids (17).

#### IV. GENETIC PROPERTIES OF LEVANSUCRASE

The molecular weight of bacterial levansucrases is reported to be in the range of 45–64 kDa. Several analogies in their primary structures have confirmed that a close relationship exists among levansucrases from Gram-negative bacteria. The molecular weight of levansucrases from Gram-negative bacteria is nearly the same, about 45–47 kDa, while those from Gram-positive bacteria are slightly larger (54–64 kDa).

Eight levansucrase genes from microorganisms have been cloned and characterized to date (18, 19). The deduced amino acid sequences are aligned in Figure 2. All levansucrases share several conserved regions, which are thought to be important for the enzyme activity. Although conservation is observed, dissimilarity exists depending on the source of the enzyme. Levansucrases from Gram-negative origin show relatively high similarity (> 50%), when compared with the Gram-positive bacterial enzymes. However, very little similarity (< 30%) exists among enzymes from the two sources. In the case of protein secretion mechanisms, they are also thought to be different on the basis of the presence or absence of a signal peptide.

**Figure 2** Multiple alignment of deduced amino acid sequences of bacterial levansucrases. Origins of levansucrases are indicated at the end of the sequences. Identical and similar residues in all levansucrases are indicated by asterisks. Regions considered to be important for activity are boxed (I–VII). Amino acid residues that are different between Gram-negative and Gram-positive origins are indicated by dots.

It is generally accepted that levansucrases from Gram-negative bacteria are secreted by a signal peptide independent pathway. It is plausible that the Gram-positive and Gram-negative genes diverged at an early stage of evolution and have separately evolved ever since. Although the amino acid sequences of levansucrases do not show any considerable homology to those of sucrose-related enzymes, the third (-EWS/AGT/SP/A-) and the fourth (-FRDP-) conserved regions are found in all fructosyl- and glucosyltransferases, sucrase, sucrose 6-phosphate hydrolase, and even in fructan-hydrolyzing enzymes. That the regions are preserved in all sucrose-related enzymes implies that they may be catalytically important regions for the hydrolysis of sucrose. The serine residue in the sixth region (-YLFTI/DS-) has been proposed as the putative residue of the catalytic site (20).

## V. BIOCHEMICAL PROPERTIES OF LEVANSUCRASE

The substrate specificity of levansucrase is extremely low. Sucrose and raffinose serve as fructosyl donors. The glucose moiety of sucrose can be replaced by various sugars such as D-xylose, L-arabinose, lactose, etc. Substrate specificity for the acceptors is, however, relatively broad. Several kinds of alcohol; mono-, di- or oligosaccharides; sugar alcohols; and levan are known acceptors. The specificity toward acceptor molecules differs depending on the catalytic properties of each enzyme. In *B. subtilis* levansucrase, a turnover number of 17,000 moles of sucrose per minute per mole of enzyme at 37°C and pH 6.0 was obtained (21).

### A. pH Optimum

The enzyme has a high activity at pH 5–6, and is stable at pH 4–7. No activity is observed below pH 3 and above pH 9. Thus, the enzyme has a very narrow spectrum of pH with a trapezoid-shaped curve.

### B. Optimum Temperature

The range of optimal temperature for levan formation is rather uniform (18–40°C) with the exception of the psychrophilic enzyme of *Z. mobilis* (0°C), *B. subtilis* (>10°C), and the thermostable enzyme *R. aquatilis* (50°C). One striking feature is that the synthesis of levan by levansucrase occurs far more effectively at low temperatures than at room temperature or at higher temperature, though the apparent activity deter-

mined in terms of glucose-releasing activity in the hydrolysis reaction is fairly small at lower temperatures. The enzyme is thermolabile and loses its activity at 45°C for 15 min.

Interestingly, *Z. mobilis* enzyme was most active at extreme temperatures < 10°C (9). Therefore, levan formation using *Z. mobilis* enzyme can be conducted in a stable operation and with less contamination problems.

### C. Cofactors

Sucrose is directly converted to levan by the enzyme without the need of any primer, nucleotide sugar intermediate, or sugar phosphate.

### D. Inhibitors and Activators

There are few reports on inhibitors and activators of the enzyme. The inhibition of the enzyme by glucose is a function of glucose concentration, and complete inhibition occurs at 16% glucose concentration. Tris-HCl buffer is an efficient inhibitor. The activity is inhibited slightly by EDTA, and no disulfide bonds are involved in the activity. Increased thermal stability and enhanced activity of the enzyme in the presence of Fe<sup>2+</sup> or Ca<sup>2+</sup> have been reported, with some exceptions (22). Polyethylene glycol 4000 has an activating effect by increasing the maximum velocity. The addition of levan in small quantities to the reaction mixture also stimulates the activity of levansucrase and causes the synthesis of the high molecular weight levan.

### E. Kinetic Constants

The  $K_m$  values of levansucrase from *B. subtilis* are ~20 mM for sucrose and 50 mM for the analog glucosido-sorbitoside at pH 6.0 and 37°C. The affinity constant for the short-chain levan (DP 40) acting as an acceptor-activator is 5 mM under the same conditions (21).

### F. Storage Property

The enzyme solution is stable at 4°C for several months without loss of activity. The enzyme was relatively resistant to freezing, thawing, and protease treatment.

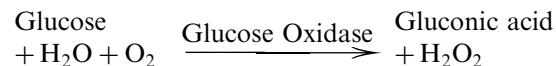

## G. Toxicity

Interestingly, the heterologous expression of levansucrase gene (*sacB*) from *B. subtilis* in Gram-negative bacteria appears to be toxic to the host (23). The lethality of gene expression was observed in a number of Gram-negative bacteria, but not in Gram-positive bacteria like *Streptomyces lividans* with the exception of *Corynebacterium glutamicum*, which contains mycolic acid in the outer membrane. This makes the bacterium behaves as Gram-negative bacterium. Thus, the use of the gene as a selection marker has been successful to a certain extent, although the molecular and biochemical basis of toxicity is still unclear.

## VI. DETERMINATION OF LEVANSUCRASE ACTIVITY

Several analytical methods can be employed for the measurement of levansucrase activity. Isotopic procedure utilizes [<sup>14</sup>C]sucrose as a substrate and measures the incorporation of isotopes into the products. This procedure is powerful when a wild-type strain with very little activity is employed as an enzyme source. The measurement of the weight of dried levan that is formed by the enzyme reaction is conducted after ethanol precipitation of the reaction mixture. Another method for the determination of levan content, which gives a linear curve at low concentrations, is to measure the optical density at visible range (450–550 nm), corresponding to the turbidity of the reaction mixture generated by the formation of levan. By paper and TLC chromatographic analyses, one can distinguish the polymeric products (nonmobile), oligomeric products, substrate, and glucose (byproducts), qualitatively or quantitatively, after visualization. Sucrose hydrolysis is commonly related to determination of levansucrase activity. The methods established are based on the fact that glucose is formed stoichiometrically in relation to the amount of fructose incorporated into products. The amount of glucose generated by enzymatic reaction can be assayed quantitatively by colorimetric enzymatic analyses (18). The enzymatic analysis, which is convenient, rapid, and highly accurate, is preferred. In this method, the reaction mixture is incubated at 37°C, at which the hydrolysis activity of levansucrase is more active than the polymerization activity (transfructosylation activity). It is followed by the coupled reactions of glucose oxidase and peroxidase toward the liberated glucose.

### First reaction:

### Second reaction:

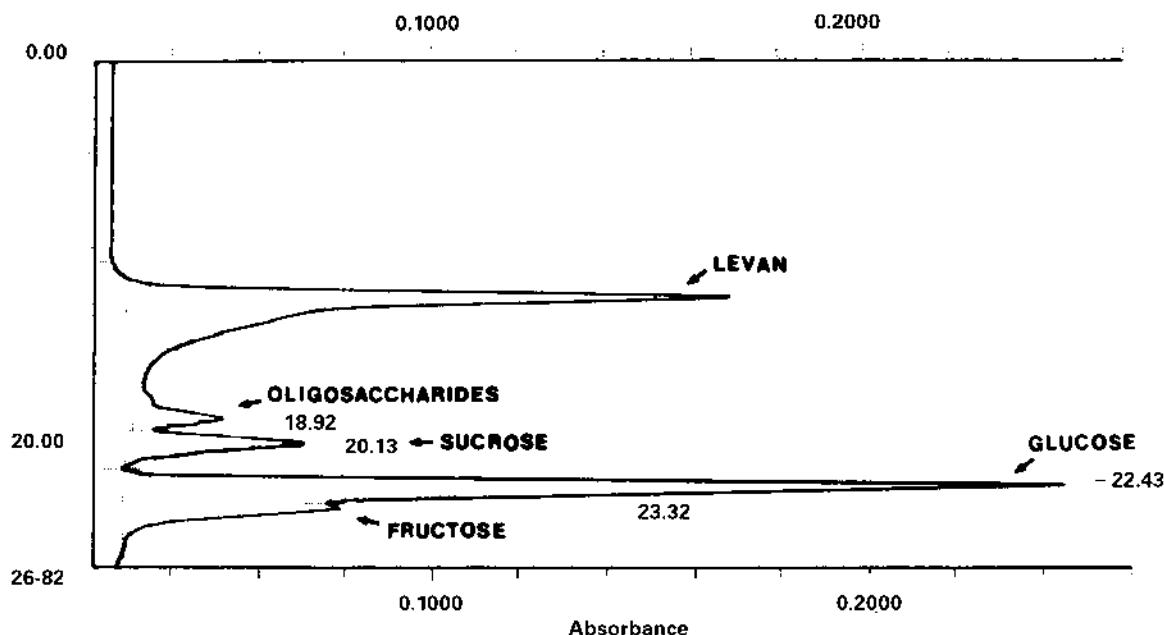

The assay is commercially available as a kit from many biological-product manufacturing companies. Alternatively, the Somogy-Nelson method could be employed. One unit of enzyme activity is defined as the amount of enzyme releasing 1 μmol of glucose per min. The HPLC method is commonly employed for the quantitative determination of all components in the reaction mixture, including levan, oligosaccharides, sucrose, fructose, and glucose. The method is described here in detail (24).

### A. Reagents

1. Substrate solution: 100 mL solution of 1% sucrose and 0.05 M acetate buffer, pH 6.0, is prepared and stored in refrigerator. The solution is stable for several months.
2. Conditions: The analysis is conducted by HPLC (Gold Systems, Beckman) with a refractive index detector and Shodex Ionpack KS-820 column (Showa Denko Co., Japan). Deionized water is used as a mobile phase at a flow rate of 0.4 mL/min.

### B. Procedure

One milliliter reaction mixture containing 1% sucrose in 0.05 M acetate buffer and enzyme (1–3 units) is incubated for 30 min. The incubation temperature depends on the enzyme source: 10°C for *Z. mobilis*, and 20°C for *R. aquatilis*. The reaction can be terminated by adjusting the pH of the reaction mixture to an alkaline range (above pH 9) with 10 mM NaOH solution. Subsequently, the mixture is filtered using a 0.45 μm pore size membrane filter and analyzed by HPLC. Oligosaccharide content is determined by using the calibration curve of raffinose as a standard. Under these conditions, a highly polymerized product (levan) and glucose are formed as major reaction products. A small amount of free fructose, oligosaccharides, and the remaining sucrose is also detected (Fig. 3). The oligosaccharide formed by levansucrase purified from *Z. mobilis* has been identified mainly as 1-ketose (25). Sugar components and linkage type of the highly poly-

**Figure 3** HPLC analysis of the reaction products formed by levansucrase with sucrose. Chromatographic conditions are described in the text. (From Ref. 9.)

merized product are determined by acid hydrolysis, methylation, and NMR shift experiments (7).

## VII. PURIFICATION

Bacterial levansucrases seem to attach on the outer surface of the membrane as well as secreted extracellularly (7, 26). In some cases, the enzyme is intracellular, but its function has not been illustrated. The profile of enzyme activity from *Z. mobilis* culture shows that the activity is maximal at the late logarithmic or early stationary phase of cells grown in sucrose medium. The initial recovery of levansucrase from the supernatant of cell cultures grown at the late logarithmic phase by ammonium precipitation is somewhat difficult. This is likely due to the low yield of proteins and the presence of polymeric compound (levan) in the culture medium, in which levansucrase is inducibly produced in the presence of sucrose. To circumvent this, the preparation of cell-associated levansucrase was employed by Pabst et al. (26). The enzyme bound to levan which is encapsulated outside of the stationary-phase grown cells can be recovered in significant amounts. This method provides an additional advantage of reducing the number of contaminated proteins.

## VIII. PURIFICATION OF LEVANSUCRASE FROM *Z. MOBILIS*

### A. Crude Enzyme

*Z. mobilis* ATCC10988 is grown in a rich medium consisting of (per liter); 50 g sucrose, 20 g yeast extract and 1 g potassium phosphate (monobasic). Cells are cultivated in a 20-L jar-fermentor (working volume 15 L) at 30°C. After 24 h, cells are harvested and washed briefly with distilled water. The pellets from 1 L culture broth are resuspended in 50 mL of 100 mM phosphate buffer (pH 6.0) and incubated at 30°C for 30 min with mild shaking to release the enzyme from the cell surface and the supernatant is saved. Cell pellets are washed once and mixed with the supernatant to yield the crude enzyme.

### B. Purification Procedures

The crude enzyme is purified according to the following procedure: first ammonium sulfate precipitation (80% saturation), ion exchange chromatography, hydroxyapatite chromatography, second ammonium sulfate precipitation (50% saturation), and gel filtration chromatography. Phosphate buffer (20 mM, pH 6.0) is used throughout the purification procedure. A

**Table 1** Summary of Levansucrase Purification Steps from *Z. mobilis*

Step	Volume (mL)	Units (total)	Protein (mg/mL)	Spec. Act. (U/mg)	Yield (%)	Purification (fold)
Cell washed solutions	1300	— <sup>a</sup>	0.35	—	—	—
1st $(\text{NH}_4)_2\text{SO}_4$	115	—	1.28	—	—	—

Source: Ref. 24.

summary of the purity and recovery of the enzyme is given in Table 1. As a result of chromatography on DEAE-Toyopearl 650 M column, two distinct peaks of sucrose-hydrolyzing activity can be seen (Fig. 4). The first peak is responsible for levansucrase; the second one, for sucrase. After the successive purification steps of the protein by hydroxyapatite chromatography and second ammonium sulfate purification, the small amount of contaminated proteins can be eliminated from the enzyme solution by gel filtration chromatography (FPLC). A single band is observed when

the purified enzyme is subjected to SDS-PAGE. The enzyme can be purified from culture broth 18.3-fold to a specific activity of  $3.75 \text{ U mg}^{-1}$  protein, with a yield of 16.5%. The molecular weight of the enzyme is  $\sim 91,000$  by Superose 12 gel filtration, and 46,000 by SDS-PAGE, indicating that levansucrase is a dimer. The optimum pH for the enzyme activity is around pH 4.0 for sucrose hydrolysis, and is around pH 5.0 for levan formation (24).

A method monitoring the presence of sucrose-splitting enzymes has been developed using electrophoresis and zymogram staining with 2,3,5-triphenyltetrazolium chloride (TTC) reagent prior to purification (27). Levansucrase activity can be easily distinguished by the formation of a white and opalescent band. The use of periodic acid Schiff (PAS) reagent to stain levan formed by levansucrase on polyacrylamide gel has also been developed (28). Some enzymes form large aggregates in nature or during purification, causing the loss of enzymes and difficulties in purification. A small amount of unknown carbohydrates may be responsible for the formation of aggregates. This problem can be overcome by the treatment with Triton X-100 (29). In the case of the *Z. mobilis* enzyme, such aggregation is not observed during purification. To eliminate the copurification of other enzymes with sucrose-splitting activity, the levan formation activity is monitored using raffinose as a substrate, which does not normally serve as a substrate for glucosyltransferase or dextran-sucrase.

**Figure 4** DEAE-anion exchange chromatogram of the extracellular saccharolytic enzymes of *Z. mobilis* ZM1. Cell washed solution from *Z. mobilis* ZM1 is put on the column ( $2.5 \times 30 \text{ cm}$ ) pre-equilibrated with 20 mM phosphate buffer (pH 6.8), and eluted with NaCl gradient (0–0.5 M). Levansucrase activity is monitored by sucrose hydrolysis activity and the type of enzymes contained in fractions is monitored by electrophoresis and zymogram staining with TTC reagent. (From Ref. 24.)

## Cyclodextrin Glycosyltransferase

Lubbert Dijkhuizen and Bart A. van der Veen

*University of Groningen, Haren, The Netherlands*

### I. INTRODUCTION

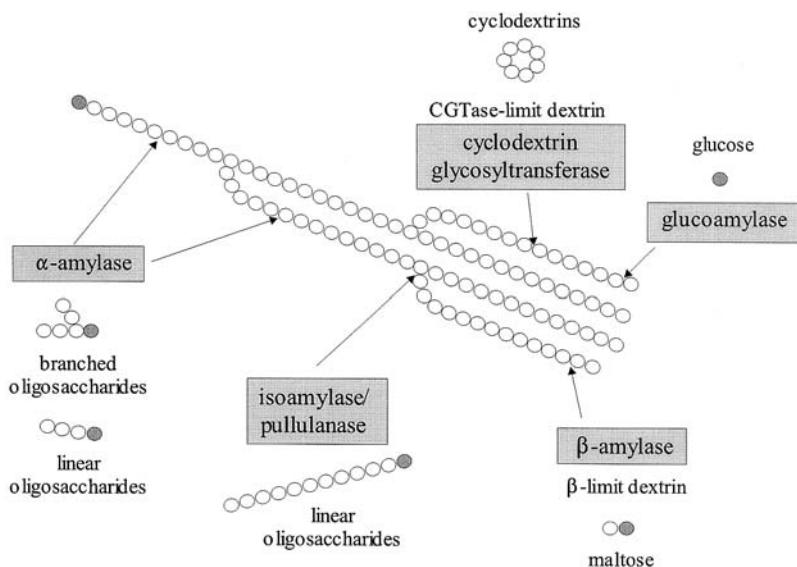

Cyclodextrin glycosyltransferase (CGTase) is a member of the  $\alpha$ -amylase family of glycoside hydrolases (family 13) (1). Enzymes of this family display a wide diversity in reaction specifications, catalyzing at least 18 different reactions. Whereas amylases generally hydrolyze  $\alpha(1\text{-}4)$  glucosidic bonds in starch molecules, CGTases mainly catalyze transglycosylation reactions. Structure/function relationships in the  $\alpha$ -amylase family have been studied extensively, clarifying the mechanistic basis of the unique activities of CGTase (2–5).

Starch and derived linear or cyclic oligosaccharides are substrates in the CGTase-catalyzed reactions. Starch consists of two types of glucan polymers: amylose and amylopectin. Potato starch for instance consists of 20% amylose and 80% amylopectin. Amylose consists mainly of linear chains of  $\alpha(1\text{-}4)$ -linked glucose residues. Amylopectin is a highly branched  $\alpha(1\text{-}4)$  glucan polymer (approximately  $\alpha(1\text{-}6}$  linkage per 20 glucose residues).

Figure 1 shows an overview of enzymes of various families active on starch (amylopectin in this case). Many starch-degrading enzymes are hydrolytic, cleaving the linkages in starch; the cleavage product subsequently reacts with water, resulting in a new reducing end. These enzymes can be roughly divided into amylases, hydrolyzing  $\alpha(1\text{-}4)$  linkages, and debranching enzymes, hydrolyzing  $\alpha(1\text{-}6)$  linkages. Examples of debranching enzymes are isoamylase (EC 3.2.1.68)

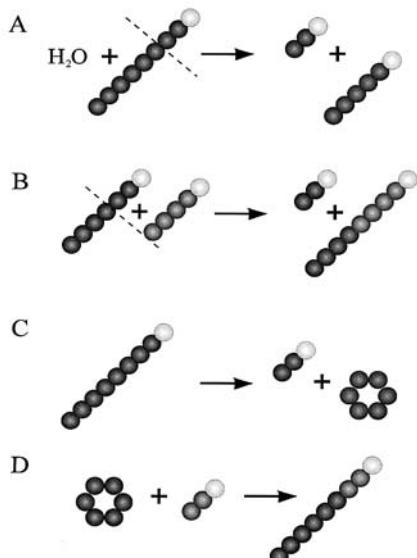

and pullulanase (EC 3.2.1.41), both members of family 13. Amylases can be further subdivided into endo- and exoacting enzymes. A typical endoacting enzyme is  $\alpha$ -amylase (EC 3.2.1.1), cleaving  $\alpha(1\text{-}4)$  bonds randomly in the starch molecule, producing (branched) oligosaccharides of various lengths. Exoacting amylases such as  $\beta$ -amylase (EC 3.2.1.2, family 14 of glycoside hydrolases) cleave  $\alpha(1\text{-}4)$  bonds at the nonreducing end of the starch molecule and hence produce only low-molecular-weight products from starch (mostly glucose or maltose). Most of these enzymes are incapable of bypassing  $\alpha(1\text{-}6}$  linkages; degradation of branched substrates therefore remains incomplete, leaving high-molecular-weight compounds (limit dextrans). In enzymes also able to cleave  $\alpha(1\text{-}6}$  linkages—for instance, glucoamylase (EC 3.2.1.3, family 15 of glycoside hydrolases) and  $\alpha$ -glucosidase (EC 3.2.1.20)—this reaction is slow compared to hydrolysis of  $\alpha(1\text{-}4)$  bonds.

CGTase (EC 2.4.1.19) is a unique member of the  $\alpha$ -amylase family. Its main products when acting on starch are cyclodextrins and highly branched high-molecular-weight dextrans (CGTase limit dextrans). CGTase has been identified in bacteria belonging to the genera *Bacillus*, *Clostridium*, *Klebsiella*, *Micrococcus*, *Thermoanaerobacter*, and *Thermoanaerobacterium* (6), and in a single archaeon, *Thermococcus* (7). CGTase is present as an extracellular enzyme and functions in the initial attack on this polymeric substrate. These bacteria subsequently use the cyclodextrins produced as carbon and energy

**Figure 1** Action of enzymes involved in the degradation of starch. (●) Glucose molecule with a reducing end; (○) glucose molecule without a reducing end. Arrows indicate preferred cleaving point on the starch molecule. (From Ref. 70.)

sources for growth. This involves a cell-associated cyclomaltodextrinase (EC 3.2.1.54), yielding glucose, maltose, and maltotriose (8). Glucose is metabolized intracellularly via glycolysis.

**Figure 2** Schematic representation of the CGTase-catalyzed reactions. Circles represent glucose residues; the white circles indicate the reducing end sugars. (A) hydrolysis; (B) disproportionation; (C) cyclization; (D) coupling. (From Ref. 65.)

CGTase enzymes generally display only a relatively low starch hydrolytic activity (Fig. 2A). They mainly catalyze transglucosylation reactions that can be described as:  $G(n) + G(m) \rightarrow G(n-x) + G(m+x)$ , in which  $G(n)$  is the donor and  $G(m)$  the acceptor oligosaccharide consisting of  $n$  and  $m$  residues, respectively. Disproportionation (Fig. 2B) can be regarded as the default reaction, and is also catalyzed by several other members of the  $\alpha$ -amylase family (e.g., 4- $\alpha$ -glucanotransferase, EC 2.4.1.25). The specific CGTase catalyzed reaction is the cyclization reaction (Fig. 2C) in which the part of the donor that has been cleaved off also acts as the acceptor, resulting in formation of a cyclodextrin. This reaction can be described as:  $G(n) \rightarrow \text{cyclic } G_x + G(n-x)$ . The reverse reaction, coupling, is also catalyzed by the enzyme (Fig. 2D).

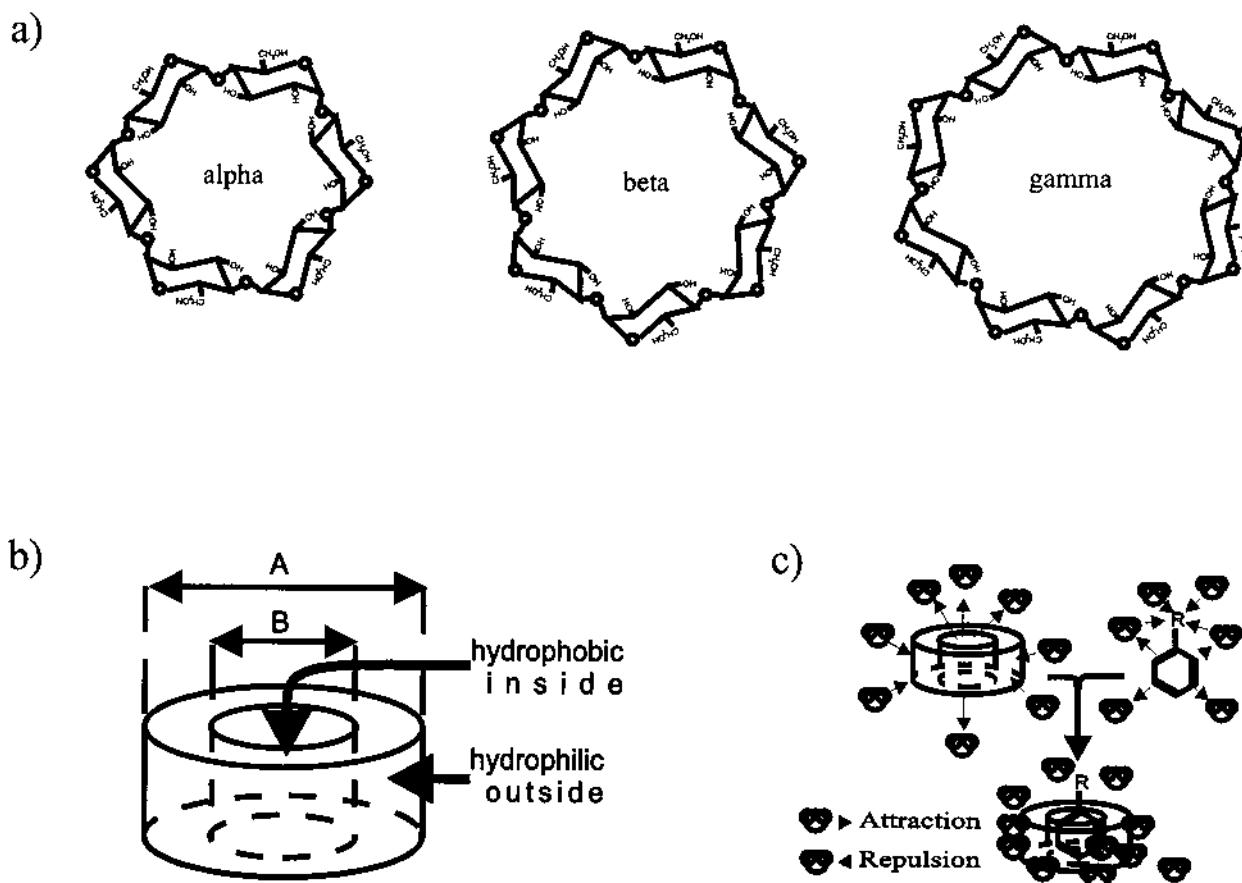

## II. APPLICATIONS OF CGTASE

The cyclodextrins produced by CGTases from starch via the cyclization reaction provide the basis for most of the applications of CGTase in the food industry. The CGTase-catalyzed coupling and disproportionation reactions, allowing synthesis of modified oligosaccharides from starch or cyclodextrins and alternative acceptor substrates, are drawing increasing attention as well. Applications of CGTase limit dextrans are also being explored.

Cyclodextrins are torus-shaped molecules of cyclic  $\alpha$ (1-4)-linked oligosaccharides mainly consisting of six, seven, or eight glucose residues ( $\alpha$ -,  $\beta$ -, or  $\gamma$ -cyclodextrin, respectively) (Fig. 3). In cyclodextrins the secondary hydroxyl groups (C2 and C3) are located on the wider edge of the ring, and the primary hydroxyl groups (C6) on the other edge; the apolar C3 and C5 hydrogens and etherlike oxygens are on the inside of the toruslike molecules. This results in a molecule with a hydrophilic outside, which can dissolve in water, and an apolar cavity, which provides a hydrophobic matrix, described as a "microheterogeneous environment" (9). Cyclodextrins form inclusion complexes with a wide variety of hydrophobic guest molecules. One or two guest molecules can be entrapped by one, two, or three cyclodextrins (10). The most important parameter for complex formation with hydrophobic compounds or functional groups is their three-dimen-

sional form and size. The driving force is the entropic effect of displacement of water molecules from the cavity (11). Another possibility is that this water causes strain on the cyclodextrin ring, which is released after complexation, producing a more stable, lower energy state (9, 11). Other parameters for complexation are charge or polarity of the guest compound and competition with other molecules from the medium. Because the inclusion complexes are quite stable, they can be separated from the medium by crystallization (12). Entrapment in cyclodextrins often results in changes in the chemical and physical properties of the guest molecules, suitable for applications in the food industry. Numerous other cyclodextrin applications, outside the scope of this review, are in analytical chemistry, agriculture, and the pharmaceutical field (5).

In the food industry, cyclodextrins find a range of applications. Cyclodextrins have a texture-improving

**Figure 3** Structure and properties of cyclodextrins. (a)  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrins; (b) 3D form and properties of cyclodextrins; a: 14.6, 15.4, and 17.5 Å for  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrins, respectively; b: 4.7–5.3, 6.0–6.5, 7.5–8.3 Å for  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrins, respectively; (c) formation of inclusion complexes of cyclodextrins and hydrophobic molecules. (From Ref. 71.)

effect on pastry and on meat products. They reduce bitterness, ill smell, and bad taste, and stabilize flavors when subjected to long-term storage. Emulsions in mayonnaise, margarine, or butter creams are stabilized with  $\beta$ -cyclodextrin. Furthermore,  $\beta$ -cyclodextrin is used to remove cholesterol from milk, yielding dairy products low in cholesterol. Marketed products involve reduced cholesterol egg yolks (Simply Eggs) by Michael Foods in the United States, cholesterol-reduced butter under *Natural* and *Ballade* trademarks by Entremont in France and Corman in Belgium, and a range of flavored salts (*Compack*) in Hungary (13). CGTase is also used in preparation of doughs for baked products; its incorporation into doughs was claimed to increase the volume of the baked product (14).

Conversion of amylose by CGTase not only yields cyclodextrins but initially also larger-size cyclic  $\alpha$ (1-4)-glucans with a degree of polymerization ranging from nine to  $> 60$  (15). Similar observations have been made with *B. stearothermophilus* branching enzyme (16) and potato disproportionating enzyme (17). These new starch structures combine various interesting properties—low viscosity, high solubility, and a high molecular weight—and are expected to find applications in the food industry (18).

The CGTase coupling and disproportionation reactions allow synthesis of a range of novel glycosylated compounds from starch or cyclodextrins as donor substrates and various acceptor molecules (19–21). A commercial example is glycosylation of the intense sweetener stevioside. This bitter compound is isolated from leaves of the plant *Stevia rebaudiana*; it has a low solubility. Glycosylation decreases bitterness and increases solubility (6).

Like most starch-degrading enzymes, the CGTase from *B. macerans*, which is used for the commercial production of cyclodextrins (22), is poorly active on native starch with its well-organized granular structure held together by internal hydrogen bonds. Heating in water (jet cooking) weakens these hydrogen bonds and causes swelling and gelatinization (23), resulting in a very viscous starch solution when performed at starch concentrations of industrial interest. This initial processing step is performed at temperatures up to 105–110°C, and  $\alpha$ -amylase is added in order to liquefy the starch to make it suitable for incubation at the lower temperatures (55°C) required for the CGTase-catalyzed production of cyclodextrins. Unfortunately, the  $\alpha$ -amylase used for liquefaction produces maltodextrins, which will act as acceptor molecules in the coupling reaction catalyzed by CGTase, severely reducing

cyclodextrin yields (6). More recently, CGTases have been characterized from thermophilic anaerobic bacteria belonging to the genera *Thermoanaerobacter* (12, 24) and *Thermoanaerobacterium* (25) which are active and stable at high temperatures and low pH values and are able to solubilize starch, thereby eliminating the need for  $\alpha$ -amylase pretreatment without any traces of low-molecular-weight oligosaccharides produced in the initial stages of the reaction (26). The use of these thermostable CGTases has the added advantage that the total cyclodextrin production time can be shortened (6). The *Thermoanaerobacter* CGTase (maximal activities at 90°C and pH 5.8) found commercial application in 1996.

### III. CGTASE PROTEIN PROPERTIES

At present, at least 38 CGTases have been identified and purified, and the corresponding genes characterized. They are all monomeric enzymes, generally 680–685 amino acids in size, yielding molecular weights of ~75 kDa. CGTases show a clear similarity in amino acid sequence, ranging from 47% to 99% homology.

Enzymes of the  $\alpha$ -amylase family share only ~30% overall amino acid sequence similarity. Four highly conserved regions have been identified in members of this family (Fig. 4). All four regions contain completely invariant amino acid residues within the  $\alpha$ -amylase family, and the functions of most of these have been elucidated by x-ray crystallography, site-directed mutagenesis, and chemical modification of various members of this family. These residues are directly involved in catalysis, either through substrate binding, bond cleavage, transition state stabilization, or as ligands of a calcium-binding site present near the active site. Three carboxylic acid groups, one glutamic acid and two aspartic acid residues, are essential for catalytic activity in  $\alpha$ -amylases and CGTases (Asp229, Glu257, and Asp328 in CGTase from *B. circulans*) (27, 28). Two conserved histidine residues, His140 and His327 (CGTase numbering), are involved in substrate binding and transition state stabilization (29, 30). A third histidine, present only in some  $\alpha$ -amylases and CGTases (His233), is involved in substrate binding and acts as a calcium ligand with its carbonyl oxygen (31, 32). Arg227 is important for the orientation of the nucleophile (Asp229; see below) (30). The role of Asp135 is not clear, but it is in close proximity to the catalytic site. Asn139 again is a calcium ligand.

In contrast to the limited similarity observed in a primary structure, the three-dimensional structures of

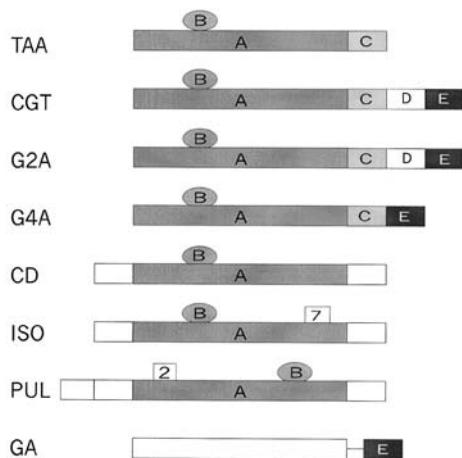

**Figure 4** Amino acid sequence alignment of the four conserved regions in members of the  $\alpha$ -amylase family. TAA:  $\alpha$ -amylase, *Aspergillus oryzae* (Taka-amylase A) (33); CGT: CGTase, *Bacillus circulans* strain 251 (31); CD: cyclodextrinase, *Klebsiella oxytoca* (72); PUL: pullulanase, *Klebsiella aerogenes* (73); ISO: isoamylase, *Pseudomonas amylofera* (74). The residues are numbered according to the CGTase from *B. circulans* strain 251. An asterisk indicates amino acid identity; a dot indicates amino acid similarity.

$\alpha$ -amylases (33) and CGTases (31, 34–37) are quite similar.  $\alpha$ -Amylases generally consist of three structural domains, A, B, and C, while CGTases show a similar domain organization with two additional domains, D and E (Fig. 5). Domain A contains a highly symmetrical fold of eight parallel  $\beta$ -strands arranged in a barrel encircled by eight  $\alpha$ -helices. This so-called  $(\beta/\alpha)_8$ -or TIM-barrel catalytic domain of 300–400 residues is present in all enzymes of the  $\alpha$ -amylase family (38). The  $(\beta/\alpha)_8$  barrel was first found in the structure of chicken muscle triose phosphate isomerase (39), but it has been shown to be widespread in functionally diverse enzymes (40). Several prolines and glycines flanking loops connecting the  $\beta$ -strands and  $\alpha$ -helices have been found to be highly conserved in these enzymes (41). The catalytic and substrate-binding residues conserved in the  $\alpha$ -amylase family are located in loops at the C-terminal of  $\beta$ -strands in domain A. The loop between  $\beta$ -strand 3 and  $\alpha$ -helix 3 of the catalytic domain is rather large and is regarded as a separate structural domain. This B-domain consists of 44–133 amino acid residues and contributes to substrate binding. The C-domain is ~100 amino acids long and has an antiparallel  $\eta$ -sandwich fold. Domain C of the CGTase from *B. circulans* strain 251 contains one of the maltose-binding sites (MBS) observed in the structure derived from maltose-dependent crystals (see below) (31). This MBS is involved in raw starch binding (42); the C-domain thus contributes to substrate binding. This C-domain may determine bond specificity, since in enzymes hydrolyzing or forming  $\alpha(1,6)$  bonds (e.g., pullulanase, isoamylase, branching enzyme) the A-domain is followed by a different domain (Fig. 5) (43). The D-domain is ~90 amino acids in size and is almost exclusively found in CGTases; it carries an immunoglobulin fold but its function remains unknown. The E-domain is more widespread in starch degrading enzymes. In enzymes of the  $\alpha$ -amylase family it is present as the C-terminal

domain; in glucoamylases (family 15 of glycoside hydrolases) it is attached to the C- or N-terminus of the catalytic domain via a glycosylated linker (Fig. 5). The E-domain consists of ~110 amino acids and is responsible for the adsorption of the enzyme onto granular starch (see below).

All CGTases studied not only catalyze the three transglycosylation reactions but also display hydrolytic activity (Fig. 2). Incubation of CGTase with starch thus may not only yield cyclodextrins but also linear products. In some cases this has resulted in misidentification of CGTase enzymes. The *Thermoanaerobacterium thermosulfurigenes* EM1 CGTase was initially identified as an  $\alpha$ -amylase because of its relatively high hydrolytic activity (44). Further studies showed that it possesses a clear cyclization activity, as in other CGTases; amino acid alignments with other CGTases also show a high overall sequence similarity, with all five domains present (25). The CGTase converts starch not only into cyclodextrins (35%) but also into linear sugars (11%) (45). In contrast, the CGTase from *B. circulans* strain 251 has minor hydrolytic activity; this enzyme exclusively forms cyclodextrins (46).

Recently the 3D structure of the *Bacillus stearothermophilus* “maltogenic”  $\alpha$ -amylase Novamyl has been determined (47). Unlike the conventional  $\alpha$ -amylases of family 13, Novamyl exhibits the five-domain structure associated with CGTase enzymes (Fig. 5, G2A). Its overall sequence similarity with CGTase is high, and the 3D structures are very similar. Most interestingly, Novamyl contains a 5 amino acid residue insertion in the B-domain, partially enclosing the active site at the -3 subsite. The absence of this insertion in CGTases allows for additional subsites, with up to -7 characterized crystallographically (32). Novamyl thus is either an  $\alpha$ -amylase or a CGTase with unusual properties. Studies of evolutionary relationships within the  $\alpha$ -amylase family have provided evidence that

**Figure 5** Domain level organization of starch degrading enzymes. CGT: CGTase, *Bacillus circulans*; G2A: maltogenic  $\alpha$ -amylase, *Bacillus stearothermophilus*; G4A: maltotetraose forming  $\alpha$ -amylase, *Pseudomonas stutzeri*; TAA:  $\alpha$ -amylase, *Aspergillus oryzae* (Taka-amylase A); CD: cyclodextrinase, *Klebsiella oxytoca*; ISO: isoamylase, *Pseudomonas amylofera*; PUL: pullulanase, *Klebsiella aerogenes*; GA: glucoamylase (family 15 of glycoside hydrolases) from *Aspergillus niger*. (From Ref. 43.)

CGTase enzymes evolved from  $\alpha$ -amylases (48). Novamyl may thus be an example of an enzyme at an intermediary stage in between “true”  $\alpha$ -amylases and “true” CGTases. It appears more likely, however, that Novamyl is a “true” CGTase with a few essential mutations modifying product specificity.

#### IV. PROPERTIES OF CGTASE ENZYMES

##### A. Catalytic Mechanism of the $\alpha$ -Amylase Family

The reactions catalyzed by CGTase and other enzymes of the  $\alpha$ -amylase family proceed with retention of the substrate’s anomeric ( $\alpha$ -)configuration. Since each substitution at a chiral center results in inversion of configuration, catalysis must proceed through a double displacement reaction (49). The first step involves a protonation of the glycosidic oxygen by a general acid catalyst, creating an oxocarbonium transition state which subsequently collapses into an intermediate (50–52). This intermediate is attacked by a water nucleophile (or the C4-OH at the nonreducing end of another oligosaccharide in case of transglycosylases, e.g., CGTase) in the second step, assisted by the base form of the acid catalyst. The mechanistic roles of the

three carboxylic amino acids in CGTase have been clarified by x-ray crystallographic studies with acarbose, a potent pseudotetraose inhibitor, bound in the active site (28). Glu257 (CGTase numbering) is the general acid catalyst, acting as proton donor; Asp229 serves as the nucleophile, stabilizing the intermediate; and Asp328 has an important role in substrate binding. For retaining enzymes the intermediate either could be an oxocarbonium ion which is electrostatically stabilized by a carboxylate, or involves formation of a covalent bond, in which one of the catalytic aspartates is presumed to act as a nucleophile. Although initially the nature of the intermediate was disputed, it is now generally accepted that the reaction proceeds via a covalent intermediate. Clear evidence for a covalent glycosylenzyme intermediate in family 13 has been obtained from rapid trapping studies with natural substrates. Low-temperature  $^{13}\text{C}$  NMR experiments have provided evidence for the formation of a  $\beta$ -carboxylacetal ester covalent adduct between maltotetraose and porcine pancreas  $\alpha$ -amylase (53). Conclusive evidence recently came from experiments involving trapping of a covalent intermediate with 4-deoxymaltotriosyl  $\alpha$ -fluoride as a substrate in the virtually inactive Glu257Gln mutant of *B. circulans* 251 CGTase (54) and the x-ray crystallographic structure of the enzyme with the covalently linked intermediate (30).

##### B. Substrate Binding in CGTases

The first important step in enzyme catalysis is binding of the substrate. In several starch-degrading enzymes a separate domain responsible for adsorption onto raw starch has been found. Evidence for a starch-binding site in CGTases separate from the active site was presented (55), and fusion of the E-domain of the *Bacillus macerans* CGTase to  $\beta$ -galactosidase demonstrated that it can indeed function as a starch-binding domain (56). The function of the E-domain has been studied in more detail with the *B. circulans* strain 251 CGTase. High concentrations of maltose are required for crystallization of this protein (57). Three maltose-binding sites (MBS) were observed at the protein surface, two of which (MBS1 and MBS3) contribute to intermolecular crystal contacts. MBS1 and MBS2 are both located on the E-domain, suggesting a role in the raw starch-binding function of this domain (31). Indeed, mutational studies revealed that MBS1 is important for (raw) starch binding, while MBS2 assists in guiding the linear starch chains into the active site via a groove at the surface of the CGTase protein (see below) (31, 42). These CGTase E-domain MBS sites interact

strongly with cyclodextrins and oligosaccharides (58). Recent studies have revealed that the raw starch-binding domain also functions in the disruption of the structure of granular starch (59).

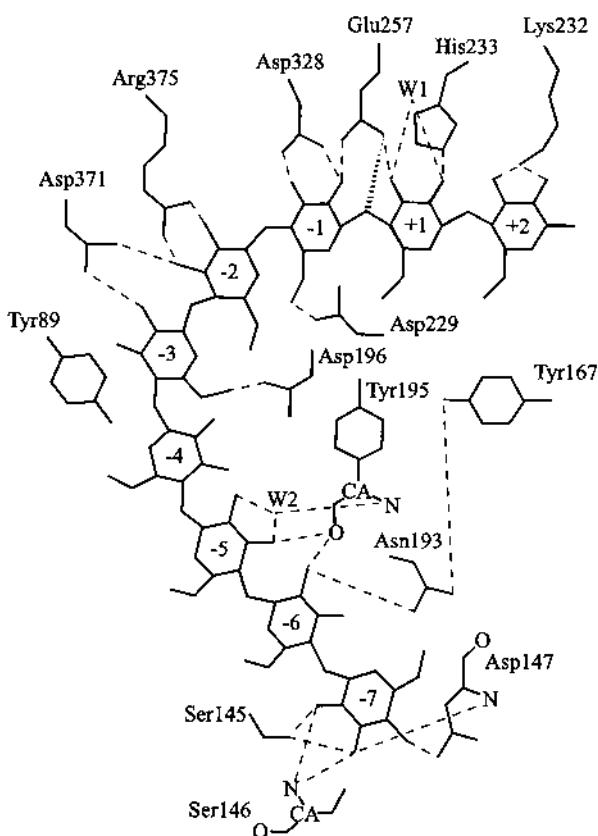

The A-domain contains the catalytic residues of CGTases, while domain B is involved in substrate binding. X-ray crystallographic studies have revealed a groove on the surface of these enzymes formed on one side by loops of the A-domain and on the other side by the B-domain. In crystal structures of CGTase from *B. circulans* strain 251 (31), where maltose molecules serve as contact points between the enzyme molecules in the crystals, the functionality of this groove in substrate binding has been shown nicely. From soaking experiments with the CGTase from *B. circulans* strain 251 the structure of this enzyme with a maltononaose inhibitor was obtained (Fig. 6), revealing in

more detail the mode of substrate binding in the groove (32). The substrate binding sites are numbered +2 to -7 [numbering according to Davies et al. (60)], with the catalytic site between sites +1 and -1. The nonreducing end of the oligosaccharide is bound at subsite -7, which agrees with the formation of mainly  $\beta$ -cyclodextrin from starch by the enzyme. Factors determining cyclodextrin product specificity in CGTases are discussed in more detail by Van der Veen et al. (4). The glucose residue at subsite -7 is located at the end of the substrate binding groove, interacting with amino acid residues of the B-domain. The glucose residues bound at subsites +1 and -1 only interact with amino acids conserved in the whole  $\alpha$ -amylase family.

### C. Effects of pH and Temperature on CGTase Activity

CGTase enzymes have been found in both neutrophilic and alkaliphilic bacteria (6, 61, 62). The optimum pH for activity is generally around pH 5–6. CGTase of the alkaliphile *Bacillus* sp. 1011 also shows maximum activity at pH 5.5, but its pH activity profile is very broad; the activity at pH 8.0 is 90% of that at pH 5.5. The mutation Phe283Leu shifted the pH curve over both acidic and alkaline pH ranges (63). Mutant His327Asn has strongly reduced activity in the alkaline pH range, down to 30% of that at pH 5.5 (29). The low and the high slopes of the pH optimum curve of *T. thermosulfurigenes* EM1 CGTase clearly changed by mutations close to the catalytic residue Glu257, the proton donor in the first step of the cyclization reaction (45). The pH optimum curve of CGTase thus may be determined by the protonation state of Glu257. Changes in the environment of Glu257 before and after substrate binding can account for the broad pH optima of CGTase.

CGTase enzymes have been characterized from both mesophilic and thermophilic sources. The *Thermoanaerobacter* sp. (12) and *Thermoanaerobacterium thermosulfurigenes* (25) CGTases display maximal activities at 80–90°C and pH 5.5–6.0. The *Thermococcus* sp. strain B1001 CGTase has a temperature optimum at 90–100°C and a pH optimum at 5.0–5.5 (7). Substrate (starch) and calcium ions generally stabilize these enzymes. Fortunately, five different CGTase 3D structures have been solved (31, 34–37), with amino acid sequence similarities > 60%, of which two are thermostable enzymes. These structures were extensively compared by Knegtel et al. (36), in combination with biochemical

**Figure 6** Schematic representation of the hydrogen bonds between the *Bacillus circulans* 251 CGTase and a maltononaose inhibitor bound at the active site. The subsites are numbered according to the general subsite labeling scheme recently proposed for all glycoside hydrolases (60). (From Ref. 32.)

data, identifying many sites contributing to thermostability. Uitdehaag and Dijkstra (64) extended these studies, focusing on the atomic B factors in any of the five CGTase x-ray structures. They concluded that Nature has chosen a strategy of stabilizing flexible loops near the active site to develop more thermostable CGTase enzymes.

#### D. Kinetic Analysis of CGTase Transglycosylation Reactions

CGTase catalyzes three transglycosylation reactions (cyclization, coupling, disproportionation; Fig. 2) with starch and derived products. In the industrial production process for cyclodextrins, all three reactions participate in starch degradation and affect the overall efficiency and outcome of the process. Rational engineering of specific CGTases thus requires detailed knowledge of the kinetic mechanisms of the different reactions. The three transglycosylation reactions catalyzed by CGTase of *B. circulans* 251 have been analyzed in detail (65). Cyclization, coupling, and disproportionation all involve the same catalytic residues (Asp328, Glu257, and Asp229). The chemical mechanism of catalysis by CGTase is a double displacement reaction involving a covalent enzyme intermediate complex (30). Nevertheless, the transglycosylation reactions were found to proceed via different kinetic mechanisms. The kinetic data are summarized in Tables 1–3. Cyclization (cleavage of an  $\alpha$ -glycosidic bond in amylose or starch and subsequent formation of a cyclodextrin) is a single-substrate reaction with an affinity for the high-molecular-weight substrate used (Paselli SA2, a starch derivative with an average degree of polymerization of 50) which was too high to allow elucidation of the kinetic mechanism. Michaelis-Menten kinetics, however, has been observed when using shorter amylose chains. The *B. circulans* 251 CGTase mainly produces  $\beta$ -cyclodextrin. Highest turnover rates were observed for this product. Coupling (cleavage of an  $\alpha$ -glycosidic bond in a cyclodextrin ring and transfer of the resulting linear malto-oligosac-

charide to the acceptor substrate methyl  $\alpha$ -D-glucopyranoside [MaDG]) proceeds according to a random ternary complex mechanism. Thus, both substrates can bind simultaneously and in random order to the active site cleft of CGTase. This leads to two apparent affinity constants for cyclodextrins and acceptor, one in the absence ( $K_M$ ) and one in the presence ( $K'_M$ ) of the other substrate (see Table 2). Disproportionation (cleavage of an  $\alpha$ -glycosidic bond of a linear malto-oligosaccharide and transfer of one part to an acceptor substrate), using 4-nitrophenyl- $\alpha$ -D-maltoheptaoside-4-6)-O-ethylidene (EPS, a maltoheptasaccharide blocked at the nonreducing end and with a *p*-nitrophenyl group at its reducing end) as the donor molecule and maltose as the acceptor molecule, proceeds according to a Ping-Pong mechanism.

Despite the two-substrate character of the disproportionation reaction, its  $k_{\text{cat}}$  value is threefold higher than that for the cyclization reaction (Table 3). This may be explained by the involvement of merely linear substrates and products in the disproportionation reaction. Consequently, the reaction rates of cyclization and coupling should be determined by the rate at which the conformation changes from linear substrate to circular product and from circular substrate to linear product, respectively. This rate of conformational change presumably differs for the various cyclodextrins, explaining the variation in cyclization and cou-

pling activities among the cyclodextrins. Also the rates of linearization and circularization for the individual cyclodextrins are different; especially, for  $\alpha$ -cyclodextrin the rate of formation through cyclization is much lower than that of degradation through coupling (Tables 1–3). In view of the different kinetic mechanisms observed for the various reactions, which can be related to differences in substrate binding in the active site, it appears possible to mutagenize CGTase in such a manner that a single reaction is affected most strongly. This opens possibilities for the rational design of enzymes displaying specific activities. Recent work, based on the detailed knowledge of the active-site architecture, has led to the construction of CGTase mutants with enhanced  $\alpha$ -cyclodextrin production (66). Current work involves rational design of mutants with decreased coupling activities and mutants with decreased transferase activities in favor of hydrolysis.

## V. DETERMINATION OF CGTASE ACTIVITY

Since CGTase catalyzes four different reactions (see above), specific assays for the determination of the various activities have been developed. The assays described are used for *B. circulans* strain 251 CGTase, which requires incubation of appropriately diluted enzyme (0.1–0.2 units of specific activity for the specific reactions) at 50°C with substrate solutions in 10 mM sodium citrate (pH 6.0) (65).

*Cyclization activity*, resulting in formation of cyclodextrins, can be determined based on the ability of the different ( $\alpha$ -,  $\beta$ -,  $\gamma$ -) cyclodextrins to form inclusion complexes with specific guest molecules. Paselli SA2, partially hydrolyzed potato starch with an average degree of polymerization of 50 (Avebe, Foxhol, Netherlands), is used as a substrate (up to 5% w/v). The Paselli SA2 solution is incubated in 10 mM citrate buffer (pH 6.0) for 10 min at 50°C before the reaction is started with appropriately diluted CGTase. At regular time intervals (0.25–0.5 min) 100- $\mu$ L samples are taken and added to 900  $\mu$ L specific detection reagent: phenolphthalein (67) or bromocresol green (68) for the detection of  $\beta$ - or  $\gamma$ -cyclodextrin, respectively.  $\alpha$ -Cyclodextrin formation can be analyzed by complexation with Methyl Orange which is, however, not very specific and whose sensitivity is low. Therefore the use of high-performance liquid chromatography is preferred, using a 25-cm Econosphere NH<sub>2</sub> 5- $\mu$ m column (Alltech Associates) eluted with acetonitrile/water (60/40, v/v) at a flow rate of 1 mL/min. Since  $\alpha$ -,  $\beta$ -, and  $\gamma$ -

cyclodextrins are produced simultaneously from the starch substrate, the  $\beta$ -cyclodextrin formed (measured using the phenolphthalein method) can be used as an internal standard. One unit of activity is defined as the amount of enzyme able to produce 1  $\mu$ mol of cyclodextrin per min.

*Coupling activity*, in which cyclodextrins (donor) are cleaved and the resulting linear oligosaccharide is linked to another (oligo)saccharide (acceptor), can be determined by measuring the amount of glucose present in the linear products formed. In this assay  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrins are used as donors in the reaction; methyl  $\alpha$ -D-glucopyranoside (M $\alpha$ DG) is used as acceptor substrate. This modified glucose does not react in the glucose detection reaction involving glucose oxidase, and therefore acceptor concentrations do not interfere with the activity measurements. Cyclodextrin and M $\alpha$ DG are incubated in 10 mM citrate (pH 6.0) for 10 min at 50°C before the reaction is started with appropriately dilute CGTase. At regular time intervals (0.5 min) 100- $\mu$ L samples are added to 20  $\mu$ L 1.2 N HCl (4°C) followed by incubation at 60°C for 10 min to inactivate the CGTase. Subsequently, the samples are neutralized with 20  $\mu$ L 1.2 N NaOH and subjected to a 30-min incubation on ice with 60  $\mu$ L (0.25 U) amyloglucosidase (EC 3.2.1.3; Sigma A-3514) in 167 mM NaAc (pH 4.5) to convert the products (linear oligosaccharides) to single glucose residues. The glucose concentration is determined with the glucose/GOD-Perid method (Boehringer Mannheim 124036). One unit of activity is defined as the amount of enzyme coupling of 1  $\mu$ mol of cyclodextrin to M $\alpha$ DG per min.

*Disproportionation activity* can be measured using 4-nitrophenyl- $\alpha$ -D-maltoheptaoseide-4-6-O-ethylidene (EPS) as a donor substrate and glucose or malto-oligosaccharides as acceptor substrate. EPS is a maltoheptasaccharide blocked at the nonreducing end and with a *p*-nitrophenyl group at its reducing end, which is generally used for the detection of amylase activity. The reaction mixtures are incubated for 10 min at 50°C before the reaction is started with appropriately diluted CGTase. At regular time intervals (0.5 min) 100- $\mu$ L samples are added to 20  $\mu$ L 1.2 N HCl (4°C) followed by incubation at 60°C for 10 min to inactivate the CGTase. Subsequently, the samples are neutralized with 20  $\mu$ L of 1.2 N NaOH and incubated for 60 min at 37°C with 60  $\mu$ L (1 unit)  $\alpha$ -glucosidase (E.C.3.2.1.20; Boehringer Mannheim Biochemica 1630385) in 833 mM potassium phosphate (pH 7.0) to liberate *p*-nitrophenol from the product of the disproportionation reaction, nonblocked linear oligosac-

charide. The pH of the samples is raised above 8 by adding 1 mL of 1 M sodium carbonate, and the absorbance at 401 nm is measured ( $\epsilon_{401} = 18.4 \text{ mM}^{-1}$ ). One unit of activity is defined as the amount of enzyme converting 1  $\mu\text{mol}$  of EPS per min.

## VI. PURIFICATION OF CGTASE

CGTase enzymes occur extracellularly, making purification relatively easy. The method used has been developed for *B. circulans* strain 251 wild-type CGTase enzyme and involves expression of the *cgt* gene in *B. subtilis*, which also excretes the enzyme (42). Production strains are grown in a batch fermentor to an optical density at 600 nm of 11–13 (for  $\sim 24$  h). Under these conditions high extracellular CGTase levels generally are produced. Cultures are centrifuged at 4°C for 30 min  $\times$  16,000g and (mutant) CGTases present in the supernatants are further purified to homogeneity by affinity chromatography, using a 30-mL  $\alpha$ -cyclodextrin Sepharose-6FF column (Pharmacia, Sweden) (69) with a maximal capacity of 3.5 mg protein/mL. After washing with 10 mM sodium acetate buffer (pH 5.5), bound CGTase is eluted with the same buffer containing 10 mg/mL  $\alpha$ -cyclodextrin. This allows purification to homogeneity of up to 100 mg of stable (mutant) CGTase proteins, with a fivefold purification and a yield close to 90%, from 1-1 culture supernatants.

### I. INTRODUCTION

Limonoids are a group of chemically related tetracyclic triterpenoids present in the plants of the Rutaceae and Meliaceae. As the bitter constituents in citrus juices, excessive limonoid levels lower the quality and value of citrus juices and have a significant negative economic impact on the citrus industry worldwide (1). However, limonoids have been shown to have anticarcinogenic activity in laboratory animals (2–5) and in cultured human breast cancer cells (6). Limonoids also have been shown to possess antifeedant activity against insects (7) and are excellent chemotaxonomic markers in the Rutaceae family plants (8). Hence, limonoids are important functional chemicals in the agriculture and food industries.

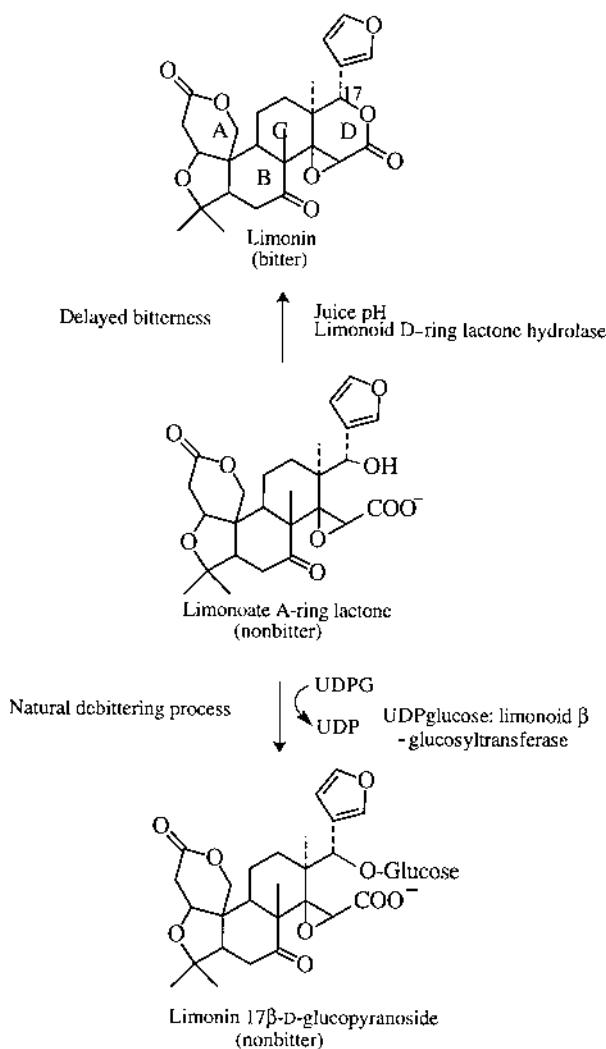

Intact citrus fruit tissues do not contain bitter limonin but contain the nonbitter precursor, limonoate A-ring lactone (LARL). In juice this precursor is gradually converted to limonin (9) (Fig. 1). This process proceeds under acidic conditions and is accelerated by the action of limonin D-ring lactone hydrolase (10). This phenomenon is generally referred to as “delayed bitterness.”

Delayed bitterness is a problem in the early- to mid-season fruits, but not in the late-season fruit. As the

fruit ripens, the concentration of LARL decreases. The mechanism of this natural debittering process was not determined until the discovery of limonoid glucosides in *Citrus* (11). As maturation progresses, limonoids are glucosylated to form nonbitter  $17\beta$ -D-glucopyranoside derivatives (12). This reaction is catalyzed by limonoid glucosyltransferase (LGTase) (EC 2.4.1.-); UDP glucose:limonoid  $\beta$ -D-glucosyltransferase) (13).

### A. Chemical Reaction Catalyzed

LGTase catalyzes the glucosylation of limonoid aglycones to form their respective  $17\beta$ -D-glucopyranoside derivatives (12–14). Seventeen limonoid glucosides have been isolated from *Citrus* and its closely related genera (15). Each has a single glucose molecule attached to the 17-position of the limonoid molecule via a  $\beta$ -glucosidic linkage, such as limonin  $17\beta$ -D-glucopyranoside (Fig. 1). The isolated enzyme from the albedo tissues of navel oranges takes both limonoate A-ring lactone and nomilinoate A-ring lactone as its substrates (13). This indicates that the enzyme is able to convert all limonoid aglycones present in *Citrus* sp. to their respective glucosides. Southern blot analysis of genomic DNA supports this observation—the gene for this enzyme is present only as a single copy in the citrus genome (16).

**Figure 1** Mechanism of delayed bitterness in extracted citrus juice and the mechanism of glucosylation (a naturally occurring limonin debittering process) in *Citrus*.

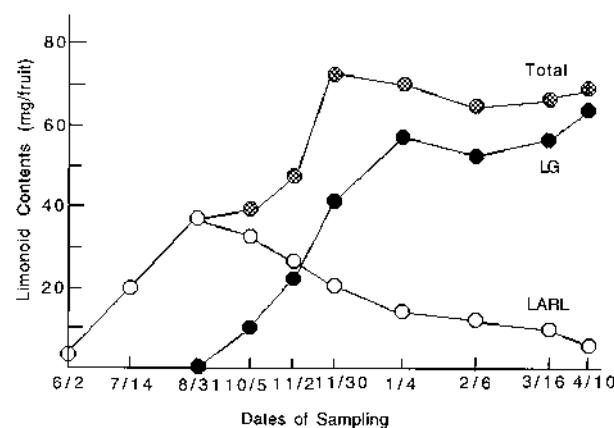

## B. Chemical Structures of Substrates

Limonoids are tetracyclic triterpenoid dilactones. Thirty-six limonoids have been isolated from *Citrus* and its closely related genera (15). An open D-ring is necessary for the glucosylation of limonoid aglycones to proceed via the LGTase reaction. In intact fruit tissue, limonoid aglycones are present in the open D-ring form, whereas in seeds they are present in both open and closed D-ring forms (1, 15). Alkaline conditions open the D-ring, whereas acidic conditions close it. The enzyme, limonoid D-ring lactone hydrolase catalyzes both the lactonization of the open D-rings and the hydrolysis of the D-ring lactones (10).

## II. IMPORTANCE TO QUALITY OF CITRUS FRUIT AND PROCESSED PRODUCTS

Delayed bitterness lowers the quality and value of citrus juices. Also, under unusual conditions such as freezing or mechanical damage, the formation of the bitter forms of limonoids occurs even in the fruit tissues. Once the intact fruit tissues are disrupted, the mixture of acidic pH and limonin D-ring lactone hydrolase activity in the fruit tissues makes the conversion of limonoate A-ring (LARL) to limonin inevitable. Limonin bitterness is a major problem in the citrus industry world-wide and decreases the market value of citrus juices.

Limonin aglycones are glucosylated in the fruit tissues during late stages of fruit growth and maturation (12, 14). Figure 2 shows the changes in LARL and limonin glucoside (LG) content of California-grown navel orange during fruit growth and maturation (12). The glucosylation of LARL begins in September and continues until the fruit is harvested which begins in November. Juice from fruit harvested in November and December has a serious delayed bitterness problem due to the incomplete conversion of LARL to the glucosides. In Valencia orange, glucosylation of aglycones also begins in September and is able to continue until fruit is harvested beginning in March (14). The Valencia orange has an additional 4 months of maturation time over that of the navel orange. During this extra time, the aglycones are almost completely converted to the tasteless glucosides. As a result, the juice from Valencia orange

**Figure 2** Changes in limonoate A-ring lactone (LARL) and limonin glucoside (LG) contents of California-grown navel oranges during fruit growth and maturation. (From Ref 12.)

does not have the bitterness problem. Many winter citrus fruits including certain varieties of Murcott orange, Shamouti orange, Iyokan, grapefruit, Natsudaidai, pummelo, Melogold, and Oroblanco have a limonoid bitterness problem (1, 17, 18).

The rate of glucosylation of limonoid aglycones is influenced by a number of factors, but the presence of LGTase is vitally important. Any stimulation of this enzyme activity by bioregulation or genetic engineering should result in the earlier reduction of LARL concentrations via conversion to the glucoside form in the fruit tissue, and consequently reduce or eliminate limonin bitterness.

### III. LGTase ACTIVITY IN COMMERCIAL CITRUS

Mandarin orange, pummelo, and citron are believed to be the three original species of *Citrus* (19). The other species and varieties are the result of centuries of natural and artificial breeding. Mandarins and citrons tend to have relatively high levels of LGTase activity, while pummels have relatively low levels. Consequently, pummelo juices, for instance, extracted from fruits harvested very late in the season have a severe limonoid bitterness problem (17). Sweet oranges, hybrids of mandarin oranges, in general have relatively high levels of LGTase activity and consequently contain high concentrations of limonoid glucosides (20). In contrast, hybrids such as grapefruit and the new varieties Oroblanco grapefruit and Melogold grapefruit more closely resemble the pummelo and have low levels of this enzyme activity (17, 18).

### IV. UTILIZATION OF LGTase

An attractive approach to solving the bitterness problem at the present is through the use of genetic engineering techniques. LGTase was chosen for genetic manipulation to create transgenic citrus trees that produce fruits free from limonin bitterness. The insertion of multiple copies of a constitutively controlled gene encoding for LGTase into commercial cultivars may result in enhancing the conversion of LARL to LG (Fig. 2) and may prevent the accumulation of significant levels of any LARL at time of early season harvest. This enhancement of the LGTase activity in transgenic plants may also increase the concentration of limonoid glucosides in the fruit tissues, which are important constituents for human health and nutrition.

Limonoid aglycones are present in high concentrations in citrus seeds (1, 21). Isolated aglycones generally are water insoluble, and among 36 aglycones isolated from *Citrus* and its closely related genera, six are intensely bitter in taste (1, 22). Mass conversion of these aglycones to limonoid glucosides is pharmacologically an important future project. It would enhance the utilization of these byproducts of citrus juice processing. Limonoid glucosides are excellent candidates for new food additives as they provide anticarcinogenic activity. They are soluble in water and are practically tasteless. An approach would be to use transgenic *E. coli* cultures containing the LGTase gene to convert limonoid aglycones isolated from seeds into limonoid glucosides in fermentation tanks. The LGTase gene has been successfully expressed in *E. coli* (16).

### V. ISOLATION OF THE LGTase GENE

Using a pair of degenerated oligonucleotide primers which were synthesized based on N-terminal and internal amino acid sequences of the purified LGTase isolated from albedo tissue of navel oranges, a cDNA clone encoding citrus LGTase has been isolated from Satsuma mandarin (*Citrus unshiu* Marc) (16) (Fig. 3). The isolated cDNA is 1732 bp in length encoding 511 amino acids with a predicted molecular mass of 57.5 kDa.

Figure 4 compares the amino acid sequences of the putative UDP-glucose binding domain of the LGTase gene with those of other glucosyltransferases (16). This region shows 43–68% identity in amino acid sequences to those of previously reported glucosyltransferases, indicating that the isolated clone conserves the features of the glucosyltransferase family. The coding region of the LGTase cDNA was ligated with an expression vector and transferred into *E. coli*. The transformed *E. coli* was grown and assayed for LGTase activity. The active protein fraction prepared from these cultures, when incubated with UDP-glucose and limonoate A-ring lactone, produced limonin glucoside.

Work is under way to transform and produce transgenic plants which express a constitutively controlled LGTase activity. It is hoped that the resulting transgenic citrus will produce fruit that is substantially free of LARL and delayed bitterness, but retain high levels of the limonoid glucosides.

## VI. PROPERTIES

### A. Properties as Protein

SDS-PAGE reveals a single protein band having an apparent  $M_r$  of 56–58 kDa (13), in agreement with the estimated  $M_r$  from DNA sequencing data discussed above. LGTase is a single subunit enzyme. Glucosyltransferases from citrus sources that utilize flavonoids and other small molecules as substrates are generally single-subunit enzymes. Flavanone glucosyltransferase from pummelo leaves has a  $M_r$  of 52 kDa (23) and flavanone glycosyltransferase from grapefruit seeds has  $M_r$  of 54.9 kDa (24).

### B. Properties as Enzyme

The enzyme displays broad activity between pH 6.5 and 9.0 with an optimal activity at pH 8.0. Activity below pH 6.5 is completely inhibited by a closed D-ring. The enzyme requires  $Mn^{2+}$  ion for its activity, and appears to be very sensitive to  $Cl^-$ . Partially purified enzyme placed into 50 mM Tris-HCl, pH 8, and stored at  $-80^\circ C$  showed a complete loss of activity. Replacing Tris buffer with 10 mM Mes-KOH, pH 7, allowed frozen storage of the enzyme with full recovery of activity (13).

## VII. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

LGTase activity can be assayed at pH 7.5 in a volume of 50–100  $\mu L$ . The assay solution contains 100  $\mu M$  UDP-glucose, 50  $\mu M$   $Mn^{2+}$ , and 39  $\mu M$  [ $^{14}C$ ]nomilinoate A-ring lactone. Assays are incubated at  $34^\circ C$  for 15–30 min. The reaction is terminated by adding 3  $\mu L$  of 1 M HCl, which also closes the D-ring of the unreacted nomilinoate A-ring lactone. Aliquots of the enzyme reaction mixture are spotted on TLC plates and developed with EtOAc-MeEtCO-H<sub>2</sub>O-

HCOOH (5:3:1:1). In this solvent system the  $R_f$  for nomilin is 0.88 and that for nomilin glucoside is 0.42. The developed plates are scanned for radioactivity with a Berthold Automatic TLC-Linear Analyser, model LB 2832 (13).

Radioactive nomilin can be produced by feeding labeled acetate to stems of lemon seedlings (25). Fresh stems are cut to 1 cm length and fed with randomly labeled [ $^{14}C$ ]Na-acetate. After 2 days of incubation with a continuous supply of water, up to 5% of the original activity is incorporated into nomilin.

Recently, a liquid chromatography-mass spectrometry (LC-MS) technique has been developed to analyze limonoids in levels as low as 40 pg (26). Thus, the method could be amended to include the use of unlabeled limonoid aglycones.

## VIII. PURIFICATION

The albedo tissue of navel oranges is homogenized in buffer consisting of 50 mM Tris-HCl, pH 8.0, 5 mM DTT, 15 mM KCl, 0.5% PVP (w/v) using a Polytron at low-medium speed for 4 min. The resulting slurry is centrifuged at 8000g for 20 min. The supernatant is brought to 40% saturation  $(NH_4)_2SO_4$  and stirred in a  $0^\circ C$  bath for 1 h. The precipitate is removed by centrifugation at 20,000g for 30 min. The supernatant is taken to 80% saturation with  $(NH_4)_2SO_4$  and stirred in a  $0^\circ C$  bath for 1 h and the precipitate is collected by centrifugation as before.

The protein precipitate is redissolved in 10 mM Mes/KOH buffer, pH 7.0, containing 15 mM 2-mercaptoethanol and 50  $\mu M$  MnCl<sub>2</sub> (Buffer A). The dissolved protein is desalting on PD-10 gel filtration column (Pharmacia), equilibrated with Buffer A. The desalted, buffer-exchanged sample is loaded onto a uridine 5'-diphosphoglucuronic acid affinity column (Sigma), having a 75-mL bed volume that is pre-equilibrated with Buffer A. The column is washed with

buffer and eluted with 10 mM UDP-glucose dissolved in Buffer A. Fractionation on a UDP-glucuronic acid affinity column results in a 55-fold increase in enzyme purification over the  $(\text{NH}_4)_2\text{SO}_4$  fraction.

The active fractions are pooled and loaded onto an HPLC Bio-Gel TSK-IEX DEAE 5PW (75 × 7.5 mm) column (BioRad) which has been equilibrated with 50 mM Tris-HCl, pH 7, with 2 mM DTT (Buffer B). A linear salt gradient, 0–400 mM NaCl, is used to elute the column over a 20-min period at a flow rate of 1.0 mL/min using Buffer B. The active fractions are collected, diluted 10-fold into Buffer C (50 mM/Tris-HCl, pH 8, with 2 mM DTT), and loaded onto the above DEAE column and eluted with Buffer C with a linear NaCl gradient, 0–400 mM, over a 20-min period at a flow rate of 1 mL/min. This procedure results in a 452-fold increase in enzyme purification (13).

## Transglutaminase

**Chang-Rak Ha and Ichiro Iuchi**

*Sophia University, Tokyo, Japan*

### I. INTRODUCTION

Transglutaminase (TGase, EC 2.3.2.13,  $\gamma$ -glutamyl-peptide, amine- $\gamma$ -glutamyl-transferase) is a class of enzymes that catalyze the acyl transfer between the  $\gamma$ -carboxyamine group of a peptide-bound glutamine residue and the primary amino group of various substrates in a calcium-dependent reaction.

TGase was first discovered in guinea pig liver and characterized by Waelsch and coworkers (1, 2), and identified as an enzyme catalyzing incorporation of polyamines into glutamine residues of proteins or peptides. Since then, the reaction of blood-clotting Factor XIII-catalyzing polymerization of fibrin has been found to be identical to that of the liver TGase. The reaction is also involved in keratinization of epidermis (3), hair formation (4), or copulatory plug formation (5). More recently, TGase has been implicated as a widely distributed enzyme that participates in various biological phenomena such as apoptosis (6), cell growth and differentiation (7), embryonic cell differentiation (8), retinoic acid-induced abnormalities of fish embryo during the early development (9), and fertilization envelope formation (10–15, 81).

There are some studies on TGase from an aspect of food science (16, 17). The TGase reaction must be closely related to the visco-elasticity of food materials such as meat and fish eggs.

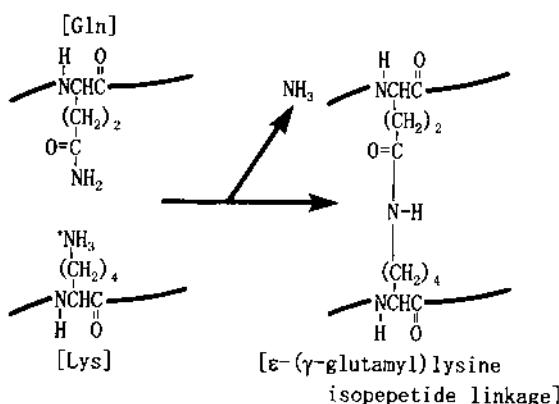

### A. Classification and Nomenclature of TGase

Classification and nomenclature of TGases have been traditionally based on the function of the TGase (blood coagulation Factor XIII), on cell, tissue, or organ containing the TGase (keratinocyte TGase, liver TGase, or prostate gland TGase), or subcellular distribution of the TGase (extracellular matrix TGase, cytosolic TGase, or membrane-bound TGase). Recently, some TGases have been frequently called by abbreviations such as TGase K (18) or C (19), and TGase 1 (3), 2 (34) or 3 (19, 20). However, these recent names are somewhat inadequate to classify the many TGases from various sources including bacteria and plants. Therefore, the traditional names will be used here.

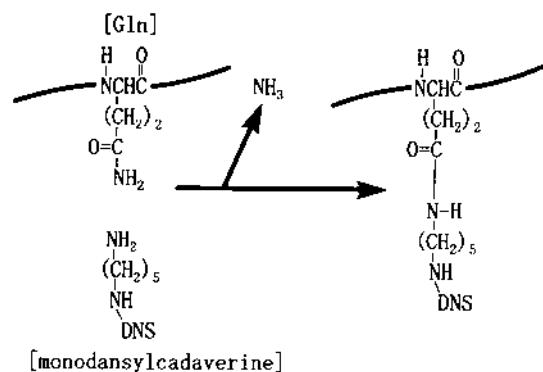

### B. Reaction Catalyzed by TGase

TGase catalyzes the following reactions.

- Formation of  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptide crosslinks between proteins or peptides, resulting in polymerization ([Fig. 1](#)).
- Incorporation of amines into proteins or peptides. This reaction plays a role in deamination or amine fixation. ([Fig. 2](#)).
- Formation of N,N-bis-( $\gamma$ -glutamyl) derivative crosslinks (Glu-CONH-R-NHCO-Glu) between proteins or peptides. ([Fig. 3](#)) (21).

**Figure 1** Formation of  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptide crosslinks between proteins or peptides, resulting in polymerization.

**Figure 2** Incorporation of amines into proteins or peptides.

## II. PROPERTIES AS PROTEIN

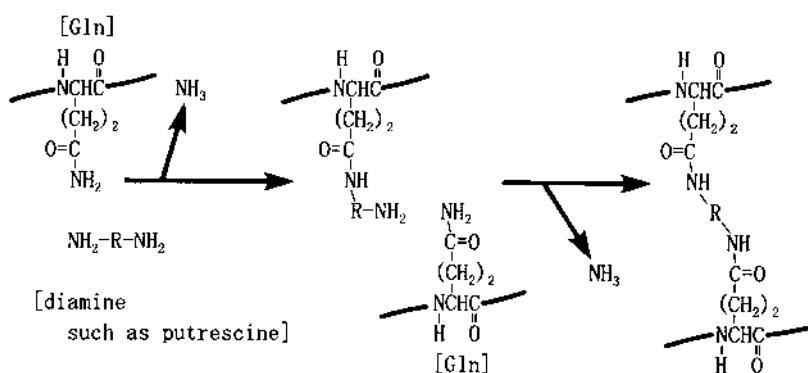

### A. Physicochemical Properties of TGase

Properties of TGase as a protein are very variable from TGase to TGase. For example, liver TGase of guinea pig is monomeric and its molecular size is  $\sim$  75 kDa. On the other hand, human blood coagulation Factor XIII (300–350 kDa) consists of two A (or a) subunits where the catalytic site is located and two B (or b) subunits. Although more investigations are necessary, it seems reasonable to conclude that TGase belongs to a highly heterogeneous family or superfamily. Some characteristics of various TGases are shown in Table 1.

Isoelectric points of various TGases are somewhat variable. Using agarose gel electrophoresis at pH 7.4, human blood clotting Factor XIII and rat tissue TGase migrate toward the anode (22), while two isoforms of secretory TGase in rat prostate gland (coagulating gland) move toward the cathode (5, 23). Using isoelectric focusing, TGases in the crude extracts were focused at pH 7.8. On the contrary, the analysis of pure enzymes revealed an additional isoelectric point at pH 8.7 (5, 23). Rat testicular tissue TGase was focused at pH 5.25 (5). Isoelectric points of many TGases have not been accurately determined. However, they can be calculated from data of their amino acid compositions (24).

### B. Primary Structure of TGase

The primary structures of various TGases have been predicted by nucleotide sequence analysis of cDNAs or genomic DNAs: blood coagulation Factor XIII [human, A subunit (25, 26); B subunit (27)], keratinocyte TGase [rat (28); mouse (20)], rat prostate gland

**Figure 3** Formation of N,N-bis-( $\gamma$ -glutamyl) derivative crosslinks between proteins or peptides.

**Table 1** Some Characteristics of Various Transglutaminases (TGases)

Source (cell, tissue, organ, etc.)	Organisms	Molecular weight (daltons)	Natural substrate	Remarks	References
Blood plasma (platelet)	Human		Fibrin, fibrinogen	Secretory TGase Factor XIII. Tetramer ( $A_2B_2$ ; 300–350 kDa). The A subunit has catalytic activity	25 26
	Human	83231	Unknown	Zymogen form of Factor XIIIIA. Dimer ( $A_2$ ; 150 kDa).	
		75490	—	B subunit	27
Prostate gland	Rat	75471		Dorsal protein 1	29
				Functions as a secretory TGase	
Egg envelope P1	Rainbow trout ( <i>Oncorhynchus mykiss</i> )	82 and 76 kDa	Secretion II protein. Egg envelope subunit proteins (45, 56 and 65 kDa)	Extracellular matrix TGase	*108 14
P2		76 kDa			13, 14
Keratinocytes	Human	89338		This group of TGases has been frequently called epidermal TGase or TGase K.	18

The molecular weights of TGases were calculated from the amino acid sequences predicted from cDNAs or genomic DNAs. The molecular sizes (kDa) were those of the TGases isolated by ordinary biochemical methods. The complete sequences of them have not been determined. The asterisk in the column of References indicates the literature where only natural substrates for TGase are described.

TGase (29), erythrocyte band 4.2 [pallidin; human (30); mouse (31)], chicken erythrocyte tissue TGase (32), guinea pig liver TGase (33), mouse macrophage TGase (34), bovine aortic–endothelial cell TGase (35), chicken limb TGase (36), mesenchyme TGase of *Ciona intestinalis* embryo (37), *Limulus* hemocyte TGase (38), and TGase of grasshopper embryo [annulin (8)]. The amino acid sequences of liver TGases of fishes [red sea bream (39); a salmon, *Oncorhynchus keta* (40)] are available.

As shown in Figure 4, amino acid sequences of various TGases were aligned by the program CLUSTAL W ver 1.7 (41) in DNA Data Base of Japan (DDJB). The overall sequences of keratinocyte TGases, human blood clotting Factor XIIIa, and mesenchyme TGase of *Ciona intestinalis* embryo were 130–150, ~50, and

~60 amino acids longer than those of other vertebrate TGases, respectively. It may be predicted that they have a large insertion at the N-terminal regions, or at the C-terminal regions. In addition, the multiple alignment reveals that the sequence of a novel human TGase X or 5 is especially characteristic in a large deletion of about 90 amino acids at the N-terminal region and an insertion of about 50 amino acids near the central region.

We tentatively analyzed molecular phylogenetic relationships of various TGases of vertebrates. The human TGase X or 5 was removed from the analysis. In addition, the amino acids corresponding to gaps were removed from the analysis. A tree was constructed by the neighbor-joining method (42) using the program MEGA (43). The tree was rooted with

the sequence of the *Ciona* TGase (Fig. 5) or *Limulus* hemocyte TGase (data not shown). At least, five paralogous groups are definitely distinguishable in vertebrates; the groups of blood clotting Factor XIIIa, keratinocyte TGases, prostate gland TGases, erythrocyte membrane band 4.2 recently named “pallidin,” and so-called tissue TGases.

A conserved amino acid sequence GQCWVF is found at the central region (e) panel of any sequence in Figure 4, which is deduced as a putative active site region for the TGase reaction. The cysteine residue in the motif is considered to be a catalytic site. However, the comparable site of the pallidin is GQAWVL for human and TQAWVS for mouse. Thus, pallidin is unique among them. The cysteine residue as a catalytic site is replaced by alanine residue. The pallidin has no TGase activity, and is considered to play a role in the regulation of erythrocyte shape and mechanical properties (30, 31). Elucidation of three dimensional structure of human blood clotting Factor XIIIa suggests that the catalytic site for its TGase activity is constructed from three residues, Cys314, His373, and Asp396 (44). Among the catalytic triad, the Cys314 corresponds to a cysteine residue in the motif GQCWVF. In addition, the His373 and the Asp396 in the Factor XIIIa are conserved in all TGase activity enzymes. However, the former is replaced by glutamine (Q) in human and mouse pallidins, the latter is by histidine (H) in mouse pallidin (Fig. 4).

The complete amino acid sequence of *Streptoverticillium* TGase has been determined (45). The TGase is a  $\text{Ca}^{2+}$ -dependent SH enzyme and contains a sole cysteine residue. The active site sequence of the TGase was predicted to be YGCVGV, which is highly homologous to that of thiol proteases such as papain and cathepsin H. The overall sequence is also significantly different from those of vertebrate TGases having the sequence GQCWVF as an active site.

Recently, three novel protein disulfide isomerases were cloned from the protozoan parasite *Giardia lamblia* (46). The enzymes are well known to be essential for forming disulfide bonds during nascent protein folding in the endoplasmic reticulum. Unlike other protein disulfide isomerases, the giardial enzymes have only one active site. The active-site sequence motif is CGHC characteristic of eukaryotic protein disulfide isomerases. Interestingly, all three enzymes have a  $\text{Ca}^{2+}$ -dependent TGase activity. There is another example like this. It has been clarified that TGase of heartworm *Dirofilaria immitis* (Filarial parasite of dog heart) has significant sequence similarity to

well-characterized protein disulfide isomerases, not to any of known TGases (47).

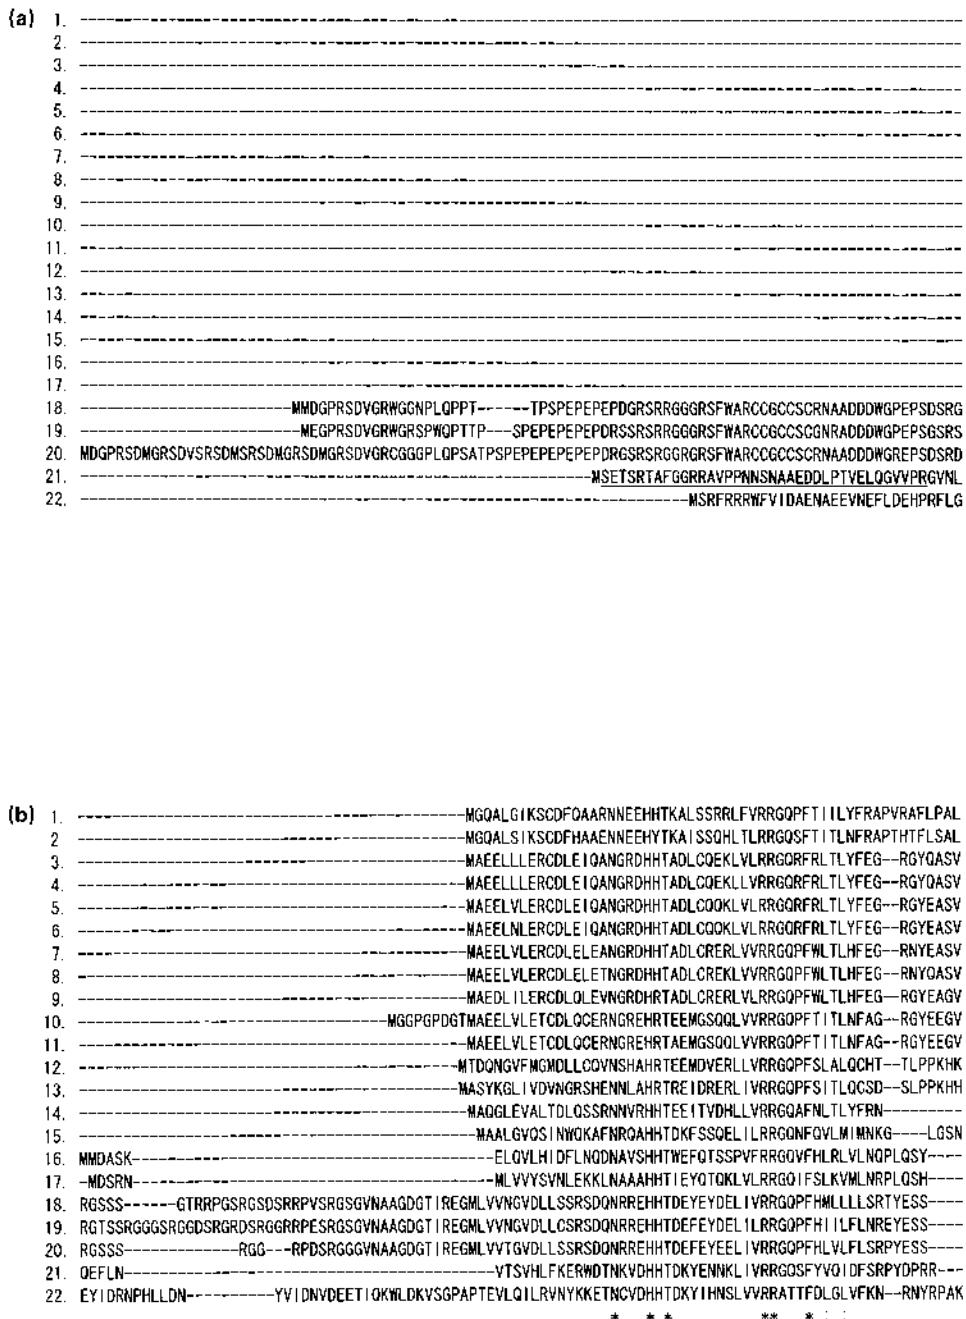

Thus, the enzyme having TGase activity is not necessarily restricted to a distinct single type of enzyme. TGase is highly polymorphic in catalytic property, active site motif, and primary structure.

### C. Three-Dimensional Structure of TGase

The three-dimensional structures of human blood coagulation Factor XIIIa and its zymogen have been determined by x-ray crystallography. The overall structure of the dimer A<sub>2</sub> is shown in Figure 6. The monomer molecule is characterized by the activation peptide from residues 1 to 37, domain 1 from 38 to 185, domain 2 from 197 to 503, domain 3 from 517 to 628, and domain 4 from 632 to 731. The connecting loops run between the domains (44, 48). Domain 1 ( $\beta$ -sandwich) contains almost exclusively  $\beta$ -structure consisting of two four-stranded  $\beta$ -sheets and forms an open barrel. Domain 3 (barrel 1) and 4 (barrel 2) contain seven  $\beta$ -strands and are topologically identical. Both domains interact closely with domain 2. Domain 2 (catalytic core) is constructed from a central six-stranded  $\beta$ -sheet, a second  $\beta$ -sheet of three strands, a  $\beta$ -hairpin, and a total of nine  $\alpha$ -helical segments. The longest  $\alpha$ -helix of 17 amino acid residues in the center of the molecule contains the active-site cysteine Cys314 constituting the above-mentioned motif GQCWVF. The other members of catalytic triad are His373 and Asp396. The catalytic triad is not accessible to solvent. The calcium is located in the core domain, near the surface of the protein.

The stereostructure of its catalytic site region is highly similar to that of cysteine proteinase, containing a cysteine at its catalytic site similarly to the TGase. A similar active site in the two different enzyme families catalyzing a reaction in opposite directions suggests that the two enzymes are in a common evolutionary lineage (49). In addition, there is a recent report that cytosolic TGase of guinea pig liver and a coagulation factor XIIIa can hydrolyze the  $\epsilon$ - $\gamma$  linkage of  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptides (129). TGase may play a dynamic role not only in promoting the formation of isopeptide bonds but also in the breaking of the bonds. The main calcium-binding site in each monomer involves the main chain oxygen atom of Ala457 and also the side chains from residues Asn436, Asp438, Glu485, and Glu490 (44).

In the processing of a zymogen to the mature form, an amino terminal activation peptide consisting of 37 residues is cleaved by thrombin and is released from

**Figure 4** Alignment of amino acid sequences of various transglutaminases. A multiple alignment of the sequences was performed by the program CLUSTAL W ver 1.7 (41) in DNA Data Base of Japan (DDBJ). The identical amino acid residues in all sequences are indicated by asterisk, and conservative changes are shown by dots. In addition, the alignment gaps are expressed by hyphens. The N-terminal 37 amino acid sequence of human blood clotting factor XIIIa (underlined in the sequence 21) is the activation peptide. The C-terminal side of arginine residue (R-37) is hydrolyzed by thrombin, and the TGase activity for the Factor XIIIa becomes apparent. The active site for TGase activity in the factor consists of the amino acid residues, Cys314 in the consensus sequence GQCWVF, His373, and Asp396 (44, 48). These triad residues are conserved in TGases other than erythrocyte band 4.2 (pallidins, 1 and 2). Such active-site motif, His and Asp are boxed.

the rest of the molecule. However, the 3D structure of thrombin-cleaved Factor XIIIa is remarkably similar to that of the zymogen. The activation peptide remains associated with the rest of the molecule (50, 51).

### III. PROPERTIES AS ENZYME

The main function of TGase is formation of  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptide crosslinks between naturally occurring proteins or peptides, resulting in polymerization (Figs. 1, 3). Amines such as hydroxylamine, mono-dansylcadaverine, cadaverine, spermine, spermidine, and putrescine can be incorporated into the protein substrate by the TGase reaction to bind covalently to glutamine residues resulting in the inhibition of the

polymerization of proteins (Fig. 2). Thus, amines are competitive inhibitors for the TGase reaction, and can be utilized as one of substrates as described above. For example, there is a report that  $K_m$  values of rat brain TGase for putrescine and N,N-dimethylcasein were 0.26 and 0.065 mM, respectively (52). The  $K_m$  values of muscle TGases of some animals will be described later. In a case of the TGase from soybean (*Glycine max*) leaves, the  $K_m$  values for putrescine, spermidine, and spermine were determined to be 0.109, 0.042, and 0.069 mM, respectively (53). Although this plant enzyme does not essentially require  $\text{Ca}^{2+}$ , the  $K_m$  values are similar to those of tissue TGases known in animals. Slime mold *Physarum polycephalum* TGase has  $K_m$  values of 0.049, 0.021, and 0.032 mM for [ $^{14}\text{C}$ ]putrescine, [ $^{14}\text{C}$ ]spermidine, and [ $^{14}\text{C}$ ]spermine, respectively (54).

**Figure 5** Molecular phylogenetic relationship among vertebrate transglutaminases. A tree was constructed by the neighbor-joining method (42) using the program MEGA (43). Bootstrap values  $> 50\%$  are shown above or below branches. Filled diamond, open circle, open diamond, open square, and filled circles indicate blood-clotting Factor XIIIa, keratinocyte TGases, prostate gland TGases, erythrocyte band 4.2 (pallidin), and tissue TGases, respectively. The groups of them are considered to be paralogous to each other. The evolutionary distance is expressed in terms of amino acid substitutions per site. The tree is rooted with mesenchyme of *Ciona intestinalis* embryo.

Inhibitors or cofactors were searched for mainly by an assay method utilizing amine incorporation. Metal ion chelating reagents such as EDTA and EGTA inhibit the activity of various TGases, which can be restored by the addition of  $\text{Ca}^{2+}$ . In addition, iodoacetic acid, iodoacetamide, and *p*-chloromercuribenzoate inhibit TGase activity, while 2-mercaptoethanol and dithiothreitol (DTT) stabilize the activity. Therefore, TGase is well known as a  $\text{Ca}^{2+}$ -dependent SH enzyme.

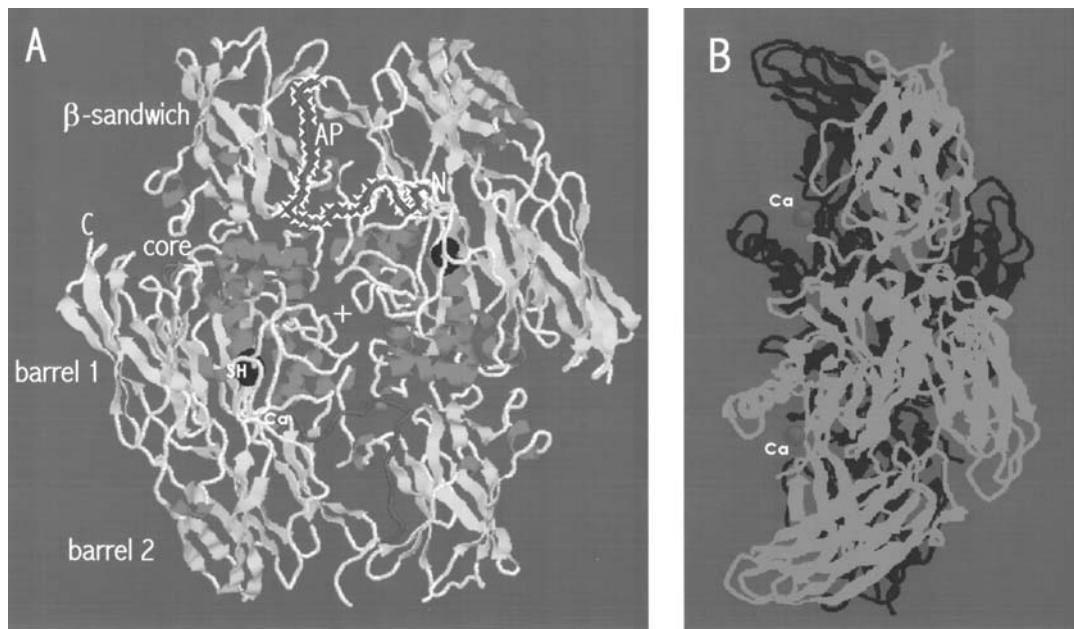

On the other hand, some synthetic compounds such as 2-[3-(diallylamino)-propionyl]benzothiophene (55), and 1,3,4,5-tetramethyl-2-[(2-oxopropyl)thio]imidazolium chloride or L-68277 (56) are well-known non-competitive inhibitors of TGase.

Tissue TGase is inhibited by nucleotides. ATP inhibits the activity of rat liver TGase in a concentration-dependent way. Complete inhibition was obtained with 3 mM ATP. ADP inhibited the TGase activity similarly to ATP, but AMP had much less inhibition. There was no significant inhibition by adenosine and adenine. CTP possessed the same inhibitory activity as that of ATP, while GTP and UTP had  $\sim 50\%$  of the ATP-induced inhibition (57). Such inhibitory effect of

ATP or GTP has been well elucidated for various tissue TGases [guinea pig liver TGase (5); erythrocyte TGase (59); Factor XIII (60); rat brain TGase (52)]. Moreover, it has been demonstrated that a human tissue TGase has nucleotide hydrolysis activity similar to ATPase or GTPase (61). This raises the possibility that the enzyme regulates cell receptor signaling (62). Studies show that the GTP and ATP hydrolysis sites are localized within the core domain of the tissue TGase (63). Recently, a 77-kDa GTP-binding protein,  $\text{G}\alpha\text{h}5$ , was isolated from pig heart membranes with a binding affinity of nucleotides in order: GTP  $>$  GDP  $>$  ITP  $\gg$  ATP, which is similar to that observed for other G-proteins involved in receptor signaling. The  $\text{G}\alpha\text{h}5$  also exhibits TGase activity (64).

The optimum pH of the TGase activity was highly variable as follows: 7.5 for 101-kDa *Physarum polycephalum* TGase (65); 8.0 for *Caenorhabditis elegans* TGase (66); 9.0–9.5 for red sea bream TGase (67), and 5–6 for egg envelope TGases of rainbow trout (13–15).

For guinea pig liver TGase, the optimal incorporation of amines into proteins occurs at pH 7.2–8.5 (2). However, the pH of optimal ammonia liberation (see

**Figure 6** Three-dimensional structure of human blood-clotting Factor XIIIIA. The coordinate file for the human blood clotting factor XIIIIA dimer [PDB Id., 1GGU (44)], which is supported by Brookhaven Protein Databank, was obtained from National Library of Medicine (NCBI), and the 3D structure was displayed by Molecular Visualization Program, RasMol ver 2.5 (128). The overall structure is characterized by the activation peptide (AP, arrow heads) and four domains, the  $\beta$ -sandwich, the catalytic core, barrels 1 and 2 (44, 48). Due to unresolved problems, it appears that each monomer is missing the eight amino acid residues from the N-terminus (1–8), the linker between the activation peptides and  $\beta$ -sandwich (30–43), the sequence between the core and barrel 1 (508–516), and the C-termini (728–731). (A) Overall structure of the Factor XIIIIA dimer. Two monomer molecules are visible in parallel, symmetrically with respect to the center of the figure (+). The cysteine residue in the catalytic site (Cys314) is represented by a solid sphere (SH). (B) Left side view of A. The left and right chains in A are displayed in light and dark, respectively. Two spheres (Ca) are  $\text{Ca}^{2+}$  ions in both molecules.

**Fig. 1**) varies with the substrate: 7.0–7.5 for unmodified insulin; 6.5–7.0 for acetylated insulin (68). On the other hand, there is a report for the same enzyme that the optimal incorporation of hydroxylamine into N-carbobenzoxy (CBZ)-L-glutaminylglycine occurs near pH 6.0 (69).

#### IV. BIOLOGICAL FUNCTION OF TRANSGLUTAMINASE

As described in the Introduction, TGase participates in various biological phenomena such as blood clotting, keratinization, hair formation, and copulatory plug formation. In the present article, we focus our attention on the following subjects to briefly review the recent development of TGase studies; apoptotic cell death, and egg envelope hardening in fish.

#### A. TGase, Reinoic Acid, and Induction of Apoptosis

Clarification of the compounds involved in natural cell death including apoptosis (programmed cell death) has become one of the most interesting subjects in biochemistry and molecular biology. One of the effective compounds in the death pathway is considered to be tissue TGase, because of a parallel induction of apoptosis and TGase activity [see the review of Fesus and coworkers (6)]. Tissue TGase-mediated crosslinking of some intracellular proteins occurs in cells undergoing apoptotic or programmed cell death (70, 71). Such protein crosslinking may stabilize the apoptotic bodies and prevent the leakage of cytosolic proteins into the extracellular space during fragmentation of cell (72). The induction and activation of TGase-mediated apoptosis are also supported by a recent study that TGase is involved in programmed cell death of *C. elegans* (66).

Retinoic acids, vitamin A derivatives, are known to participate in various biological phenomena by mediation of their receptors, retinoic acid receptors (RARs), and retinoid X receptors (RXRs). Especially, the findings are interesting that retinoids induce apoptotic death in various cells [human neuroblastoma cells (73); human myeloma cell line RPMI 8226 (74); embryonic stem cells (75); mouse thymocyte (76)]. For example, there is a report that apoptosis is in part inhibited by the antisense oligonucleotides for RAR message during the differentiation of mouse embryonic stem cells into neuronal cells; that is, the decreased expression of RARs may inhibit apoptosis (75).

In the pathway of apoptotic cell death, retinoids have been suggested to induce the expression of TGase in the cells; that is, the TGase gene, especially tissue TGase gene, is one of the retinoid-responsive genes. The induction is not related to binding of retinoid receptor monomers to the DNA. Homo- and heterodimeric retinoid receptor complexes bind to distinct retinoids response elements (RREs) embedded in the regulatory regions of retinoid-responsive genes (77). Recently, such RREs have been identified in the promoter regions of mouse tissue TGase gene and characterized (78). The element has been suggested to be capable of binding to and being activated by both RAR/RXR heterodimer and RXR homodimer receptor complexes.

## B. Egg Envelope TGases

Recently, TGases in eggs of the rainbow trout *Oncorhynchus mykiss* have been well characterized with special reference to egg envelope (chorion) hardening. Some properties of the TGases will be described in detail because it is considered to be important in food science.

Unfertilized eggs are very fragile, while fertilized/activated eggs are very tough. An unfertilized egg of rainbow trout was broken by pressing it with the weight of less than ~20 g. A fertilized/activated egg incubated at 10°C overnight was resistant to the weight of 2–3 kg. Such toughness was due to the hardening of the egg envelope (chorion). During the hardening process,  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptide crosslinks in the chorion increased 6 (unfertilized egg chorion) to 43 nmol/mg dry chorion (fertilized egg chorion). Moreover, 49-, 56-, and 65-kDa proteins constituting the unfertilized egg chorion were gradually polymerized, and the chorion became insoluble in protein denaturants such as 3% SDS, 8 M guanidium hydrochloride, and 12 M urea. In addition, monodansylcadaverine inhibited both the polymerization of chorion

proteins and the hardening of chorion (11). These studies have raised a possibility that TGase is responsible for chorion hardening (79, 81).

Further studies showed that the activity of TGase was not localized in unfertilized egg cytoplasm but was exclusively in the egg chorion (11, 12); that is, the TGase was an extracellular matrix TGase. Thus, the chorion is a functional structure in coexistence with the enzyme and the substrate.

Two TGases, P1 and P2, were extracted and purified from the chorion and were partially characterized. They had an ability to catalyze the formation of  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptide crosslinks among 49-, 56-, and 65-kDa subunit proteins of the chorion, to polymerize all the subunits, and to harden the chorion. The activity of P1 enzyme was apparent exclusively in the medium of low ionic strength such as 10 mM Tris-HCl (pH 7.2), while that of P2 was apparent both in 10 mM Tris-HCl (pH 7.2) and in isotonic saline (0.143 M NaCl-10 mM Tris-HCl, pH 7.2). P1 consisted of 82- and 76-kDa proteins, but the amino acid compositions were highly identical. P2 consisted of a homogenous 76-kDa protein (13, 14). After egg activation, P1 enzyme was processed into a 48-kDa enzyme and its activity was enhanced. As the 48-kDa TGase remains localized in the chorion, it must crosslink the subunit proteins at the restricted sites of the chorion. On the contrary, P2 enzyme was released into perivitelline space after activation of the egg. It may uniformly polymerize the chorion subunit proteins (15). The released P2 enzyme corresponds to the chorion-hardening enzyme initially suggested by Zotin (80, 81).

It has been suggested that the processing of chorion TGases after egg activation is caused by the action of an EDTA- or leupeptin-sensitive proteinase(s). In addition, the enzymes become active by  $\text{Ca}^{2+}$  released from the activated eggs (15, 81). Thus, a main biological function of chorion TGases is the fertilization/egg activation-associated hardening of the chorion to prevent the eggs from environment-derived mechanical and chemical hazard (81).

## V. TRANSGLUTAMINASE STUDY IN FOOD SCIENCE

Unfertilized eggs of salmonid fishes including rainbow trout are frequently treated with a high concentration of salt (~7% NaCl) and are utilized as food. During food processing, the activity of the chorion TGases survives, resulting in a gradual formation of isopeptide crosslinks between egg proteins (82). It is conceivable that the

TGase reaction contributes to the viscoelastic character of salted eggs. In fact, unfertilized eggs are very fragile, while salted eggs have hardness as a desirable food.

Although more investigations are necessary, TGases have been found in unfertilized eggs of other fishes: *Oncorhynchus masou*, *Salvelinus leucomaenoides* (82), carp *Cyprinus carpio* (83), medaka *Oryzias latipes* (79, 84), cod *Gadus morhua* (85), and sea urchin *Strongylocentrotus purpuratus* (10). TGase in fish eggs must play a role in forming a desirable texture as food as well as in the hardening of egg envelope after fertilization. However, changes of egg proteins induced by food processing remain unclear.

TGases were prepared from muscles of scallop (*Patinopecten yessoensis*), botan shrimp (*Pandalus nipponensis*), squid (*Todarodes pacificus*), carp, rainbow trout, and atka mackerel (*Pleurogrammus azonus*), and their properties were characterized (86). The  $K_m$  value of carp TGase for monodansylcadaverine was 0.33 mM, while the other enzymes had values of 0.01–0.03 mM. The  $K_m$  values for succinylated casein of scallop, botan shrimp, squid, carp, rainbow trout, and atka mackerel enzymes were 1.2, 0.3, 1.8, 0.3, 0.2, and 0.1 mg/mL, respectively. In the presence of 0.5 M NaCl or 0.5 M KCl (isotonic to sea water), the activities of TGases from marine invertebrates, scallop, botan shrimp, and squid were enhanced about 11-, two-, and sixfold, respectively. On the contrary, there was no effect of such concentrations of NaCl on the fish enzymes. Muscle TGases may play a role in food processing.

High pressure at near 300 Mpa is considered to induce gelation and denaturation of salted paste surimi, a myofibrillar concentrate of fish muscle. Endogenous TGase that survives at the high pressure promotes gelation of Alaska pollock surimi (17). In addition, there is a review article with regard to food processing that TGase is applicable for food protein deamination to improve solubility, emulsification, foaming, and other functional properties of the proteins (16). The use of the enzyme must be more desirable than other chemical treatments in speed, mild reaction conditions, and their high specificity. Especially, it may prevent foods from contamination of pollutants such as endocrine disturbers.

## VI. DETERMINATION OF TRANSGLUTAMINASE ACTIVITY

A convenient assay method for measuring the TGase activity was developed by Lorand and Gotoh (87). This method is based on the incorporation of mono-

dansylcadaverine into a protein such as N,N-dimethylcasein (Fig. 2). The standard reaction mixture, slightly modified by Ha and Iuchi (11, 12) is as follows:

Stock solution	Volume ( $\mu$ L)	Final concentration
Tris-HCl (pH 7.2), 200 mM	250	50 mM
2-mercaptoethanol, 200 mM	25	5 mM
CaCl <sub>2</sub> , 1.0 M	5	5 mM
Monodansylcadaverine, 2.0 mM	250	0.5 mM
N,N-dimethylcasein, 1.0%	200	0.2%
Enzyme sample and some reagent	270	—

The mixture was incubated at appropriate temperature for various times, and the reaction was terminated by adding 1.0 mL of 10% trichloroacetic acid. After centrifugation, the precipitate was washed several times with ethanol-ether (1:1), dried by vacuum pump, and dissolved into 3 mL of 8 M urea-5% sodium dodecylsulfate (SDS)-50 mM Tris-HCl (pH 8.6). The intensity of fluorescence of the solution was measured by excitation at 355 nm and with emission at 525 nm, using 1 nmol/mL monodansylcadaverine as a standard. For human blood coagulation Factor XIII (fibrinolipase), the unit of TGase activity has been defined as amine incorporation unit (AIU) (87). For egg envelope TGase of rainbow trout, 1 unit of the activity was defined as 1 nmol of monodansylcadaverine incorporated into dimethylcasein per hour at 10°C (MIU: monodansylcadaverine incorporation unit) (13).

Monodansylcadaverine in the above reaction mixture can be replaced by biotinylated cadaverine (88, 89) and other amine derivatives. A novel, sensitive chemiluminescent assay was recently developed to quantitate the acyl transfer activity of blood coagulation Factor XIIIa or liver TGase, utilizing 6-[N-(4-aminobutyl)-N-ethylaminol]-2,3-dihydrophthalazine-1,4-dione as a substrate (90). As a more sensitive method, a <sup>14</sup>C- or <sup>3</sup>H-labeled putrescine or spermidine substrate has been frequently used (91, 92).

A fluorescent dipeptide compound, 1-N-(carbobenzoxy-L-glutamylglycyl)-5-N-(5'-N', N'-dimethylamino-1'-naphthalenesulfonyl)-diamidopentane (CBZ-Gln-Gly-C-DNS 1), was synthesized and was used as a substrate for assaying the activity of bacterial TGase or guinea pig liver TGase (93). The glutamine peptides were incorporated into lysine residues of  $\alpha\text{s}_1$ -casein. Thus, the method is based on measuring incorporation of a glutamine residue into a protein or peptide.

A fluorometric, high-performance liquid chromatographic (HPLC) assay for TGase activity has been described (94). This method used the small synthetic

peptide benzyloxycarbonyl-L-glutaminylglycine and monodansylcadaverine as substrates. The reaction product was separated by reverse phase HPLC, and was quantitated by fluorometry. An apparent  $K_m$  of purified guinea pig liver TGase was  $\sim 35$  mM for the peptide substrate.

A microtiter plate assay using human fibrinogen as an immobilized substrate has been developed for coagulation Factor XIII (88). Factor XIII was activated by  $\text{Ca}^{2+}$  and thrombin, added to fibrinogen immobilized on a plate, and then assayed by adding biotinylated cadaverine. After the reaction was terminated by adding EDTA, the quantity of incorporated biotin was determined with streptavidin- $\beta$ -galactosidase. Microtiter plates coated with N,N-dimethylcasein are also available as an immobilized substrate.

## VII. ISOLATION OF TRANSGLUTAMINASE

Methods used for isolation of different types of TGases have been recently reviewed by Bergamini and Signorini (95) and by Wilhelm and coworkers (92). Some data for the purification procedures are summarized in Table 2.

In addition to secretory TGases such as blood-clotting Factor XIII and copulatory plug-forming TGase in secretions from prostate gland, tissue TGases frequently occur in cytosol and are therefore extractable by homogenization of materials such as tissue and organ with conventional buffer solutions. Some TGases bind to cell membrane, cellular particles, or extracellular matrix. As described above, egg envelope TGases of rainbow trout, extracellular matrix TGases, were nearly completely extracted by repeated homogenization with isotonic saline (0.143 M NaCl, 10 mM Tris-HCl, pH 7.2) (11–14). Rat liver particulate TGase has been partially extracted by three times homogenization of pellet fractions with a sucrose buffer. However, the extraction was not complete. The TGase was further extracted by homogenization of the remaining particulate fractions with 1% Lubrol-WX (96). In contrast to these TGases, the TGase activity in egg envelope of the fish medaka (*Oryzias latipes*) was never extracted by homogenization with 5 mM 2-mercaptoethanol, 0.5 M NaCl, 1% Tween 20 or 0.6 M CHAPS (3-[ $\gamma$ (3-cholamidopropyl)dimethylammonio]-1-propane-sulfonate) (Ha and Iuchi, unpublished data).

At the next step of purification, TGases in the extracts are frequently concentrated by various methods. A usual method for the concentration is ammonium sulfate precipitation; 25–50% saturation for TGase of secretions of coagulating glands and dorsal prostate (5), or 50–60% saturation for testicular tissue TGase of rat (5) and bovine (95). Such enrichment has been performed by protamine precipitation (liver TGases of rodents) (97) or by ethanol precipitation (Factor XII of human placenta) (98). In addition, ion exchange column chromatography may be available for concentration of TGase.

Conventional chromatographic methods such as gel filtration, ion exchange, and hydrophobic column chromatography are applicable for isolation or purification of TGases, as summarized in Table 2.

Purification methods based on isoelectric points of TGases also have been useful. Preparative isoelectric focusing in a granulated Sephadex G-75 gel bed was performed for isolation of TGase from secretions of coagulating glands and dorsal prostate of rat (5, 23). In addition, epidermal TGase from cow muzzle was finally purified using zone electrophoresis in combination with gel filtration chromatography on a Sephadex G-200 column (99).

Affinity chromatography is particularly useful for purifying various TGases. The  $\text{Ca}^{2+}$ -dependent affinity chromatography using casein-Sepharose was employed for the isolation of rat liver cytosolic TGase (100). In the presence of 5 mM  $\text{Ca}^{2+}$ , the enzyme was bound to the column, and elution was achieved using 5 mM EGTA. Recently, TSKgel Heparin-5PW (Tosoh, Tokyo) or GTP-agarose (Sigma) was used to purify rat brain TGases (52). GTP-agarose affinity chromatography was desirable because GTP has been known to bind to tissue TGases to inhibit their activities. Immunoaffinity column chromatography has been employed for one-step purification of guinea pig TGase, where the supernatants of guinea pig liver homogenates were applied to an affinity column conjugating a monoclonal antibody against guinea pig liver TGase (101).

## VIII. COMMENTS

- As shown in Table 1, natural substrates for many TGases remain unidentified. Recently, a novel histone modification was found in the testis of the starfish (*Asterina pectinifera*) (102, 103), involving formation of an  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptide crosslink between a glutamine residue of histone H2B and a lysine residue of histone H4. Although a biological role of the TGase has not been well clarified, there is

	CM-cellulose	Human epidermal TGase	Cation exchange column chromatography	121
Hydrophobic column chromatography	Phosphocellulose	Rat prostate gland TGases (purified from the secretions)		126
	SP-Sepharose	Egg envelope TGases of rainbow trout	Not retained	13, 14
	Phenylalanine-Sepharose 4B	Liver TGase		124
	Phenyl-Sepharose	Rat testicular tissue TGase		5, 23, 95

(Continued)

**Table 2** Continued.

Purification Steps		Transglutaminases	Remarks	References
Affinity column chromatography	Casein-Sepharose	Guinea pig liver TGase		100
	Heparin-Sepharose	Tissue TGase of human erythrocyte		120
	TSK heparin 5PW	Rat brain TGase		52
	GTP-agarose	Rat brain TGase		52
	Blue-Sepharose CL-6B	Human erythrocyte		122
Immunoaffinity	Immunoaffinity	Guinea pig liver TGase	Antibody to cytosolic TGase	125
		Guinea pig liver TGase	Monoclonal antibody to guinea pig liver TGase	101
		Guinea pig liver TGase		124
Other column chromatography	Hydroxyapatite on Biogel-HTP	Guinea pig liver TGase		127
	Zinc-chelating Sepharose 6B	Rat liver TGase		117
		<i>Limulus</i> hemocyte TGase		
Preparative isoelectric focusing		Rat prostate gland TGases (purified from the secretions)	pH 4.0–9.0	5, 23

a possibility that the TGase-mediated crosslink formation of nuclear proteins is closely related to some important cellular events.

2. Antibodies specific to several TGases are commercially available: antitransglutaminase II (Mono) (Quartett GmbH, Berlin, Germany); and antitransglutaminase (type II) (Upstate Biotechnology Inc., Waltham, MA, US). These antibodies may be cross-reactive to various TGases. For example, a polyclonal antibody against guinea pig liver TGase was crossreactive to human keratinocyte TGase (104), and a monoclonal antibody against guinea pig liver TGase recognized a TGase present in mouse dermal fibroblast (105).

3. Recently, a distinct enzyme cleaving  $\epsilon$ -( $\gamma$ -glutamyl) lysine isopeptide crosslinks between proteins or peptides was found and termed isopeptidase (106). In the medicinal leech, *Hirudo medicinalis*, this same enzyme is called destabilase (107).

## ACKNOWLEDGMENTS

The authors wish to thank Dr. D. Wong U.S. Department of Agriculture, Agricultural Research Service, Western Regional Research Center, for critical reading of the present article. Our studies cited in the present article were supported in part by Grant-in-Aid from Ministry of Education, Science,

Sports, and Culture of Japan to I.I. Thanks are also due Irikawa Trout Hatchery, Tokyo, and Fuji Trout Farm, Shizuoka, for supplying rainbow trout eggs.

## Feruloyl Esterases

**Craig B. Faulds**

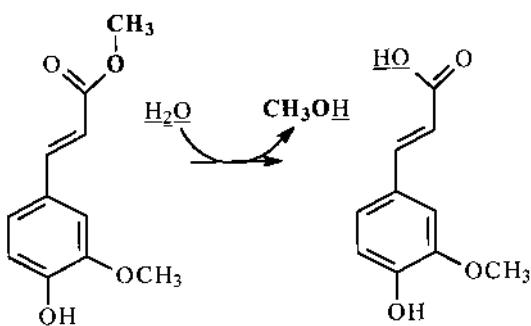

*Institute of Food Research, Colney, Norwich, England*

**Gary Williamson**

*Nestlé Research Centre, Lausanne, Switzerland*

### I. INTRODUCTION

Feruloyl esterases (ferulic acid esterase, cinnamoyl esterase, cinnamoyl ester hydrolase, FAE,\* FE, etc.) belong to the class of carboxylesterases (EC 3.1.1.1). These esterases catalyze the hydrolysis of ester-linked ferulic acid groups from a wide range of substrates. The product is a phenolic carboxylic acid and an alcohol.

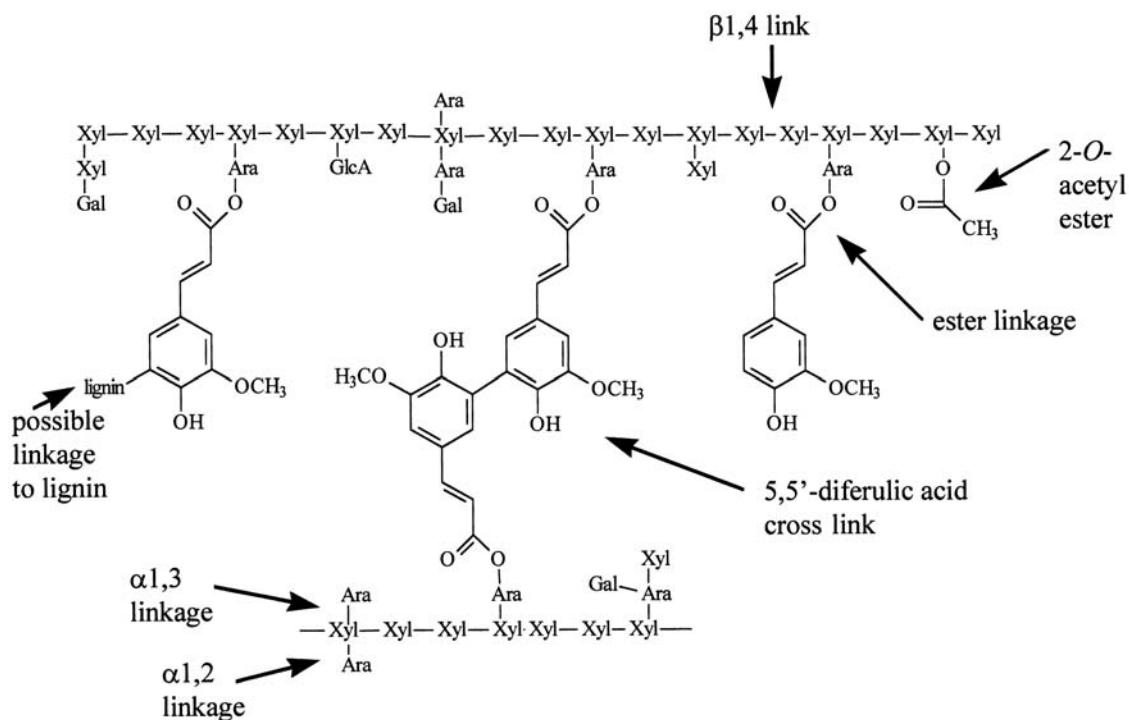

\* Abbreviations: AEBSF, 4-(2-amino-ethyl)-benzenesulfonyl fluoride; AraF, ferulic acid-arabinose ester; BLAST, basic local alignment search tool; CinnAE, type-B feruloyl esterase from *Aspergillus niger*; DFP, di-isofluorophosphate; EDTA, ethylenediaminetetra-acetic acid; FAE, feruloyl esterase; FAEA, type-A feruloyl esterase from *Aspergillus niger*; FE, feruloyl esterase; HPLC, high-pressure liquid chromatography; MFA, methyl ferulate; SDS-PAGE, sodium dodecylsulfate polyacrylamide gel electrophoresis.

Arabinoxylans and certain pectins contain ester-linked ferulic acid as shown in Figures 1 and 2 (1). The ferulic acid can be either monomeric or in one of several dimeric forms (2) (Fig. 3). Free ferulic acid and two of the ferulate dimers (5-5' mainly, but also the 8-O-4'-linked dimer) are released from arabinoxylans in wheat bran or from pectins in sugar beet pulp by some feruloyl esterases. This activity is greatly enhanced by xylanases (3).

### II. IMPORTANCE TO FOOD QUALITY AND UTILIZATION IN FOOD PROCESSING

The action, amount, and importance of endogenous feruloyl esterase in foods are unknown. Plants, especially cereals, produce feruloyl esterases (4). The role of these enzymes in plant tissue has yet to be elucidated. Endogenous activity could influence structural and textural properties during processing. Most microbial feruloyl esterases are secreted into the culture medium. Generally, monosaccharides and oligosaccharides do not induce production of feruloyl esterases but may be involved in other aspects of their regulation. Polymeric substrates such as oat spelt xylan, wheat bran, pectins, and maize bran induce production of a mixture of different forms of feruloyl esterase. Addition of free ferulic acid to the culture medium further stimulates production of feruloyl esterases (5).

**Figure 1** Simplified structure of arabinoxylan, emphasizing the attachment of ferulic acid.

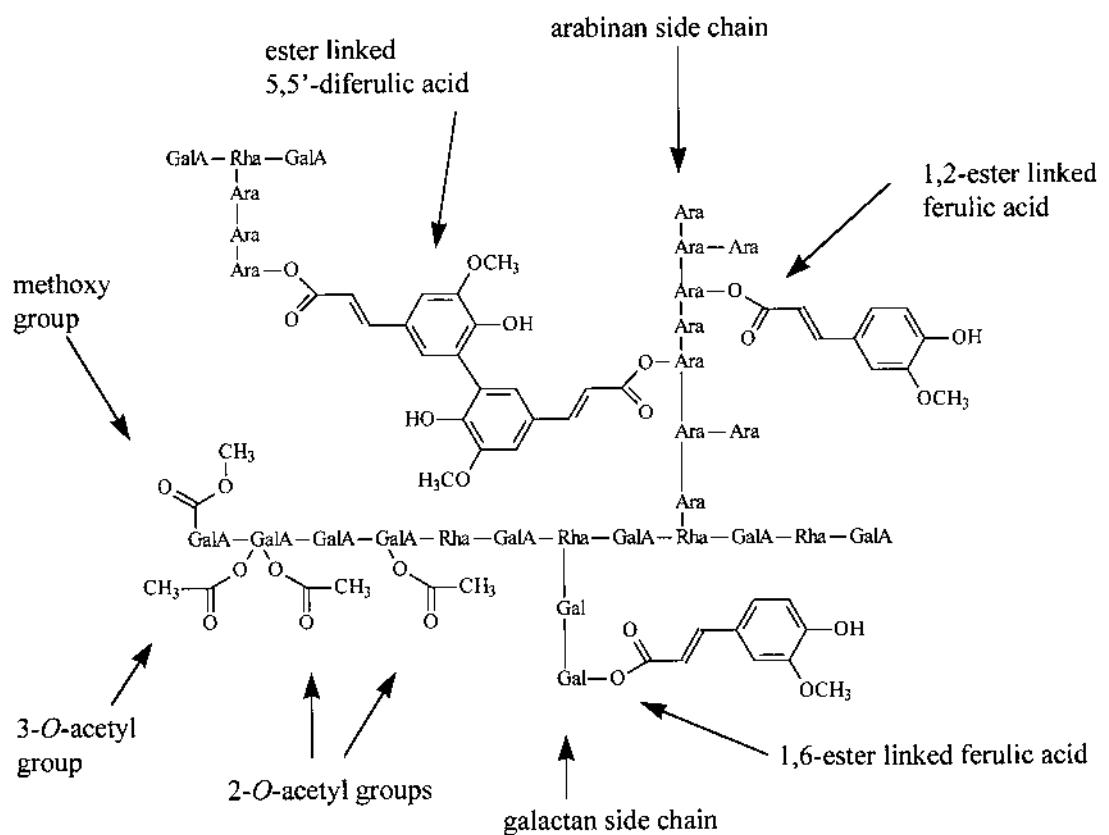

The commercial production of vanillin from agro-industrial wastes such as cereal brans and sugar beet pulp requires treatment of the starting materials with enzyme mixtures containing xylanase and feruloyl esterase. The released ferulic acid is bioconverted by microbes (*Aspergillus niger*, *Pycnoporus cinnabarinus*, *Pseudomonas* spp.) into vanillin (6, 7). Other possible uses are in baking or any food process involving plant cell walls.

### III. PROPERTIES OF THE PROTEIN

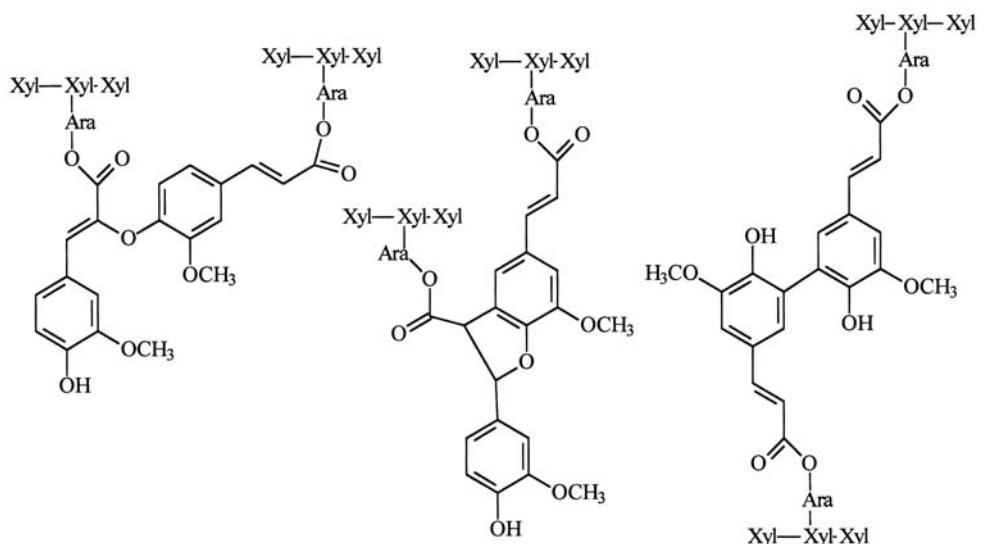

In recent years, the number of microbial cinnamoyl esterases identified has reached  $> 30$ , with 10 genes sequenced. Some esterases are part of a modular complex (8–9), contain cellulose-binding modules (10, 11), or exist as only a catalytic domain (12). No structural data have been published, although recently a crystal of the cinnamoyl esterase domain of XynZ from the anaerobic bacteria *Clostridium thermocellum* was obtained (13). Two feruloyl esterases will be considered here: feruloyl esterase A (FAE-III as purified from culture supernatants of *A. niger* CBS120.49 or recombinant FAEA;  $M_r = 29,700$ ) (14), and CinnAE ( $M_r \sim 150,000$  [dimer]), also from *A. niger* (15).

Other enzymes that have been purified are listed in Table 1. FAEA from *A. niger* and from *A. tubingensis* show 92% homology in amino acid sequence (12), but there is very little similarity between the feruloyl esterases sequenced to date. The primary protein sequence of FAEA shows some homology to lipases. Based on this homology, FAEA possesses conserved residues at the active site: the nucleophilic serine (residue 133), the catalytic acid (Asp174), and the catalytic base (His247). Based on modeling studies using the lipase template and on chemical modification using dithiobisnitrobenzoic acid treatment of denatured enzyme, FAEA has three intramolecular disulfide bonds and one free cysteine. CinnAE has not yet been cloned, but BLAST searches of short protein sequences show no homology with any other protein.

There is limited glycosylation of FAEA, while CinnAE is extensively glycosylated, possibly up to 40% (ww). *A. tubingensis* FAEA is more susceptible to proteolysis than *A. niger* FAEA, and this can give rise to multiple bands on Western blots in culture supernatants. This susceptibility may be due to residue differences at locations on the protein surface (16). Although no more than one gene encoding feruloyl esterases have been sequenced from a single source, there is some evidence of enzymatic isoforms existing.

**Figure 2** Simplified structure of sugarbeet pectin, emphasizing the attachment of ferulic acid.

**Figure 3** The most abundant diferulic acids found in plant cell walls: 8-0-4', 8-5' benzofuran and 5-5' diferulic acids linked to sugars.

**Table 1** Ferulic Acid Esterases Purified from Microbial Sources

FAE-I was purified from a commercial source of pectinase originally obtained from *a. niger* (17). On the basis of physical properties and substrate specificity, it may be a posttranslationally modified form of CinnAE. Likewise, FAE-II was also purified from the pectinase preparation and may be a posttranslationally modified form of FAEA.

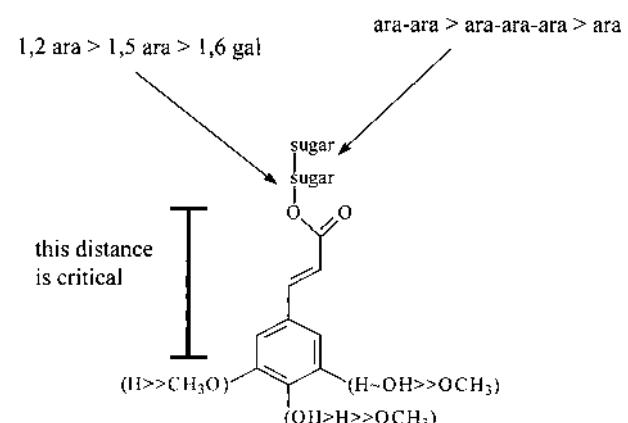

#### IV. ENZYMATIC PROPERTIES

Although there have yet to be any reports on active site inhibitor kinetics or active site mutagenesis of feruloyl esterases, the mechanism of action of these esterases is probably analogous to other serine esterases and lipases, and involves a nucleophilic serine (Ser133 in FAEA), which can be modified by the reagent, di-isofluorophosphate (DFP). By analogy with lipases, a catalytic acid and base are also essential. CinnAE activity is lost on modification with AEBSF, which also indicates the involvement of an active site nucleophilic serine. Feruloyl esterases isolated to date do not require the presence of a cofactor.

Tables 2–8 show the activity of FAEA and CinnAE on a range of different substrates. The substrate can be considered to be two moieties, a phenolic and an esterified group, either a sugar or alkyl substituent. A summary of the specificity of each enzyme is shown in Figures 4 and 5. Methyl caffeate is not a substrate for FAEA, but competitively inhibits it with a K<sub>i</sub> of ~1.5 mM (18). Based on the selective hydrolytic activity shown in these tables, a putative classification of fer-

uloyl esterases has been proposed: type A (e.g., *A. niger* FAEA) and type B (e.g., *A. niger* CinnAE, *P. funiculosum* FAEB), although there are exceptions (e.g., *P. fluorescens* XYLD), and not all enzymes displaying feruloyl esterase activity have been tested for activity using all the substrates used for FAEA and CinnAE. There is clearly a dependence of the rate of reaction on the number and nature of sugars in the substrate (**Tables 6, 7**) (19). However, it is not known if this is due to the presence of subsites on the esterases. The pH optimum of FAEA is 5.0, and that of CinnAE is 6.0.

The stability of FAEA to thermal and chemical denaturation has been studied. Thermodynamic parameters are shown in **Table 8**. FAEA is most stable at pH 5–6, where it retains ~50% of its catalytic activity after 1 h incubation at 60°C (20).

Like many esterases, feruloyl esterases catalyze the reverse reaction—i.e., synthesis of an ester bond (21). Although this reaction has only been reported with pentanol, the potential is there to make feruloylated esters with novel biological activities and applications.

## V. MEASUREMENT OF FERULOYL ESTERASE ACTIVITY

To measure feruloyl esterase activity, a range of low-molecular-weight synthetic methyl esters can be used as substrates, as described above (**Fig. 6**). Suitable natural substrates, which are feruloylated, are wheat arabinoxylan or sugar beet pulp (**Figs. 1, 2**). The rate of

reaction is increased in the presence of a xylanase or arabinofuranosidase/arabinanase respectively.

**Table 9** shows the activity of native FAEA and recombinant FAEA on methyl ferulate at pH 6.0, 37 °C (12). The assay for feruloyl esterases can be performed in several ways, but the most convenient is to use methyl ferulate as a substrate and monitor the reaction in a spectrophotometer (19). The limitation of this method is that the absorbance of methyl ferulate makes it difficult to use the substrate at concentrations about the  $K_m$ . As a standard method, the

total assay volume is 0.6 mL in disposable semimicro cuvettes with a 1-cm path length. For higher substrate concentrations, 0.3 mL in 0.1-cm path length cuvettes can be used. Dissolve methyl ferulate in methanol and add a small amount to 100 mM MOPS, pH 6.0. Determine the  $A_{335}$  of a solution of ~100 μM ( $A_{335} = 1.4$ ;  $E_{335}$  for MFA is 1400 M $^{-1}$  cm $^{-1}$ ). Add 0–100 μL of the enzyme solution to appropriate volumes of assay mixture so that final volume is 0.6 mL (1-cm path length) or 0.3 mL (0.1 cm) and incubate at 37°C. Calculate the rate using  $\Delta E$  of

FA — Ara — Ara — Ara	0	109

The most accurate and time-consuming assay for the measurement of the release of ferulic acid is by HPLC. This is the only assay that can be used when measuring the release of phenolic acids (ferulic acid and dimers) from insoluble plant cell wall-derived material (26). Samples of plant material (e.g., 10 mg) and enzyme preparation diluted in buffer (in a total volume of 0.5 mL) are incubated at a specific temperature for selected times. It is important to mix the reaction tube during this step to ensure complete interaction between the enzyme and the substrate. Reactions are stopped by the addition of glacial acetic acid (0.2 mL) and centrifuged, and the supernatant is filtered through a 0.22-μm filter. The

**Table 9** Thermodynamic Parameters for FAEA

$\Delta G (H_2O)$ (kJ/mol) with GuHCl as denaturant (30°C, pH 6.0)	Slope ( $m$ ) (kJ/mol.M) with GuHCl as denaturant (30°C, pH 6.0)	[GuHCl] <sub>1/2</sub> (M) (30°C, pH 6.0)	$k_{(unfolding)}$ (sec <sup>-1</sup> ) (60°C, pH 6.0)	$k_{(unfolding)}$ (sec <sup>-1</sup> ) (60°C, pH 6.0) with 0.1 mM sinapic acid
16.5	-11.9	1.38	0.0076	0.0066

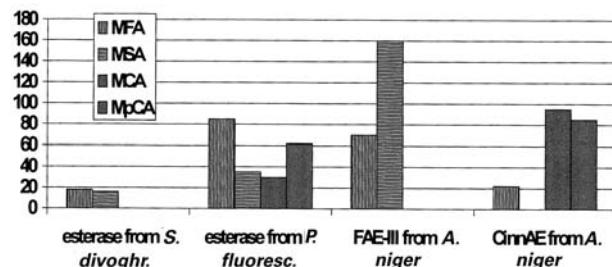

The rate of irreversible thermal denaturation is given by the first-order rate constant,  $k_{(unfolding)}$ , and the stability is slightly increased in the presence of sinapic acid, which is a product of the hydrolysis of methyl sinapate.

supernatant is then injected onto an HPLC column (e.g., Spherisorb ODS 3), and the amount of free phenolic acid released is quantified from a standard curve (27).

## VI. PURIFICATION PROCEDURES

Most microbial feruloyl esterases are extracellular. In this section, we describe the purification of FAEA from *Aspergillus niger* (14). Slight variations of these procedures have been used for a number of microbial feruloyl esterases.

Prepare 20 L of liquid media (2 L media in each 5-L conical flask) containing 1.0% (w/v) oat spelt xylan, incubate with *Aspergillus niger* (CBS, 120.49) at 25°C and 120 rpm for 4 days. At the end of the incubation, pass the culture supernatant through a double layer of muslin, and clarify by centrifugation (4000 rpm/15 min at 4°C). The culture supernatant is concentrated to 800 mL (10,000 M<sub>r</sub> cutoff). Concentrated culture supernatant is fractionated by 50–80% saturated ammonium sulfate, and the pellet from 80% saturation is resuspended in 80–100 mL of 50 mM sodium phosphate, pH 7.0, 1 mM EDTA, the solution made up to 1 M (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and then filtered through a 0.45-μm cellulose acetate filter. Hydrophobic interaction chromatography (HIC) is carried out using two buffers: Buffer A—50 mM phosphate, pH 7.0, 1 mM EDTA, 1.7 M (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>; Buffer B—50 mM phosphate, pH 7.0, 1 mM EDTA. The prepared sample is loaded into a HiLoad column (200 mL). FAEA elutes at 100% Buffer B. The fractions containing activity are then again subjected to a repeat hydrophobic interaction chromatography step. The pooled FAEA sample from the previous step is made 1 M (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, filtered through a 0.45-μm cellulose acetate filter, and then applied again to a smaller HiLoad (50 mL) column with the same gradient. The active fractions are then applied to an anion exchange column using MonoQ (10/10) with a gradient of Buffer A: 20 mM Tris-HCl, pH 8.5, 1 mM EDTA to Buffer B: 20 mM Tris-HCl, pH 8.5, 1 mM EDTA, 1 M KCl. FAEA elutes at 35% Buffer B. At this stage, the enzyme is essentially pure

by SDS-PAGE. Feruloyl esterases are relatively stable when stored frozen between pH 5 and 6.

## Lipase

**Dominic W. S. Wong**

*U.S. Department of Agriculture, Albany, California, U.S.A.*

### I. INTRODUCTION

Lipases (EC 3.1.1.3) are key enzymes involved in fat digestion in vertebrates by converting insoluble triacylglycerols into more soluble products, fatty acids and monoacylglycerols, that can easily be assimilated by the organism. The lipolysis process is controlled by gastric lipase in the stomach that hydrolyzes dietary fat (triacylglycerols) to fatty acids and diacylglycerols, which are further converted by pancreatic lipase in the intestine to fatty acids and monoacylglycerols for intestinal absorption. Most lipases have a basic pH optimum. Only lipase isolated from lingual or gastric tissue have an acidic pH optimum. Lipases for food processing are obtained from edible forestomach tissue of calves, kids, or lambs, and animal pancreatic tissues as purified edible tissue preparations or as aqueous extracts (1). Industrial lipases are also produced by the controlled fermentation of *Aspergillus niger* var., *Aspergillus oryzae* var., *Candida rugosa*, and *Rhizomucor miehei* as a powder or liquid. Typical applications in the food industry include lipid hydrolysis, manufacture of cheese and cheese flavors, modification of lipids, manufacture of dairy products and confectionery goods, and development of flavors in processed foods (2).

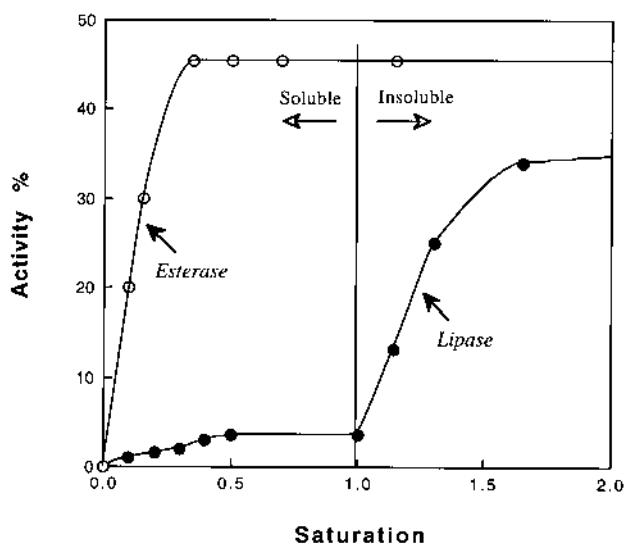

### II. CLASSIFICATION

Esterases are classified under hydrolases which are subdivided according to the action on the type of ester

bonds. Lipases hydrolyze carboxylic ester bonds of triacylglycerols to diacylglycerols and carboxylates. According to IUBMB nomenclature (3), triacylglycerol lipase or lipase (trivial name) has the systematic name of triacylglycerol acylhydrolase, and a code number of EC 3.1.1.3. The pancreatic enzyme acts only on an ester-water interface, with the outer ester links preferentially hydrolyzed. Other important lipolytic enzymes include phospholipases A1 (EC 3.1.1.32) and A2 (EC 3.1.1.4), which are phosphoglyceride acylhydrolases, and phospholipases C (EC 3.1.4.3) and D (EC 3.1.4.4), which are phosphoric diester hydrolases. Triacylglycerol lipases are distributed widely in animals, plants, and microorganisms. Animal lipases including pancreatic, gastric, intestinal, and milk have been investigated. Microbial lipases are found in *Rhizomucor miehei*, *Rhizopus delemar*, *R. niveus*, *Geotrichum candidum*, *Candida rugosa* (*C. cylindracea*), *C. antarctica*, *Humicola lanuginosa*, *Pseudomonas glumae*, *Ps. aeruginosa*, *Ps. cepacia*, *Ps. fragi*, and *Staphylococcus hyicus*. The present discussion will focus on pancreatic lipases and fungal lipases which have been extensively investigated in terms of their reaction mechanisms and known crystal structures.

### III. INTERFACIAL ACTIVATION

Lipases constitute a special class of esterases that acts specifically on water-insoluble esters at oil-water interfaces. Sarda and Desnuelle (4) first demonstrated in a quantitative way that pancreatic lipase exhibits very

**Figure 1** Hydrolysis of triacetin by pancreatic lipase and esterase. (Adapted from Ref. 4.)

little activity when triacetin, a short fatty acid chain triacylglycerol, is in a monomeric (soluble) solution (Fig. 1). However, when the triacetin concentration exceeds the solubility limit and the insoluble substrate forms emulsified particles separated from water by an interface, the lipase activity increases dramatically. Adsorption of lipase at the interface is followed by a 10<sup>3</sup>-fold activation. This unique phenomenon of lipases in catalyzing a heterogeneous reaction that involves interfacial activation—a sharp increase in the enzyme activity once the substrate solubility is exceeded and a lipid-water interface appears—is in great contrast to esterases that act on water-soluble substrates and show a normal Michaelis-Menten-type dependence on substrate concentration. (See Sec. V for more details.)

#### IV. MOLECULAR STRUCTURE

Numerous amino acid sequences of lipases are known, primarily deduced from DNA sequencing. A total of 58 entries are listed in the Swiss-Prot: *Bos taurus* (bovine) pregastric, pancreatic lipase; *Rattus norvegicus* (rat) hepatic, pancreatic, lingual, pancreatic lipase related protein; *Mus musculus* (mouse) hepatic, pancreatic lipase; *canis familiaris* (dog) gastric, pancreatic lipase-related protein; *Homo sapiens* (human) hepatic, pancreatic, gastric, pancreatic lipase-related protein; *Cavia porcellus* (guinea pig) pancreatic; *Oryctolagus cuniculus* (rabbit) pancreatic; *Equus caballus* (horse)

pancreatic; *Sus scrofa* (pig) pancreatic; *Candida rugosa* (yeast) (formerly *Candida cylindracea*); *C. albicans* (yeast); *Moraxella* sp; *Geotrichum candidum* (*Oospora lactis*); *Myocastor coypus* (Coypu) (Nutria) pancreatic, pancreatic lipase-related protein; *Chromobacterium viscosum*; *Rhizomucor miehei*; *Rhizopus oryzae* (R. *delemar*); *R. niveus*; *Staphylococcus epidermidis*; *S. hyicus*; *S. aureus*; *Saccharomyces cerevisiae* (baker's yeast); *Photohabdus luminescens* (*Xenorhabdus luminescens*); *Yarrowia lipolytica* (*Candida lipolytica*); *Aeromonas hydrophila* extracellular lipase; *Burkholderia cepacia* (*Pseudomonas cepacia*); *Ps. aeruginosa* lactonizing lipase; *Pseudomonas* sp. (strain KWI-56); *Ps. fluorescens*; *Ps. glumae*; *Ps. fragi*; *Pseudomonas* sp. (strain 109) lactonizing lipase; *Psychrobacter immobilis*; *Canadida antarctica* (yeast) (*Trichosporon oryzae*); *Bacillus subtilis*; *Vibrio cholerae* lactonizing lipase.

The crystal structures of a number of lipases have been solved, including those of *Bos taurus* (bovine) pancreatic lipase; *Sus scrofa* (pig) pancreatic lipase; *Rattus norvegicus* (rat) pancreatic lipase-related protein; *Homo sapiens* (human) gastric, pancreatic lipase, lipase complexed with colipase and phospholipid, lipase complexed with colipase and inhibited by undecane phosphonate methyl ester; *Cavia porcellus* (guinea pig) pancreatic lipase related protein; *Equus caballus* (horse) pancreatic lipase; *Canis familiaris* (dog) pancreatic lipase related protein; *Chromobacterium viscosum* lipase; *Candida antarctica* lipase with phosphonate inhibitor; *Rhizopus niveus* lipase; *R. delemar* lipase; *Candida rugosa* (formerly *C. cylindracea*) lipase, lipase complexed with (IR)-methyl hexyl phosphonate, lipase complexed with doecanesulfonate, lipase complexed with hexadecanesulfonate, lipase complexed with hexadecanesulfonate, lipase complexed with (IS)-menthyl hexyl phosphonate; *Pseudomonas cepacia* lipase; *Ps. glumae* lipase; *Candida antarctica* lipase; *Rhizomucor miehei* lipase, complex with diethylphosphate, complexed with n-hexylphosphonate ethyl ester; *Geotrichum candidum* strain atcc 34614 lipase; and *Humicola lanuginosa* lipase.

#### A. Pancreatic Lipases

The porcine pancreatic enzyme is a glycoprotein composed of 450 amino acids with a calculated MW of 50,084 daltons. The enzyme consists of six disulfide bridges, Cys4-Cys10, Cys91-Cys102, Cys238-262, Cys286-297, Cys300-Cys305, and Cys434-450, with two free cysteines, Cys 104 and Cys 182 (5–8) (see also Swiss-Prot). The porcine pancreatic enzyme is

N-glycosylated at Asn167. The glycosylation site Asn167-Gly168-Thr169 in the porcine enzyme is conserved in the human and canine lipases, and the glycan structure of porcine pancreatic lipase has been elucidated (9). In contrast to the human, porcine, and canine pancreatic lipases, the horse, ovine, and bovine enzymes are not glycosylated. Heterogeneity of the glycan moiety at Asn167 gives rise to 4 isoforms, L<sub>A1</sub>, L<sub>A2</sub>, L<sub>B</sub>, and L<sub>C</sub>, with the less anionic L<sub>B</sub> the major form (70%) in the porcine enzyme (10). Unlike most of the pancreatic enzymes which are secreted as proenzymes and further activated by proteolytic cleavage in the small intestine, pancreatic lipases are directly secreted as a 50-kDa active enzyme.

The porcine lipase comprises two domains (7). The larger, N-terminal domain (residues 1–336) has an  $\alpha/\beta$  structure, containing the catalytic triad: Ser153, Asp177, and His264. The C-terminal domain (residues 337–450) assumes a  $\beta$ -sandwich, and contains the binding site for colipase. In the human pancreatic lipase, the central parallel  $\beta$ -sheet of the  $\alpha/\beta$ -domain has nine strands cross-connected by  $\alpha$ -helices or loops, whereas the C-terminal  $\beta$ -sandwich is formed by two layers of  $\beta$ -sheet, each of four antiparallel strands (11). The crystal structure of the horse enzyme shows close resemblance (8). A significant discovery in the x-ray crystallographic investigation is the existence of a surface loop or flap covering the active site. This “lid” must be repositioned via a conformational change during interfacial activation to allow the substrate to enter the active site. In a lipase-colipase system, the lid, together with the colipase, forms a continuous hydrophobic surface which serves as the lipid binding site of the complex at the interface.

## B. Microbial Lipases

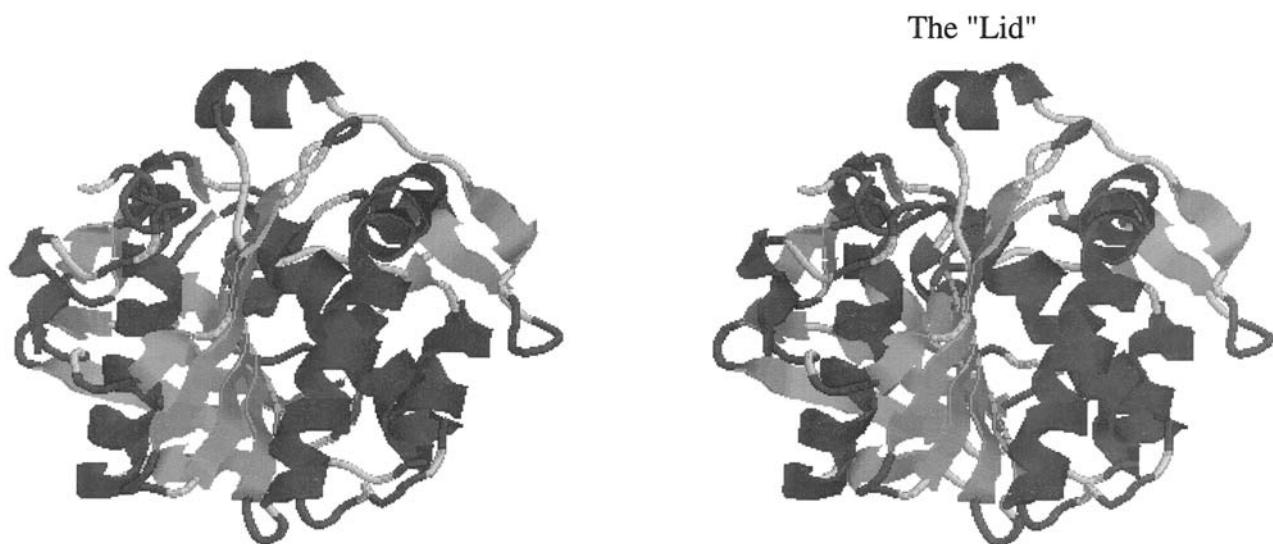

Microbial lipases have been extensively studied owing to their potential industrial applications. The phycomycete fungus *Rhizomucor miehei* (formally *Mucor miehei*) produces an extracellular lipase that hydrolyzes a broad spectrum of lipid substrates found in animal plants. The lipase is synthesized as a precursor containing a signal peptide and a propeptide, in addition to 269 amino acid residues of the mature enzyme which has a calculated MW of 29,472 daltons (12). The secreted lipases were purified in two isoforms, A (pI = 3.9) and B (pI = 4.3), because of partial deglycosylation in posttranslational processing (13). The *Geotrichum candidum* lipase also exists in two isoforms, I (pI = 4.56) and II (pI = 4.46) (14). Both have the same chain length of 544 amino acid residues (exclud-

ing the signal peptide of 13 residues), with a calculated MW of 59,085, containing two and three N-glycosylation sites, respectively (15). However, lipases I and II, with an overall 84% identity in the two sequences, are encoded by separate genes, *lip1* and *lip2* (16, 17). The asporogenic yeast *Candida rugosa* (formerly *C. cylindracea*) produces extracellular lipase in multiple forms, five of which have been cloned and sequenced: lipase I (pI 4.5), II (pI 4.9), III (pI 5.1), IV (pI 5.7), and V (pI 5.5) (18, 19). All five genes code for 57-kDa proteins of 534 amino acid residues.

The *Rhizomucor miehei* lipase, similar to pancreatic lipases, is an  $\alpha/\beta$ -type protein. The enzyme molecule consists of a central parallel eight-stranded  $\beta$ -sheet folded onto a highly amphipathic N-terminal helix (Fig. 2) (20–22). All the connecting loops are right-handed, and hence located on one side of the  $\beta$ -sheet. Three disulfide bonds, Cys29–Cys268, Cys40–Cys43, and Cys235–Cys244, provide a global stabilization to the protein. The active center containing the catalytic triad (Ser144···His257···Asp203) is buried under a helical “lid” that is amphipathic in nature. When the enzyme is adsorbed at the lipid-water interface, the lid undergoes conformational changes to roll back from the active site. The hydrophobic side of the lid is exposed to the interface, thereby expanding the non-polar surface area surrounding the active site. This stabilization of the open form of the lipase at the interface in effect creates a catalytically active enzyme to attack the triacylglycerol molecule with the lipid phase.

The *Geotrichum candidum* lipase has an  $\alpha/\beta$  structure with a central mixed  $\beta$ -sheet formed by 11 strands, seven of which are parallel (23, 24). The helices and loops connecting the strands are found on both sides of the  $\beta$ -sheet. Two disulfide bonds are present: Cys61–Cys105, and Cys276–Cys288. The active site, consisting of the catalytic triad Ser217–His463–Glu354 is concealed by two nearly parallel  $\alpha$  helices.

The general molecular architecture has been observed in lipases from other microbial sources, including *Candida rugosa* (25), *C. antarctica* (26), *Rhizopus delmar* (27), *Pseudomonas glumae* (28), and *Ps. aeruginosa* (29). The major difference between the molecular structures of the pancreatic and the microbial enzymes is that the former contains a C-terminal domain serving as the binding site for colipase which is required for facilitating the interfacial catalysis in the presence of bile salts, whereas the latter is devoid of this domain. It should also be noted that lipases do not all subscribe to the phenomenon of interfacial activation. For example, the *Pseudomonas aeruginosa* lipase lacks a lid-like helical loop structure covering the

**Figure 2** A stereo view of *Candida rugosa* lipase (PDBID: 1trh).

active site, and does not show interfacial activation (30). A lipase isolated from guinea pig was found to carry a deletion in the lid sequence, and shows no interfacial activation (31). In addition to providing accessibility of the active site for the substrate, the opening of the lid causes a concomitant conformational change for proper positioning of the residues forming the oxygen hole during catalysis (22, 25).

## V. COLIPASE

Adsorption of protein molecules at the lipid-water interface often leads to unfolding and denaturation. For pancreatic lipases, adsorption at the interface results in decreased activity and consequently inactivation. In the physiological environment, the activity of pancreatic lipases is regulated by the presence of bile salts (cholic and chenodeoxycholic acids conjugated with glycine or taurine, such as taurodeoxycholate, glycodeoxycholate, or taurocholate) and other amphiphilic compounds, such as phospholipids and proteins. The presence of bile salts creates a negatively charged film on the triacylglycerol micelle that prevents lipase adsorption (32, 33). The cooperative formation of an enzyme–bile salt complex with a dissociation constant of  $1.4 \times 10^{-15}$  M prevents the adsorption to the interface (34). For a pancreatic lipase to act at the interface, the enzyme requires the binding of colipase, a 10-kDa protein also secreted by the exocrine pancreas, to facilitate adsorption of the enzyme at bile salt-coated lipid-

water interface. The inhibitory action of bile salts is observed on both microbial and pancreatic lipases, but the activity of the pancreatic enzyme can only be restored by the addition of pancreatic colipase, indicating that specific interactions occur between the pancreatic lipase and colipase (35).

Porcine pancreatic colipase is a single polypeptide chain containing 96 amino acid residues with five disulfide bridges, and has an isoelectric point of 5.0 (36). Its primary structure has been determined by protein sequencing (37, 38). The protein is synthesized as a procolipase of 101 amino acid residues, and the active form, colipase<sub>96</sub>, is produced by proteolytic (tryptic) removal of the N-terminal pentapeptide (Val-Pro-Asp-Pro-Arg) (39, 40).

Colipase consists of a small N-terminal region and a three-fingers region held together by disulfide bridges (41, 42). Colipase exhibits an overall amphipathic character with most hydrophilic residues found in the N-terminal region, whereas most of the hydrophobic residues are located at the tip of the fingers in the opposite side that constitute the lipid-binding site (43–46).

Binding of colipase to lipase occurs between two hairpin loops (residues 44–46, 65–67) in the N-terminal region of colipase, and the  $\beta$ -sheet of the C-terminal domain of the lipase molecule (41, 46). The interactions are mostly hydrophilic with the formation of two salt bridges and six hydrogen bonds. Porcine pancreatic lipase binds to colipase to form a 1:1 complex with a  $K_d$  of  $5 \times 10^{-7}$  M in the absence of an interface (34, 47, 48). In the presence of 2 mM sodium tauro-

deoxycholate and 150 mM NaCl, binding of lipase to colipase at pH 7.0 has a  $K_d$  of  $2 \times 10^{-6}$  M (49).

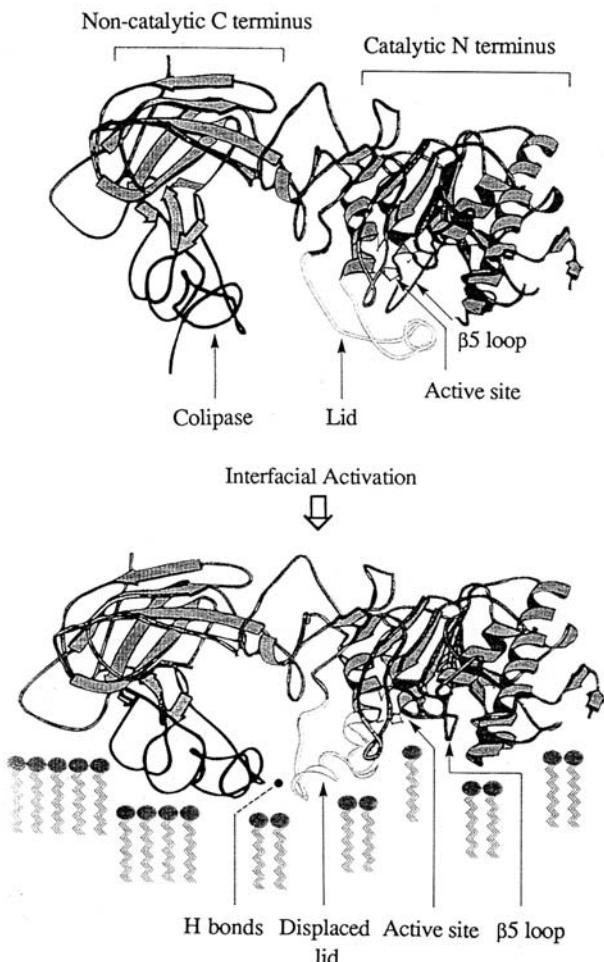

The binding of colipase to the bile salt–liquid substrate at the interface involves the three-finger region that forms a hydrophobic surface interacting with the lipid (Fig. 3) (41). The central finger consists of three highly conserved Tyr residues (Tyr55, Tyr58, Tyr59 in porcine prolipase) in a strongly hydrophobic loop (also designated as the tyrosine loop region) that has long been implicated as the lipid-binding site (50–52). The binding of colipase to the substrate, tributyrin, at pH 7.0 in the presence of 4 mM sodium taurodeoxycholate and 150 mM NaCl has a dissociation constant  $K_d = 3.3 \times 10^{-7}$  M (53). The binding of colipase to an emulsion of long-chain triacylglycerols stabilized with

phosphatidylcholine and glycerol showed a  $K_d$  of  $1.2 \times 10^{-6}$  M in the presence of 4 mM sodium taurodeoxycholate and 150 mM NaCl at pH 7.0.

Colipase also binds to the surface helix (the lid) covering the catalytic triad of lipase in its open conformation (54, 55). The interaction is mediated by three hydrogen bonds between Arg38, Leu16, and Glu15 of colipase, and Val246, Ser343, and Asn240 of the lid. The binding serves to stabilize the lid during activation, and provides an extended hydrophobic surface that constitutes the lipid–water interface binding site, which is more than 50 Å in length and has a surface area of approximately 965 Å<sup>2</sup> (42, 56).

## VI. REACTION MECHANISM

All lipases and esterases contain an active Ser in a consensus sequence G-X-S-X-G which is reminiscent of the pentapeptides in serine proteases (Gly-Asp-Ser-Gly-Gly in the trypsin family, and Gly-X-Ser-X-Ala in subtilisin) (Fig. 4) (57). That most lipases are susceptible to inactivation with classic serine protease inhibitors, such as diisopropylphosphofluoridate and diethyl-p-nitrophenyl phosphate, has long been implicated as evidence that lipases belong to the mechanistic class of serine proteases. Recent structural analyses have been shown conclusively that lipases contain the same constellation of the catalytic triad, Ser···His···Asp, present in all serine proteases, although the topological position of the individual residue's side chain varies (11, 20). It has also been demonstrated that the

hydrolysis of dissolved *p*-nitrophenyl acetate by pancreatic lipase proceeds via an acyl enzyme intermediate (Fig. 5) with  $k_3 = k_{\text{cat}}$  (deacylation) =  $0.11 \pm 0.01 \text{ min}^{-1}$ ,  $k_2$  (acylation) =  $7 \pm 0.7 \text{ min}^{-1}$ ,  $K_{m(\text{app})} = 0.22 \pm 0.02 \text{ mM}$ , and  $K_S = 15 \text{ mM}$ , and that the relation  $k_{\text{cat}}/K_m$  equals  $k_2/K_S$  is consistent with an acylenzyme mechanism (58). Using *p*-nitrophenyl butyrate as the substrate, the  $k_{\text{cat}}/K_m$  values of *Candida cylindracea* lipases A and B have been reported to be  $2.51 \times 10^7$ , and  $0.42 \times 10^7 \text{ sec}^{-1} \text{ M}^{-1}$ , respectively (59). In the hydrolysis of *p*-nitrophenyl laurate in mixed micelles with Triton X-100, the apparent  $k_{\text{cat}}/K_m$  values are  $3.0 \times 10^5$  and  $5.6 \times 10^5 \text{ sec}^{-1} \text{ M}^{-1}$ , respectively for lipase A and B (60).

Since the pioneering work by Matthews et al. (61) on the 3D structure of chymotrypsin, the mechanistic nature of the catalytic triad during catalysis by serine proteases has been the focus of extensive investigations. In the original model of double proton transfer, the catalytic triad is described as a charge relay system involving a concerted double transfer of protons from Ser-OH to His-N<sub>e2</sub> and from His-N<sub>δ1</sub> to Asp-O<sub>δ2</sub> with a schematic representation (Asp-COOH...N-Im-NH...O-Ser). The negative charge on the carboxylate anion is transferred fully to the carbonyl oxygen of the substrate (62–64). An alternative mechanism proposes that the proton of Ser-OH is transferred to His-N<sub>e2</sub> without the concomitant transfer of the His-N<sub>δ1</sub> proton to the adjacent carboxylate anion (65, 66). NMR and neutron diffraction studies, as well as theoretical calculations of the energetics, suggest that the Asp residue remains ionized and the imidazole is protonated at the transition state to form a charged structure [Asp<sup>−</sup>...His<sup>+</sup>...Ser<sup>−</sup>] (67–70). In this model, positive character will develop on the His imidazole, as negative

charge builds up on the carbonyl oxygen from the formation of the new carbon-oxygen bond via the nucleophilic attack of the Ser-O<sup>−</sup> at the carbonyl carbon of the substrate.

Taking into account that the lipase-catalyzed hydrolysis of monomeric substrates involves the Ser...His...Asp triad and the formation of an acylenzyme, the following mechanism can be envisioned to occur based on the catalytic pathway of serine proteases (Fig. 6).

1. The enzyme first binds the substrate to form a Michaelis-Menten adsorption complex.
2. Nucleophilic attack by the essential Ser-OH on the acyl carbon of the substrate yields a covalent tetrahedral intermediate. This step is facilitated by general base catalysis by the His in the triad.
3. A collapse of the intermediate to an acylenzyme involves the His-catalyzed protonation of the ester oxygen of the leaving group.
4. In the following step, deacylation of the acylenzyme occurs with H<sub>2</sub>O assisted by general base catalysis involving the His, resulting in the formation of a tetrahedral intermediate.
5. Finally, protonation of the Ser causes the breakdown of the intermediate, resulting in liberation of the product as a carboxylic acid.

It has been well established that oxyanion-binding sites in the proteases, for example, Ser221 and Asn155 in subtilisin, form hydrogen bonds to the carbonyl oxygen of the scissile peptide bond, contributing to the stabilization of the charge distribution and the reduction of the ground-state energy of the tetrahedral intermediate (71). In human lipase, the repositioning of the lid induces a second conformational change in the vicinity of the active site. This brings the Phe78 sided

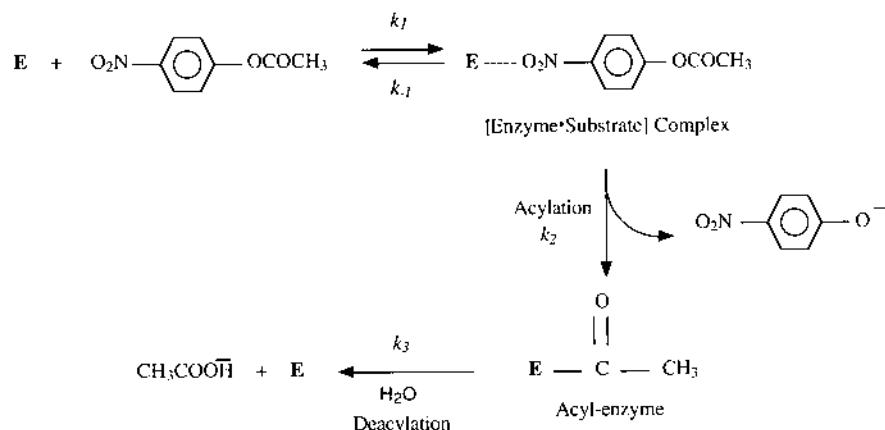

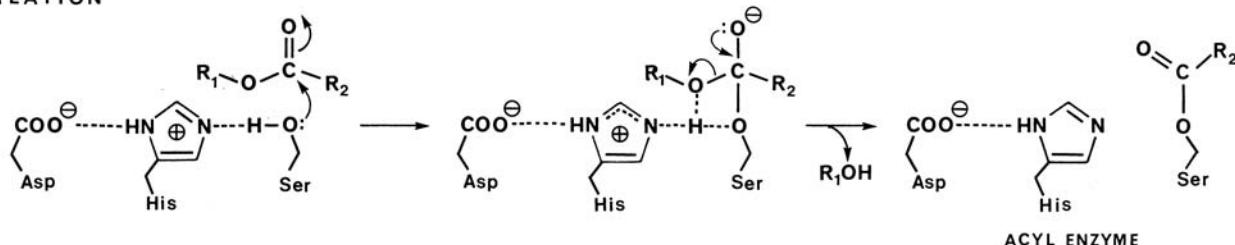

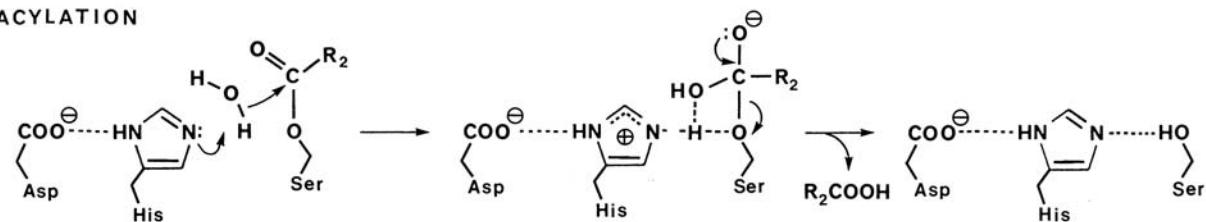

Figure 5 Lipase-catalyzed hydrolysis of *p*-nitrophenyl acetate.

## ACYLATION

## DEACYLATION

**Figure 6** Proposed reaction mechanism showing acylation and deacylation via the formation of an acylenzyme intermediate. (From Ref. 122.)

chain into a position for its main chain nitrogen to stabilize the negatively charged oxyanion (Ser153-O $\gamma$ ) developed in the tetrahedral intermediate (8). In the *Rhizomucor miehei* lipase, the movement of the lid in the active conformation results in the positioning of the hydroxyl and amide bond nitrogen of Ser82 for its interactions with and stabilization of the ester carbonyl oxygen of the substrate complex (22). In the *Candida rugosa* lipase, the open state involves a change in the conformation of the lid, leading to a movement of the NH of Ala132 into a proper position for the oxyanion hole (25).

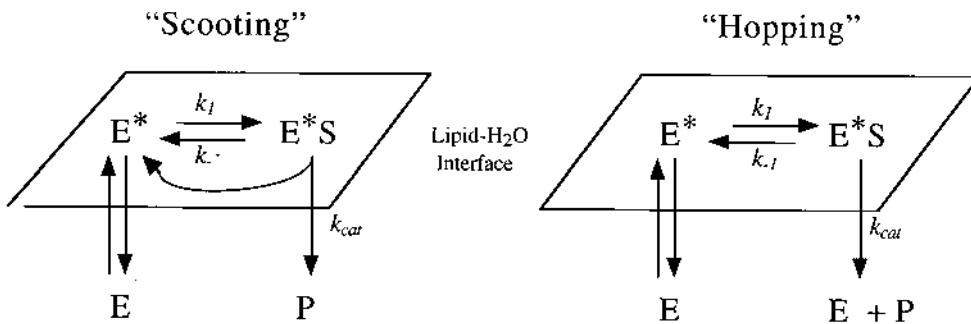

The kinetic behavior of lipases at the lipid-water interface is far more complicated than what is described above for the hydrolysis of dissolved substrates. The lipase in the aqueous phase must first bind to the interface ( $E \rightarrow E^*$ ) before it can bind to the substrate. Physically, it involves movement of the lid, and the enzyme assumes an open conformation. In addition, the lipase regenerated in the deacylation step can either diffuse from the interface or stay bound (Fig. 7). The pathway through which  $E^*$  is recycled can be described by two different models (72, 73). In the “scooting” model,  $E^*$  stays in the interface between catalytic turnovers. In the extreme situation, it remains bound to the interface until all substrate has been depleted. In the “hopping” model, only a small amount of the substrate will be hydrolyzed in each binding event. In the extreme situation, the binding

and the desorption of the bound enzyme at the interface occur after each catalytic turnover cycle. The *Pseudomonas glumae* lipase exhibits a kinetic behavior which is explained by the hopping model (74). Lipoprotein lipase shows a similar mode of action (75).

## VII. ACYL TRANSFER REACTIONS

In the reaction mechanism described above for lipase-catalyzed hydrolysis of lipids, deacylation involves nucleophilic attack of the acylenzyme by H<sub>2</sub>O. This step can also be accomplished by other nucleophiles, such as alcohols and amines, resulting in an acyl transfer instead of hydrolysis. In an aqueous environment, hydrolysis is the favorable route, whereas in organic media, the acylenzyme is exposed to nucleophiles without competition from H<sub>2</sub>O, and acyl transfer prevails. It has been shown that *Rhizomucor miehei* lipase retains high rates in esterification and transesterification at water activity < 0.0001 (76).

The acyl transfer reaction provides a novel use of lipases as catalysts in organic synthesis. Using amines as nucleophiles, esters can be converted to the corresponding amides in organic media at ambient temperature. For example, *Candida antarctica* lipase-catalyzed aminolysis of ethyl octanoate gives a 95% yield of octanamide (77). Peptide bonds can be formed

**Figure 7** “Scooting” and “hopping” models of interfacial catalysis. (Adapted from Ref. 72, 73.)

between N-acetyl-L-(amino acid)-2-chloroethyl esters and amides of L or D amino acids (78). This reaction can be utilized in the production of optically active amides by taking advantage of the regio- and stereospecificity of the enzyme (79). Using hydroxyacid esters, bifunctional molecules containing both a methyl ester and an OH group as substrates, lipases can catalyze intermolecular or intramolecular condensation to give corresponding oligomers or lactones as the product (80, 81). The preference for oligomerization or lactonization depends on the chain length and degree of substitution of the substrate. This reaction has been exploited for the synthesis of optically active  $\gamma$ -substituted lactones from symmetrical hydroxycarboxylic acid esters (82). Lipases have been used in the regioselective acylation of sugars, the process of which can rarely be effectively performed in organic synthesis and often requires multisteps of protection and deprotection of the various hydroxyl groups. Porcine pancreatic lipase catalyzes transesterification between monosaccharides (glucose, galactose, mannose) and trichloroethyl carboxylates in pyridine resulting in the selective acylation at the C6-OH (83). Sucrose esters, used as emulsifiers in food, cosmetics, and medicines, can be synthesized by the lipase-catalyzed transesterification of sucrose with esters of fatty acids (84). In similar reactions, nucleosides and furanose and pyranose derivatives can be selectively acylated (85, 86).

One of the lipase-catalyzed reactions important to the food industry is the interesterification of triacylglycerols. In these reactions, a triacylglycerol reacts with a fatty acid, alcohol, or fatty acid alkyl ester, to produce a mixture of new triacylglycerols resulting from a rearrangement of the fatty acid moieties. Chemical catalysts such as sodium metal or sodium alkoxide can promote interesterification; however, acyl migration

among the triacylglycerol molecules is nonspecific with random distribution of the acyl fatty acids. By exploiting lipases as catalysts, it is possible to generate products enriched with the new fatty acids at specific positions, thereby changing the physicochemical properties of triacylglycerols (87, 88). For example, in the interesterification of a triacylglycerol/fatty acid mixture catalyzed by 1,3-specific lipase, the product consists of novel triacylglycerols with the fatty acid selectively incorporated to the 1- and 3-positions, and no enrichment at the 2-position. Using *Geotrichum candidum* lipase which has specificity for *cis*-9 unsaturated fatty acids, linolenic acid, for example, can be selectively exchanged and enriched in an interestified triacylglycerol mixture. Miller et al. (89) studied the kinetics of interesterification of trilaurin and lauric acid catalyzed by *Candida cylindracea* lipase in cyclohexane. The reaction follows a two-step mechanism: initial hydrolysis of the trilaurin to dilaurin and lauric acid with  $K_m = 7.8 \times 10^{-3}$  M, and  $k_{cat} = 0.9 \text{ sec}^{-1}$ , and subsequent reesterification of dilaurin and lauric acid with  $K_m$  values of  $1.7 \times 10^{-2}$  M (lauric acid) and 0.16 M (dilaurin), and  $k_{cat} = 3 \text{ sec}^{-1}$ . The use of microbial lipases in nonconventional solvents, such as supercritical fluids, has also been investigated as a means of improving the activity and stability of the enzyme for promoting acyl transfer reactions in an anhydrous environment (90).

### VIII. LIPASE SPECIFICITY

The types of specificity that can be ascribed to lipases include:

1. Substrate specificity: The enzyme shows a different rate of lipolysis of various acylglycerols, tri-, di-, and monoacylglycerols, or various types of fatty acids.

2. Positional specificity: The enzyme catalyzes the release of fatty acids preferentially at the primary ester, secondary ester, or nonspecific at all esters.

3. Stereospecificity: The enzyme hydrolyzes the two primary esters (*sn*-1 or *sn*-3) at different rates (91).

Porcine pancreatic lipase has specificity for acylglycerols in the order: 1,3-triacylglycerol > 1(3)-monoacylglycerol > 2-monoacylglycerol (91). Eicosapentaenoic and docosahexaenoic acids at the 1(3)-position are resistant to the action of lipase (92). The enzyme shows the same reactivity on palmitoyl, linoleyl, and linolenoyl groups at the 1(2)-position. However, triacylglycerols containing hydroperoxy linoleic or linolenic acids at the 1(3)-position are hydrolyzed at rates about two times higher than those of the unoxidized fatty acids in the corresponding positions (93). Lipolysis rates of the porcine pancreatic lipase on esters of saturated fatty acids increase with chain length until C9, which approaches the rates of the oleates. Substitutions or unsaturation, in particular at C2-C5, lead to increased resistance to hydrolysis (94). It has been demonstrated that human and rabbit gastric lipases have a stereospecificity for the *sn*-3 ester bond of trioctanoin or triolein (95). Pancreatic lipase cleaves the ester bonds in the *sn*-1 and *sn*-3-positions without selectivity (96).

The *Geotrichum candidum* lipase is known to show a rather unique specificity for the hydrolysis of fatty acids with a *cis*-9 or *cis,cis*-9,12 unsaturations in preference to the *trans*-isomers or corresponding saturated fatty acids (97, 98). The isoform lipase B exhibits a very high degree of specificity for mono-unsaturated fatty acid esters of *cis*-9 double bonds, whereas lipase A hydrolyzes a wide variety of fatty acid esters (99, 100). Similar to pancreatic lipases, a majority of the microbial lipases attack preferentially the 1(3)-position of triacylglycerols, with exceptions, such as *Corynebacterium acnes*, *Staphylococcus aureus*, and *Candida cylindracea* lipases which hydrolyze all three positions (101–103). The isoforms III and IV from *Geotrichum candidum* have been shown to cleave the 2-position ester bond of triolein at nearly twice the rate of the cleavage of the 1(3)-position (104). *Candida natarctica* lipase A shows a preference for *sn*-2 when trioctanoin and triolein are used as substrates, whereas lipase B is selective for *sn*-3 (105). The *Rhizopus arrhizus* lipase shows stereospecificity with *sn*-1 preference toward trioleylglycerols, while the *Chromobacterium viscosum* enzyme has *sn*-3 selectivity (105). It has been demonstrated that structural variations at the *sn*-2 position cause a

change in the stereoselectivity. The preference of *Chromobacterium viscosum* lipase is shifted from *sn*-3 to *sn*-1 when the *sn*-2 acylester is replaced by a non-ester alkyl chain (106).

## IX. MEASUREMENT OF LIPASE ACTIVITY

Numerous methods have been used for measuring the activity of lipases, and can be classified into the following groups: (a) titrimetry based on the neutralization of the free fatty acids released with time in the hydrolysis of triacylglycerols by titration with NaOH; (b) use of chromogenic reagents to form color complexes with free fatty acids, or substrates conjugated with a chromophore or fluorophore to form fatty acid products, that can be monitored spectrophotometrically or fluorimetrically (107, 108); (c) use of radioactive triacylglycerols and measurement of the release of radiolabeled fatty acids (109); (d) chromatographic analysis of the fatty acid released (110); and (e) enzymatic conversion of the release fatty acid to products that can be measured by spectrophotometry (111). For a comprehensive review of this subject, refer to Beisson et al. (112).

The following is a procedure for measuring the rate of hydrolysis of emulsified trioleylglycerol titrimetrically based on Vorderwulbecke et al. (113). A mixture of trioleylglycerol (1 g) and Triton X-100 (30 mL) is heated to 55°C and added to a NaCl solution (0.9%, 200 mL H<sub>2</sub>O, preheated also to 55°C) slowly under stirring. The final mixture is cooled to room temperature and the pH adjusted to 8.0 with 1 M NaOH. For enzyme activity assay, 25 mL of this solution is prewarmed to 37°C, adjusted to pH 8.0, before the addition of lipase. Fatty acids released are continuously titrated with 10 mM NaOH at pH 8.0 and 37°C using a recording pH stat. The lipase activity is expressed as International Enzyme Units where 1 unit corresponds to the release of 1 μmol of fatty acid per min related to the volume of the reaction mixture or to the amount of substrate transformed. The specific activity is expressed as U/mg of pure lipase.

Trioleylglycerol (18:1/18:1/18:1) exists in a liquid form at the assay temperature and can be readily emulsified. It satisfies the definition of a “true” substrate for lipases, in particular if it is hydrolyzed in an emulsion. Emulsifiers other than Triton include Tweens, SDS, bile salts, and stabilizers such as gum arabic which can be used. The high salt in the reaction mixture is used to suppress interfacial charge effects, otherwise

causing inhibition of the enzyme. Tributyrlyglycerol (4:0/4:0/4:0) is another substrate used in many investigations because of the convenience that it can be dispersed without the use of emulsifiers. However, it does not meet the definition of a substrate for lipase, and it is also hydrolyzed by some esterases. The choice of pH, temperature, substrate types, inclusion/exclusion of emulsifiers, and other parameters, depends on the aim of the investigation. Refer to Jensen (114) for a critical assessment of this subject.

Lipase activity can be screened using a zymogram procedure where the PAGE gel is overlaid with a chromogenic substrate, such as resorufin ester (1,2-O-dilauryl-rac-glycero-3-glutaric acid resorufin ester) dissolved in dioxane with deoxycholic acid. Bands containing lipase activity show up as a pink band over a white background (115). A plate assay has been used to detect lipase-producing bacteria or to quantify lipase activity in the culture (116). Lipase activity is detected by the formation of orange fluorescent halos around lipase-producing colonies when incubated in agar plates containing trioleylglycerol and rhodamine B. The logarithm of lipase activity is linearly related to the zone diameter.

## X. PURIFICATION OF LIPASE

Triacylglycerol lipase has been purified to homogeneity from pancreas of a number of species, with the porcine enzyme the most thoroughly investigated. The procedure originally developed by Verger et al. (117)

essentially includes an aqueous extraction of a defatted pancreas powder, followed by DEAE-cellulose and Sephadex G-100 chromatographic steps. Various modifications of the purification have been described (10, 118, 119). The procedure, according to Brockman (119), consists of (a) delipidation of fresh porcine pancreas tissue by chloroform-n-butanol; (b) extraction of lipase with potassium phosphate buffer containing NaCl and diisopropylfluorophosphate; (c) affinity chromatography using hydrophobic glass beads; and (d) DEAE-cellulose chromatography (Table 1). Colipase contamination can be removed by additional chromatography on concanavalin A-Sepharose or hydroxyapatite (120). The use of fresh pancreas is critical, as most commercial pancreatic powders may contain degraded lipase, and so is the addition of di-isopropylfluorophosphate to the buffer for inhibition of proteolytic enzymes present in the extract.

Purification of extracellular lipases from microbial sources is less cumbersome than from animal tissues. *Rhizomucor miehei* lipase is purified by passing the culture supernatant onto an anion exchange column, following by affinity chromatography on Con A-Sepharose, hydrophobic interaction chromatography (Phenyl-Sepharose), and gel filtration (12, 13). The *Geotrichum candidum* lipases I and II have been obtained by ethanol precipitation, gel filtration (Sephadryl-200 HR), anion exchange (Mono Q), and chemofocusing (Polybuffer exchanger 94) (14). A similar scheme has been used to purify multiple isoforms of *Candida rugosa* lipase (25).

**Table 1** Purification of Triacylglycerol Lipase from Porcine Pancreas

	Volume (mL)	Total activity ( $10^{-4} \times U$ )	Total protein (mg)	Specific activity (U/mg)	Yield (%)	Colipase (mol%)
1. Extraction of delipidated pancreas	190 ± 7	96 ± 13	1.1 ± 0.1 × 10 <sup>4</sup>	87	100	—
2. Concentration by 3.5 mM taurodeoxycholate eluate from hydrophobic beads	107 ± 16	35 ± 14	220 ± 90	1590	36	—
3. DEAE chromatography						
Fraction I (lipase B)	189	21.1	33.0	6360	7.3	≤ 1.2
Fraction II (lipase B + A)	170	9.7	17.1	5610	3.3	12.3
Fraction III (lipase B + A)	224	12.4	24.0	5120	4.3	62.0

Enzyme U = 1 mmol of butyric acid released per min. Volume, activity, and protein are expressed as average ± SD from three preparations subsequently combined for DEAE chromatography.

## Chlorophyllase

Roger F. McFeeters

*U.S. Department of Agriculture and North Carolina State University, Raleigh, North Carolina, U.S.A.*

### I. INTRODUCTION

Chlorophyllase (EC 3.1.1.14) was first described in 1913 (1). When attempts have been made to detect it, chlorophyllase has been found in all green plants and algae. Chlorophyllase can hydrolyze alcohols esterified to the propionic acid side chain on C<sub>7</sub> of the porphyrin ring of chlorophylls, pheophytins, and various derivatives of these compounds. In addition, it can catalyze transesterification reactions (2) that result in the addition of a variety of side chains to the porphyrin ring. See Table 1 and Figure 1 for the nomenclature of chlorophyllase substrates. A previous review of this enzyme has been published by Drazkiewicz (3).

### II. MEASUREMENT OF CHLOROPHYLLASE ACTIVITY

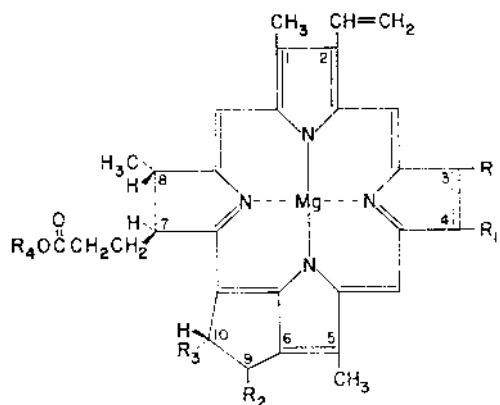

Chlorophylls or pheophytins are the usual substrates for chlorophyllase activity assays. These compounds are insoluble in water. Therefore, either reactions must be done with the substrate solubilized into an aqueous buffer system using a surfactant, or there must be sufficient organic solvent, usually acetone, added to the reaction mixture to dissolve the substrate. McFeeters et al. (4) provided an example of the aqueous buffer system adapted from the earlier procedure of Klein and Vishniac (5). Examples of the use of acetone to solubilize substrates are Weast and Mackinney

**Table 1** Structures for Substrates and Inhibitors of Chlorophyllase<sup>a</sup>

Compound	Mg <sup>2+</sup> (±)	7, 8 Position reduced (±)	R	R <sub>1</sub>	R <sub>2</sub>	R <sub>3</sub>	R <sub>4</sub>

(6) and Shioi et al. (7). The reaction is stopped, and the product is separated from the remaining substrate by partitioning between an organic phase and an aqueous acetone phase after KOH solution is added to raise the pH. For measurement of pheophytin or chlorophyll hydrolysis, McFeeters et al. (4) added 60% hexane:40% acetone and KOH solution to raise the reaction mixture pH to 8.5. The final proportion of solvents was 50% hexane, 33.3% acetone, and 16.7% water. After separation of the two phases, substrate depletion or, preferably, product formation is measured spectrophotometrically. To measure hydrolysis of methyl and ethyl chlorophyllides or pheophorbides, McFeeters (8) used a mixture of hexane, acetone, and 2-butanone to separate reaction products from the substrates.

### III. PURIFICATION

Chlorophyllase was first purified to homogeneity by Moll and Stegwee (9). Subsequently, Shioi et al. (7) developed a somewhat simplified method. A homogeneous preparation of the enzyme was prepared from *Chlorella protothecoides* with over a 50% yield using a butanol extraction, ammonium sulfate precipitation, and chromatography on size exclusion columns (Table 2). The same procedure, except that the butanol solubilization step was unnecessary, resulted in purification of the enzyme from tea leaf sprouts but with only a 9.6% yield (10). Trebitsch et al. (11) purified chlorophyllase from the flavedo of mature green oranges, determined the N-terminal sequence of the purified enzyme, and used it for generation of antibodies to chlorophyllase. Tauchiya et al. (12) purified two

chlorophyllase isozymes from mature *Chenopodium album* leaves using hydrophobic chromatography, ConA Sepharose, heparin, and ion exchange HPLC on two different columns. The presence of isozymes was confirmed by N-terminal sequencing of the separated chlorophyllases and by showing that the 10th amino acid from the N-terminus was different (Fig. 2). However, the N-terminal sequences of the *Chenopodium* isozymes had no homology with the sequence from orange chlorophyllase (11) or with any other published protein sequence (Fig. 2).

### IV. PROPERTIES

The molecular weight for chlorophyllase has been reported to range from 27 to 65 kDa. Chlorophyllase from citrus fruit peel was found to be 27 kDa in one study (13) and 35 kDa in another (11). *Phaeodactylum* was reported to have two enzymes that were 43 and 46 kDa in size (14). Isozymes from *Chenopodium album* were 41.3 and 40.2 kDa (12). The largest size chlorophyllase reported to date was 65 kDa in *Chlorella regularis* (15). Most frequently, however, molecular size has been found to be near 38 kDa. This includes the chlorophyllase from *Chlorella protothecoides* (7), tea leaf sprouts (10), sugar beet leaves (16), and rye seedlings (17).

Most often, chlorophyllases have been found to have pH optima near pH 7. However, McFeeters et al. (4) and Ogura (18) found chlorophyllases from *Ailanthus altissima* and tea, respectively, had acidic optima. McFeeters et al. (4) showed a pH optimum near 7 could be obtained erroneously if the pH of the aqueous phase in the usual organic solvent/aqueous partitioning mixtures was not raised by the addition of KOH. Therefore, earlier reports of pH optima for chlorophyllases may be in error. This work indicated the absence of ionizable groups in the enzyme that affected substrate binding, but there did appear to be a  $pK_a$  3.4 group in the active site of the enzyme involved in substrate hydrolysis. Use of acetone in the reaction mixture when determining the optimum pH of chlorophyllase could raise the apparent  $pK_a$  of this group and give a higher pH optimum in the presence of acetone than in the absence of this solvent.

The effect of different substituents of the chlorophyll *a* molecule on the ability of chlorophyllase to bind and hydrolyze potential substrates has been investigated. The picture that emerges is that of a rather high specificity esterase. First, chlorophyllase does not require the presence of a metal ion in the center

**Table 2** Purification of Chlorophyllase from *Chlorella protothecoides*<sup>a</sup>

Purification step	Protein (mg)	Total activity (units)	Specific activity (U/mg protein)	Purification (-fold)	Yield (%)

Source: Ref. 7.

of the tetrapyrrole ring. This is demonstrated by the fact that chlorophyllase has been found to hydrolyze chlorophylls and pheophytins with similar  $K_m$  and  $V_{max}$  value (4). Kinetic data suggested that the  $K_m$  is a binding constant for those substrates. Data have not been obtained to determine the effect of different metal ions in the porphyrin ring on chlorophyllase hydrolysis. Transesterification experiments have shown that chlorophyllase can use a variety of primary and secondary alcohols in place of phytol alcohols as substrates (2). This implies that the enzyme can also hydrolyze chlorophyllide esters of the same alcohols. Protochlorophyll and 1-vinyl protochlorophyll are not hydrolyzed by chlorophyllases, but they bind with affinities similar to pheophytin *a* (4). This showed that a double bond between C<sub>7</sub> and C<sub>8</sub> does not affect binding to chlorophyllase but that it prevents hydrolysis of phytol. Similarly, removal of the carbomethoxy group from C<sub>10</sub> of pheophytin greatly reduces hydrolysis rates with little effect upon binding (4). Fiedor et al.

(19) found that chlorophylls a' and b' were not hydrolyzed by chlorophyllase from two different plants and that the presence of these isomers did not affect the hydrolysis rates of the corresponding chlorophylls. These results suggested that a carbomethoxy group on the opposite side of ring V, as occurs in chlorophyll, prevents both binding and hydrolysis of chlorophylls a' and b'. Comparison of the kinetics of hydrolysis of methyl pheophorbide *a* with 9-hydroxy methyl pheophorbide *a* showed that introduction of a hydroxyl group at C<sub>9</sub> in ring V reduced the binding affinity of substrate dramatically while, at the same time, having little effect on substrate hydrolysis rate (8).

There is little information available on the stability of chlorophyllase from different plants. In general, assays for activity have been performed at 30°C at a pH near 7. Recently, a 30°C optimal temperature was reported for chlorophyll hydrolysis by crude chlorophyllase extracts from artichoke (20). Chlorophyllase activity was nearly inactivated during a 1-h incubation

at 45°C. Partially purified chlorophyllase from *Ailanthus altissima* retained > 90% of its activity during a 1-h incubation between pH 3.7 and 9.2 (4).

## V. FUNCTION IN CHLOROPHYLL METABOLISM

There has been uncertainty for many years whether chlorophyllase is active in chlorophyll biosynthesis or degradation in plants. However, Rudiger et al. (21) have demonstrated the existence of a chlorophyll synthase which catalyzes esterification of chlorophyll using geranyl geranyl pyrophosphate as the substrate. The geranyl geranyl ester is then reduced to phytol, the usual side chain in the chlorophylls of higher plants. There is the possibility that "chlorophyll synthase" and "chlorophyllase" are two names given to the same enzyme investigated in different ways, as was assumed by Dogbo et al. (22).

However, the information available on the substrate specificity of chlorophyllase described above compared to the substrate specificity of chlorophyll synthase activity strongly suggests that these are different enzymes. For example, pheophorbide *a* is not a substrate for chlorophyll synthase (23), but the pheophytins are readily hydrolyzed to pheophorbides by chlorophyllase (4). In addition, pyrochlorophyllide *a* is a good substrate for chlorophyll synthase (24), but the  $V_{max}$  for pyropheophytin hydrolysis by chlorophyllase is only 2.5% as large as the  $V_{max}$  for pheophytin hydrolysis (8). Langmeier et al. (25) concluded there is little doubt that chlorophyllase is indispensable for chlorophyll degradation. This was based upon evidence that pheophorbide *a* is a required intermediate in the degradation of chlorophyll to fluorescent linear tetrapyrrole compounds. However, it may not be the first enzyme in the degradative pathway because Mg<sup>2+</sup> removal may occur prior to phytol hydrolysis (25).

## VI. LOCATION AND PHYSIOLOGICAL CHANGES

Brandis et al. (26) found chlorophyllase to be associated with the chloroplast envelope and not with chlorophyll-protein complexes, as has been reported earlier (27). This has been confirmed by Matile et al. (28). They also found that pheophorbide *a* oxygenase, the enzyme responsible for degrading the cyclic tetrapyrrole chlorophyll degradation product to a linear tetrapyrrole, is located in the chloroplast envelope.

They suggest that the initiation of chlorophyll degradation must involve a mechanism to transport chlorophyll from the thylakoid pigment-protein complexes to the chloroplast envelope where chlorophyllase is located.

Trebitsh et al. (11), using chlorophyllase antibodies to detect chlorophyllase molecules, found that chlorophyllase was synthesized de novo when green oranges were exposed to ethylene to speed ripening. The senescence-delaying plant regulators gibberellin A<sub>3</sub> and N<sup>6</sup>-benzyladenine inhibited the synthesis of chlorophyllase, which could be induced by ethylene.

## VII. SIGNIFICANCE IN FOOD PROCESSING

Chlorophyllase appears to be of limited significance in food processing and storage. Dephytylated chlorophyll derivatives, particularly pyropheophorbide *a*, have been implicated in photosensitization reactions in humans. It has been observed that higher levels of these derivatives in food supplements prepared from leaf protein concentrate (29) or dried *Chlorella* cells (30) is correlated with chlorophyllase activity in the plant or alga.

Pheophorbides derived from chlorophylls have been observed in pickles (31), fermented olives (32), and coleslaw (33). Modeling of these data suggested that, in coleslaw, chlorophyllase converted pheophytins to pheophorbides after the chlorophylls were initially converted to pheophytins by the low pH (34). In the fermented vegetables, chlorophylls were first converted to chlorophyllides by chlorophyllase, and, as acid formed during fermentation, the chlorophyllides converted to pheophorbides (34). While pheophytins and the corresponding pheophorbides have the same visible spectra in organic solvents, Heaton et al. (33) observed that the color of coleslaw changed as chlorophyllase hydrolyzed pheophytins to the corresponding pheophorbides.

Efforts have been made to promote retention of green color in processed vegetables by treating them to increase formation of chlorophyllides from chlorophylls (35). This was done on the assumption that magnesium ions would be removed more slowly from chlorophyllides than chlorophylls. However, it has been shown that chlorophyllides lose the magnesium ion more rapidly than do chlorophylls (36). Ihl et al. (20) found that inactivation of chlorophyllase in green artichokes correlated with optimum color retention for microwave and boiling-water blanching procedures.

## Phytase

**Onno Misset**

*DSM Patents & Trademarks, Delft, The Netherlands*

### I. INTRODUCTION

Phytate (*myo*-inositol 1,2,3,4,5,6-hexakis dihydrogen phosphate) is the primary source of inositol and storage form of phosphorus in plant seeds. Approximately 75% of the total phosphorus in plants is in the form of phytic acid. Animal feed is primarily of vegetal origin (i.e., oilseed meals, cereal grains, and legumes) and will therefore contain a lot of phytate.

In contrast to polygastric animals such as ruminants, monogastric animals like humans, pigs, and poultry have only a limited microbial population in the upper part of the digestive tract and are not able to use phytate as a phosphorus source. Consequently, to supply these animals with phosphate, inorganic phosphate has to be added separately to the feed. Phosphorus from phytate ends up in the manure, which gives rise to serious environmental pollution. Degradation of phytate by exogenous enzymes would therefore avoid or lower the necessity to add inorganic phosphate and reduce the amount of phosphorus from phytate in the manure.

Phytate is also considered an antinutritional factor because of its strong chelating properties. The phosphate moieties of phytic acid are able to bind di- and trivalent metal ions such as calcium, magnesium, zinc, and iron. The chelating properties of inorganic phosphate are much less than those of phytate. Degradation of phytate in this case would considerably reduce the metal chelation properties of plant-derived animal feed.

Phytases are enzymes that are capable of hydrolyzing the phosphate groups from phytate. Several com-

mercial phytase products have been developed and used as a feed additive since 1991.

For reviews of phytate and phytases, the reader is referred to (1) and (2, 3), respectively.

### A. Chemical Reaction Catalyzed

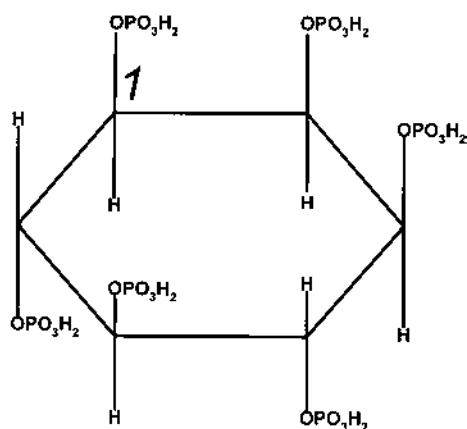

Phytase catalyzes the hydrolysis of the 6-monophosphate esters in phytate (*myo*-inositol 1,2,3,4,5,6-hexakis dihydrogen phosphate) via intermediary penta-, tetra-, tri-, di-, and monophosphates ultimately to inorganic phosphate and *myo*-inositol.

### B. Chemical Structure of Substrate

Phytic acid was described for the first time in 1903, and its chemical structure (Fig. 1) was elucidated in 1914 (3). The chemical formula is C<sub>6</sub>H<sub>18</sub>O<sub>24</sub>P<sub>6</sub> and it has a molecular weight of 659.86 Da. Because phytate carries six phosphate groups, it can be regarded as a multi-substrate molecule. Upon successive hydrolysis, the resulting penta-, tetra-, tri-, di-, and monophosphate forms of *myo*-inositol are again substrates for phytase.

### C. Classification According to Enzyme Commission Nomenclature

Two different types of phytases are known and classified accordingly: EC 3.1.3.8 and EC 3.1.3.26. They belong to the class of hydrolases (group 3), acting on

**Figure 1** Structure of phytic acid. Carbon 1 of the *myo*-inositol ring has been indicated.

ester bonds (subgroup 1), in particular phosphomoноesters (subsubgroup 3).

EC 3.1.3.8 is a 3-phytase (recommended name) and hydrolyzes first the ester bond at the 3-position of the substrate. The systematic name is *myo*-inositol hexakisphosphate 3-phosphohydrolase. EC 3.1.3.26 is 6-phytase (recommended name) and hydrolyzes first the ester bond at the 6-position of the substrate. The systematic name is *myo*-inositol hexakisphosphate 6-phosphohydrolase.

## II. NATURAL OCCURRENCE OF PHYTASE

Phytases are found in both the plant and microbial kingdoms. While most plant phytases belong to the class of 6-phytases (EC 3.1.3.26), most microbial phytases are considered to be 3-phytases (EC 3.1.3.8). However, not all publications mention whether the phytase involved is a 3- or 6-phytase; the reason for this is that it is rather complicated to determine the nature of the *myo*-inositol pentaphosphate (1,2,4,5,6 or 1,2,3,4,5) generated by the enzymes.

The occurrence of phytase in germinating plants has been reviewed recently (2, 5). The first phytase preparations were of plant origin; Suzuki et al. in 1907 isolated them from rice and wheat bran (3). All present-day commercial phytase products are derived from filamentous fungi, in particular from *Aspergillus* spp. For this reason this chapter will further focus on the microbial, in particular fungal, phytases.

Extensive screening programs have been carried out in the past and are still carried out today. These pro-

grams have resulted in a long list of bacteria, yeasts, and fungi that produce 3-phytase or 6-phytase either intra- or extracellular phytase (Table 1). Many fungal phytases were identified a few decades ago (7, 8), and resulted in most of the *Aspergillus* phytases known today. There is a tendency to screen more for phytases from thermophilic strains or from microorganisms that are present in the gastrointestinal tract of ruminants. As can be seen in Table 1, fungal phytases are more abundant than phytases derived from yeasts or bacteria.

In addition to screening, protein engineering via site-directed mutagenesis of existing phytases has resulted in enzymes with increased specific activity (36) and thermostability (37).

### III. INDUSTRIAL APPLICATION OF PHYTASE

The most important industrial application of phytase is in animal nutrition for reasons set out in Section I. When added to pig and poultry feed, the normal addition of inorganic phosphate can be lowered considerably, and the amount of undigested phytate in the manure of the animals is reduced substantially (30–60% depending on the type of diet composition and animal). These and other related subjects have been documented in great detail in the BASF Reference Manual entitled Phytase in Animal Nutrition and Waste Management (38) and will not be further dealt with here.

At present only a limited number of phytase products are commercially available (Table 2). The first phytase product, which entered the market in 1991, is manufactured by DSM (Gist-brocades) and sold by BASF under the trade name Natuphos. This product contains the phytase PhyA from *Aspergillus niger* (*ficiuum*) NRRL3135 and is available as powder, granulate, or liquid (e.g., see [www.natuphos.com](http://www.natuphos.com)).

<sup>a</sup> Genetically modified organism.

In addition to its application as a feed additive, it has been suggested that phytase can also be used advantageously in the starch-processing industry during the liquefaction step of cornstarch (42). The function of phytase is mainly to degrade the phytate that has been shown to be an EIC (enzyme-inhibiting composition) inhibiting especially the alpha-amylase that is used in the liquefaction step.

### IV. PROPERTIES AS PROTEIN

#### A. Molecular Weight

Most of the phytases from fungi and yeast are glycosylated. This means that their molecular weight is composed of the total of the amino acids of the (mature) protein and the molecular weight of the attached sugar chains. Furthermore, since most phytases are extracellular enzymes, their genes are encoding for a precursor protein that is slightly larger than the final mature secreted enzyme, the difference being the signal peptide that is the responsible signal for the excretion process. Therefore, we can discriminate among the following molecular weights for phytases:

1. Precursor phytase, not glycosylated—calculated from the amino acid sequence derived from the gene sequence.
2. Mature phytase, not glycosylated—calculated from the amino acids (gene) sequence and the experimentally determined maturation site (e.g., via N-terminal amino acid sequencing of the purified enzyme).
3. Mature, glycosylated phytase—experimentally determined by various methods (see below).

Table 3 summarizes the availability of amino acid sequences derived from either the corresponding gene sequences or from Edman degradation. The fungal PhyA and PhyB genes encode precursor phytases with 439–487 amino acids, corresponding to molecular weights ranging from 47 to 53 kDa (Table 4). In the

case of the PhyA phytase of *Aspergillus ficuum* (strain NRRL 3135), the molecular weight of the precursor phytase (51,086 daltons; Table 4) could be calculated from the gene-derived sequence (43, 44). In addition, the mature protein was also sequenced completely by Edman degradation (45). A comparison of the two sequences allowed identifying the position of the maturation site; it was found that the signal peptide consists of 23 amino acids, resulting in a mature protein of 444 amino acids with a calculated molecular weight of 48,846 daltons. The chemically and gene-derived sequences of the mature protein were found to be identical.

In a recent study, Wyss et al. (49) determined the molecular weights of several fungal phytases by SDS-PAGE, analytical ultracentrifugation, and gel filtration analysis (see Table 4 for a summary). The experimentally determined molecular weights are much larger than the values calculated on the basis of the amino acid sequences. The difference in molecular weight must be attributed to the glycosyl chains that are attached to the enzymes. The authors concluded that all phytases are monomers and that the contribution of the sugar chains to the molecular weight of the glycosylated mature enzyme could amount to 20–65%.

## B. Primary, Secondary, Tertiary, and Quaternary Structures

The primary sequences of some 20–25 phytases are known. Table 2 shows that many of these sequences are available at the Web from sequence databases such as SWISS-PROT, TrEMBL, and PIR. Yet, many (new) sequences are available from the patent literature only.

Pairwise alignment of the amino acid sequences and calculation of the homology revealed that the phytase sequences can be derived into three groups: fungal phyA sequences, fungal phyB sequences, and “others” such as the sequences from *Bacillus*. The homology within a group can be as high as 45–97% as is illustrated in Table 5 for the fungal PhyA phytases. Between the groups the homology is much lower; i.e., between phyA and phyB the homology is 23–27% whereas no significant homology exists between the *Bacillus* phytases and the fungal phyA and/or phyB phytases (not shown). Figure 2 shows a multiple alignment of fungal PhyA sequences. The N-terminal residues with a gray background have been shown or are suggested to belong to the signal peptide. Residues in white with a black background are conserved in at least five sequences.

The secondary and tertiary structures of phytase are known in great detail because the first 3-D structure of phytase from *A. niger* (*ficuum*) was recently determined by x-ray crystallography at a resolution of 2.5 Å by researchers of Hoffman–La Roche (50). To be successful in crystallizing the phytase, the enzymes had to be deglycosylated completely.

The structure has an  $\alpha/\beta$ -domain similar to that of rat acid phosphatase and an  $\alpha$ -domain with a new fold (Fig. 3). The high homology that exists between fungal PhyA phytases suggests that all these phytases (Table 5 and Fig. 2) will have the same secondary structural elements and tertiary fold and topology.

Not all the 444 amino acids could be detected in the electron density map: residues 1–6 and 249–252 (numbering of the mature protein; add 23 to obtain the precursor protein numbering) were not visible, presumably because of too high a mobility. All 10 cysteine residues are involved in a disulfide bridges: Cys8–17, Cys48–391, Cys192–442, Cys241–259, and Cys413–421. The amino acid alignment in Figure 2 shows that, with the exception of the cysteines involved in bridge Cys8–17, the eight other cysteines and therefore the four disulfide bridges are completely conserved in the fungal PhyA phytases. Amino acids involved in catalysis and substrate binding will be discussed later.

### C. Isoforms

#### 1. From Different Genes

In *Aspergillus ficuum* and *A. awamori*, two phytase genes have been identified: PhyA and PhyB (Table

3). The homology between these two types of phytases is relatively low, and the enzymological properties are very different (51).

In relation to phytases, several publications also refer to acid phosphatases (EC 3.1.3.2). However, these enzymes show no amino acid sequence homology with phytases whatsoever, and also their substrate spectrum differs from phytase since they cannot use phytate as a substrate (51, 53). Therefore, fungal PhyA phytases can be regarded as very specialized acid phosphatases because of their unique property to efficiently dephosphorylate phytic acid.

### 2. From Posttranslational Modification

Extracellular phytases undergo two posttranslational modifications: glycosylation and maturation. Glycosylation takes place in the Golgi apparatus of eukaryotic cells like fungi and yeast (and not in prokaryotic cells such as bacteria), and it involves only those proteins that are secreted by the cell. Glycosylation is known to generate a heterogeneous population of glycoproteins. Since the glycosyl chains contribute substantially to the molecular weight of phytase, the molecular weight will show a distribution around an average value instead of having one single value.

Glycosylation of different phytases depends on the microbial expression system (49). In *Aspergillus*, glycosylation was found to be moderate, whereas it was excessive and highly variable in *Humicola polymorpha*.

and *Saccharomyces cerevisiae*. On the basis of the consensus Asn-Xxx-Ser and Asn-Xxx-Thr sequences, potential N-linked glycosylation sites in *A. niger* phytase were identified at positions 27, 59, 105, 120, 207, 230, 339, 352, 376, and 388. However, the multiple alignment of the amino acid sequences shows that only the consensus sequences at two positions: Asn207 and Asn339 are conserved. Apparently, different phytases can become glycosylated at different positions. Although the effect of glycosylation on enzyme structure and function is always under debate, the dif-

ferent glycosylation patterns will certainly affect properties such as molecular weight, isoelectric point, solubility, and possibly also thermostability but much less likely the enzyme activity.

Translocation of the protein over the cell membrane is mediated by the signal peptide. During this process, the signal peptide is cleaved off by signal peptidases. This process can also give rise to heterogeneity at the N-terminus of the mature protein (49). In Figure 2, a gray background marks the (putative) signal peptides of the various phytases.

**Figure 3** Schematic representation of the phytase structure. The cylinders represent the  $\alpha$ -helices and the arrows the  $\beta$ -strands. The left-hand side of the molecule is the  $\alpha/\beta$ -domain and the right-hand side the  $\alpha$ -domain. (Picture courtesy of Dr. Jan-Metske van der Laan.)

### 3. Proteolysis

When fungal phytases were expressed in an *Aspergillus niger* strain and stored as concentrated culture supernatants, Wyss et al. (49) found that the enzymes were susceptible to limited proteolytic cleavage. In some cases, this proteolysis was accompanied with activity loss (*A. fumigatis*) but not in others (*E. nidulans*). In the latter case, the fragments remained associated with each other as was shown by gel filtration experiments, and the complex was as active as the intact enzyme. Determination of the cleavage sites was done by N-terminal sequencing of the proteolytic fragments. Comparison with the 3-D structure of the *A. niger* enzyme showed that proteolysis occurred at exposed loops on the surface of the molecule. By site-directed mutagenesis of the cleavage site amino acid residues it was possible to reduce the proteolytic susceptibility without affecting the specific activity of the mutant enzyme (49).

When expressed in *Hansenula polymorpha*, no proteolysis of the fungal phytases was observed.

## V. PROPERTIES AS ENZYME

### A. Substrate Specificity

Phytases are known as acid phosphatases capable of cleaving phosphate monoester bonds. In addition to phytic acid, phytases have been reported to be able

to hydrolyze many other phosphate esters. **Table 6** summarizes the  $k_{cat}$ ,  $K_M$ , and  $k_{cat}/K_M$  values of the phytase from *A. niger* strain NRRL3135 for various phosphate ester substrates. Phytase has the highest affinity for phytate with six phosphate groups (IP6) as can be deduced from the low  $K_M$  values compared with the values for the other substrates. The highest  $k_{cat}$  values are found with the phytate substrates, in particular IP4 and IP3, for which  $k_{cat}$  is even much higher than for the IP6 substrate. The highest specificity constants ( $k_{cat}/K_M$ ) are observed for the phytate substrates that are 10 to 1000-fold higher than for the other substrates. In conclusion, phytate is the “best” substrate for phytase.

In a comparative study, Wyss et al. (53) measured the specific activities of nine fungal and bacterial phytases and acid phosphatases with 14 different substrates at a fixed concentration of 5 mM and at pH 5.0 and 37°C (Fig. 4). The results clearly show that the phytases from *A. niger*, *A. terreus*, and *E. coli* have a narrow specificity compared to the other enzymes. Their highest specific activities are obtained with phytate while 30% or lower values of the phytate specific activity were found with the other 13 substrates. On the contrary, the phytases from *A. fumigatis*, *E. nidulans*, and *M. thermophilus*, and the acid phosphatases from *A. niger* (measured at pH 5.0 and pH 2.5) display higher activity toward a broader range of substrates. However, their activity toward phytate is much lower than the activity of *A. niger*, *A. terreus*, and *E. coli* phytase, or not even detectable (acid phosphatase).

### B. Effect of Environmental Factors

Environmental factors such as pH and temperature exert their effect on two enzyme properties: activity and stability. Both properties are important since they determine the final application properties of the enzyme.

The pH dependence of the phytase activity has been studied extensively for various phytases from fungal and bacterial origin (Table 7). In general, the fungal phytases are active in the acid-neutral region, while the bacterial phytases behave the same (*E. coli*) or display their activity in the alkaline region (e.g., *Bacillus*). Various research groups found that the PhyA phytase from *Aspergillus niger* NRRL3135 has a broad pH optimum ranging from pH 2.5 to ~6. The profile is remarkable in the sense that two optima are found—one at pH 4 and another at pH 5.5.

To be active at the pH of the digestive tract of animals (i.e., neutral in the chicken's crop and acidic in the stomachs), a phytase is required to possess the pH activity profile as displayed by PhyA phytase from *A. niger* (*ficuum*) NRRL3135.

The activity of phytase increases with temperature until a maximum is observed. This maximum is usually caused by inactivation of the enzyme due to instability. Table 7 shows that the temperature optimum of the various phytases ranges from 45°C to 65°C.

The stability of phytase, in particular its thermostability, is an important property in view of its application as a feed additive. Namely, during the feed pelleting step, steam is injected which results in an increase of the temperature up to 65–95°C and sometimes even higher. Consequently, phytase, which has already been added to the feed at this stage, must be able to withstand these temperatures; otherwise, too much activity will be lost. This demand for thermostability explains the continuous screening efforts for more thermostable phytases and/or the protein engineering activities to improve the thermostability of existing phytases. Also, improved formulations of phytase comprising stabilizing additives are continuously developed in order to deliver stability to the enzyme during the feed pelleting step.

Wyss et al. (55) compared the thermostability of *A. niger* phytase (the currently used commercial phytase—Table 2), the *A. fumigatis* phytase, and *A. niger* acid phosphatase. Both in solution studies and in feed pelleting trials, the *A. fumigatis* enzyme proved to be more thermostable than the *A. niger* enzyme. This better thermostability, however, is counteracted by a fivefold lower specific activity of the *A. fumigatis* enzyme compared with the *A. niger* enzyme (Table 8).

The same research group also used protein engineering to improve the thermostability of phytase (37). A so-called consensus phytase was designed that has an amino acid sequence consisting of the most conserved residues found at each position in the phytases from *A. niger* (two sequences), *A. awamori*, *A. terreus* (two sequences), *A. fumigatis* (five sequences), *A. awamori*, *A. terreus* (two sequences), *A. fumigatis* (five sequences), *A. nidulans*, *T. thermophilus*, and *M. thermophila*. This consensus phytase proved to have the highest thermostability among all the other phytases mentioned. The temperature optimum of the activity was ~70°C (compare with Table 7) and also the melting temperature as measured with differential scanning calorimetry (78°C)

was higher than of the other phytases (up to 63.3°C for the *A. niger* phytase).

### C. Specific Mechanism of Action

Phytases hydrolyze phosphomonoester bonds in a variety of substrates and as such belong to the class of phosphatases. This class can be divided into three groups: alkaline, acid, and protein phosphatases (56). The acid phosphatases can be further subdivided into low- and high-molecular-weight (~18 kDa and 50–60 kDa, respectively). Examples of the last group are the extracellular fungal enzymes and the purple acid phosphatases with binuclear Fe-Fe and Fe-Zn centers in their active site.

Phytases belong to the group of histidine high-molecular-weight acid phosphatases. They hydrolyze phytate and other phosphoesters in a two-step mechanism (Ping-Pong) involving a covalent phosphorylated histidine adduct enzyme intermediate (57, 58). In the first partial reaction, the phosphorylated substrate molecule binds to the enzyme to give the noncovalent Michaelis complex which is then followed by transfer of the phosphate group to the active-site histidine. In the second partial reaction, a water molecule dephosphorylates the enzyme, resulting in free enzyme and inorganic phosphate. The consequence of this mechanism is that in case of chiral substrates, net retention of the configuration at the phosphorus atom will occur, consistent with two successive associative in-line phosphoryl transfers, each of which occurs with inversion of the configuration.

Sequence alignment of phytases shows that there is a conserved R<sup>81</sup>H<sup>82</sup>G<sup>83</sup>A<sup>84</sup>R<sup>85</sup> sequence (residues 81–85 in the *A. niger* precursor sequence numbering). On the basis of chemical modification studies of arginines and lysines, Ullah et al. suggested that this sequence contains an essential arginine and histidine residue (59, 60), which was confirmed by site-directed mutagenesis experiments in the *E. coli* acid phosphatase (57). The 3D structure of *A. niger* phytase indeed confirmed that this peptide was involved in substrate binding (50). Therefore, it is very likely that the histidine in the peptide mentioned is involved in the phosphorylation/dephosphorylation cycle. The conserved peptide, at least residues R<sup>81</sup>H<sup>82</sup>G<sup>83</sup>, has been found to be conserved in other members of the group of acid phosphatases, some bisphosphatases, and some mutases which all make use of a phosphohistidine intermediate (59, 61).

Beta-naphthylphosphate	22	0.53	42	13	58°C, pH = 5.0	52

The structure of phytase was compared with the structure of rat acid phosphatase (50). The substrate profile of phytase differs from the rat acid phosphatase in that phytase is able to hydrolyze the large phytate compared to the smaller substrates of the rat enzyme. Inspection of the active site of the two enzymes reveals on one side of the substrate-binding pocket the following conserved residues (numbering of the *A. niger* precursor protein): Arg81 (Arg11 in the rat acid phosphatase), His82 (His12), Gly83 (Gly13), Arg85 (Arg15), Pro87 (Pro17) of the RHGxRxP peptide as well as Arg165 (Arg79), His361 (His257), and Asp362 (Asp258) which all belong to the  $\alpha/\beta$ -domain of the enzyme. On the other side of the substrate-binding pocket (the  $\alpha$ -domain) no similarities were found. Here, the active site of the phytase is much larger than that of the rat acid phosphatase, thus allowing the accommodation of the larger phytate substrate.

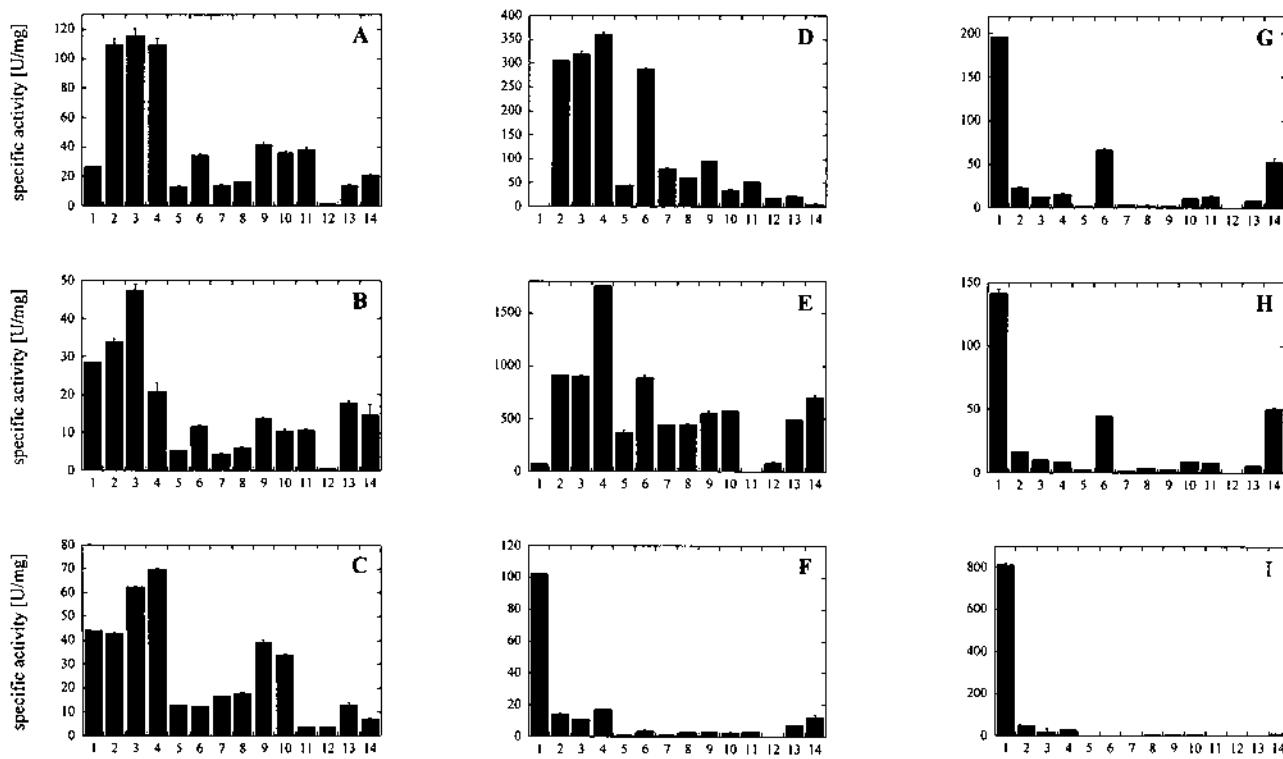

A molecular modeling study of the phytase–phytate complex showed that all conserved charged

active-site residues (Arg81, His82, Arg85, Arg165, His361, and Asp362) are involved in electrostatic interactions with the scissile 3-phosphate group of the substrate. Furthermore, His82 is in a favorable position to make the nucleophilic attack at the phosphorus and Asp362 is in a position to protonate the leaving alcohol [for a further discussion see (50)].

## VI. PHYTASE ASSAYS

The (specific) activity of phytase is usually determined with its natural substrate phytate or the chromogenic substitute *para*-nitrophenylphosphate. The first assay involves the detection of the liberated inorganic phosphate while the second one detects the yellow *para*-nitrophenol spectrophotometrically.

Many conditions have been reported in the literature for the phytase assay using phytate as a sub-

**Figure 4** Substrate specificities of wild-type phytases and *A. niger* pH 2.5 acid phosphatase. All substrates were used at a concentration of 5 mM. 1, Phytic acid; 2, *para*-nitrophenyl phosphate; 3, phenyl phosphate; 4, fructose 1,6-bisphosphate; 5, fructose 6-phosphate; 6, glucose 6-phosphate; 7, ribose 5-phosphate; 8,  $\alpha$ -glycerophosphate; 9,  $\beta$ -glycerophosphate; 10, 3-phosphoglycerate; 11, phosphoenolpyruvate; 12, AMP; 13, ADP; 14, ATP. (A) *A. fumigatis* phytase; (B) *A. nidulans* phytase; (C) *M. thermophila* phytase; (D) *A. niger* pH 2.5 acid phosphatase; (E) *A. niger* pH 2.5 acid phosphatase (measurements obtained at pH 2.5 instead of pH 5.0); (F) *A. niger* phytase; (G) *A. terreus* CBS phytase; (H) *A. terreus* 9A1 phytase; (I) *E. coli* phytase. <i>Paxillus involutus</i> PhyA1	810	37°C, pH = 5.5	6
<i>Paxillus involutus</i> PhyA2	1370	37°C, pH = 5.5	6
<i>Trametes pubescens</i>	1450	37°C, pH = 5.5	6
<i>Escherichia coli</i>	811 ± 216	37°C, pH = 5.0	53
<i>Bacillus subtilis</i> B13	88	37°C, pH = 7.5	27

strate. The basic principle, however, is the same. Variations exist with respect to the incubation temperature, pH, and choice of buffer, substrate concentration, and the like. A suitable assay is carried out as follows (44): 100 μL enzyme solution or distilled water as a blank is added to 900 μL of a solution composed of 0.25 M sodium phosphate buffer, pH 5.5, and 1 mM phytic acid (sodium salt). The resulting mixture is incubated for 30 min at 37°C. The reaction is stopped by the addition of 1 mL of 10% trichloroacetic acid. After the reaction has terminated, 2 mL of a reagent composed of 3.66 g of FeSO<sub>4</sub> · 7 H<sub>2</sub>O in 50 mL of ammonium molybdate solution (2.5 g (NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub> · 4 H<sub>2</sub>O and 8 mL H<sub>2</sub>SO<sub>4</sub>, diluted to 250 mL with demineralized water), is added. The intensity of the blue color is measured spectrophotometrically at 750 nm. The measurements are indicative of the quantity of phosphate released in relation to a calibration curve of inorganic phosphate in the range of 0–1 mM. One unit of phytase is defined as the amount of enzyme that is capable of forming 1 μmole of phosphate per minute. Specific activities of various phytases are summarized in Table 8.

The activity of phytase can also be determined conveniently by using *para*-nitrophenylphosphate (PNPP) as a substrate. The conditions for this determination are as follows: 10 μL of an enzyme solution is added to a solution containing 890 μL of 0.25 M sodium phos-

phate, pH 4.0, and 100 μL 10 mM PNPP. The absorbance of the liberated *para*-nitrophenol is measured spectrophotometrically at 30 nm as a function of time. The absorbance increase (ΔA/min) can be converted to a rate expressed in μM/min using an extinction coefficient of 3690 M<sup>-1</sup> cm<sup>-1</sup>. One unit of phytase is defined as the formation of 1 μmole of *para*-nitrophenol per minute.

## VII. PURIFICATION

Numerous purification methods for the various phytases discussed here have been published in the literature; for a summary see Table 9. In general, the complexity of the method and number of steps involved depend on the expression level of the enzyme. This means that for the purification of phytase from nonrecombinant strains, more steps are required to obtain a homogeneous phytase preparation than pure phytase from overexpressing strains.

## ACKNOWLEDGMENTS

I would like to acknowledge my colleagues Dr. Rob Beudeker and Dr. Jan-Metske van der Laan for helpful discussions and critically reading the manuscript.

## $\alpha$ -Amylases

**Dominic W. S. Wong and George H. Robertson**

*U.S. Department of Agriculture, Albany, California, U.S.A.*

### I. INTRODUCTION

$\alpha$ -Amylases (EC 3.2.1.1) are endoglucanases that catalyze the cleavage of internal glucosidic bonds in starch and related polysaccharides to yield dextrins and oligosaccharides with the anomeric C1-OH in the  $\alpha$ -configuration. The  $\alpha$ -1,4 bonds near  $\alpha$ -1,6 branches are resistant to hydrolysis. Extensive hydrolysis of amylopectins with  $\alpha$ -amylases produce “ $\alpha$ -limited dextrins,” as cleavage terminates at the  $\alpha$ -1,6 bonds.  $\alpha$ -Amylase plays a central role in carbohydrate metabolism of microorganisms, plants, and animals. Microbial  $\alpha$ -amylases derived from *Bacillus licheniformis* or related organisms for commercial applications are stable at temperatures  $> 90^{\circ}\text{C}$ , relatively less dependent on  $\text{Ca}^{2+}$  ions, and active over a wide pH range.

$\alpha$ -Amylase for food processing is obtained by controlled fermentation of *Bacillus stearothermophilus*, *Bacillus subtilis* containing a *Bacillus megaterium* or *Bacillus stearothermophilus*  $\alpha$ -amylase gene, as an off-white to brown, amorphous powder or a liquid. Typical applications include preparation of starch syrup, dextrose, alcohol, beer, and bakery products.  $\alpha$ -Amylase is used industrially in the liquefaction of starch to produce dextrins which are further saccharified by glucoamylase to yield glucose feed stock for corn syrup, fuel ethanol, or beverage alcohol production. In the baking industry,  $\alpha$ -amylase is added to the dough to ensure a continuous supply of fermentable sugar for yeast growth and gas production. In the textile industry, mechanical weaving of fabrics often requires the coating of threads with a starch “size,”

and  $\alpha$ -amylase is used for desizing to finish the fabric.  $\alpha$ -Amylase is one of the enzymes incorporated into laundry detergents to remove starchy stains from fabrics, and to increase the efficiency and reduce chemical ingredients in detergents.

### II. CLASSIFICATION

Glycosidases are classified under hydrolases which are subdivided into those hydrolyzing *O*-glycosyl, *N*-glycosyl, and *S*-glycosyl compounds (EC 3.2.1, 3.2.2, and 3.2.3).  $\alpha$ -Amylase hydrolyzes internal 1,4- $\alpha$ -D-glucosidic linkages in oligosaccharide or polysaccharide in a random manner with the reducing groups liberated in the  $\alpha$ -configuration. According to the IUBMB recommendation (1),  $\alpha$ -amylase (trivial name) therefore has the systematic name of 1,4- $\alpha$ -D-glucan glucanohydrolase, and a code number of EC 3.2.1.1. This classification scheme is based on the type of reaction catalyzed and the substrate specificity of the individual enzyme.

More recently, an alternative classification of glycosyl hydrolases based on amino acid sequence similarities has been proposed (2–4). There are 70 families according to this classification, and most  $\alpha$ -amylases belong to family 13, together with pullulanases (EC 3.2.1.41), cyclomaltodextrin glucanotransferase (EC 2.4.1.19), cyclomaltodextrinase (EC 3.2.1.54), and trehalose-6-phosphate hydrolase (EC 3.2.1.93). However,  $\alpha$ -amylases from *Dictyoglomus thermophilum*, *Methanococcus jannaschii*, *Pyrococcus*

*furius*, and *Pyrococcus horikoshii* belong to family 57. This classification scheme is based on the direct relationship between sequence and folding similarities, and it provides a convenient tool to predicting mechanistic information. However, classification based on sequence and structural similarities may cause unnecessary confusion because in this scheme, an enzyme is defined by its primary sequence as a protein, but not directly by its intrinsic catalytic functions.

### III. MOLECULAR STRUCTURES

Numerous amino acid sequences of  $\alpha$ -amylases are known, primarily deduced from DNA sequencing. A total of 70 entries are listed in Swiss-Prot: *Aeromonas hydrophila*, *Alteromonas haloplanktis*, *Dictyoglomus thermophilum*, *Escherichia coli*, *Bacillus amyloliquefaciens*, *B. megaterium*, *Bacillus* sp. (strain B1018), *B. circulans*, *B. stearothermophilus*, *B. licheniformis*, *B. subtilis*, *Paenibacillus polymyxa* (*Bacillus polymyxa*), *Butyrivibrio fibrisolvens*, *Methanococcus jannaschii*, *Streptomyces lividans*, *S. violaceus* (*Streptomyces venezuelae*), *S. griseus*, *S. limosus* (*Streptomyces albidoflavus*), *S. hygroscopicus*, *S. thermophilus*, *Clostridium acetobutylicum*, *Thermoanaerobacter thermosulfurogenes* (*Clostridium thermosulfurogenes*), *T. ethanolicus* (*Clostridium thermohydrosulfuricum*), *T. thermohydro-sulfuricus* (*Clostridium thermohydrosulfuricum*), *T. saccharolyticum*, *Thermomonospora curvata*, *Pyrococcus furiosus*, *P. horikoshii*, *Salmonella typhimurium*, *Aspergillus niger*, *A. awamori*, *A. oryzae*, *A. shirousami*, *Schizosaccharomyces pombe* (fission yeast), *Sacch-*

*aromycopsis fibuligera* (yeast), *Debaryomyces occidentalis* (yeast) (*Schwanniomyces occidentalis*), *Oryza sativa* (rice), *Triticum aestivum* (wheat), *Hordeum vulgare* (barley), *Vigna mungo* (rice bean) (black gram), *Drosophila melanogaster* (fruit fly), *D. mauritiana*, *D. yakuba*, *Aedes aegypti* (yellow fever mosquito), *Dermatophagoides pteronyssinus* (house-dust mite), *Tribolium castaneum* (red flour beetle), *Pecten maximus* (king scallop) (pilgrim's clam), *Tenebrio molitor* (yellow mealworm), *Sus scrofa* (pig), *Homo sapiens* (human), *Rattus norvegicus* (rat), and *Mus musculus* (mouse).

The sequences of  $\alpha$ -amylases from different origins have very few discernible similarities, with the exception of four short, highly conserved segments (5–15) (Fig. 1). The three catalytic residues (two Asp and one Glu), as well as residues involved in substrate binding, are located in these four highly conserved regions which are also found in GGTase (*Bacillus macerans*), pullulanase (*Klebsiella aerogenes*), isoamylase (*Psudomonas amylofera*),  $\alpha$ -glucosidase (*Saccharomyces carlsbergensis*), and cyclodextrinase (*Thermoanaerobacter ethanolicus*), suggesting that these enzymes may participate in the same type of reaction mechanism (16). Several microbial  $\alpha$ -amylases—*Bacillus circulans* (17), *Bacillus subtilis* (18), *Bacillus stearothermophilus* (19), *Streptomyces limosus* (20), *Chalara paradoxa* (21), *Lactobacillus amylovorus* (22), and *Cryptococcus* sp. S-2 (23)—are known to digest not only soluble starch, but raw starch granules. In addition, porcine pancreatic  $\alpha$ -amylase (24) and barley  $\alpha$ -amylase (25) contain C-terminal segments that have been identified to be a raw starch-binding site. The raw starch-binding sequences found

in  $\alpha$ -amylases from microbial sources exhibit a high degree of similarity to the starch binding segments in a number of bacterial  $\beta$ -amylase and GGTases and fungal glucoamylases. The alignment suggests an evolution path according to species rather than individual enzyme specificity (26). Some microbial enzymes, for example, *Streptomyces*  $\alpha$ -amylase, contain a glycine rich segment segregating the C-terminus from the rest of the molecule. This arrangement is reminiscent of glucoamylases where the catalytic domain and the starch-binding domain are attached via a highly glycosylated linker (27, 28). However, the domain-linker-domain architecture is not a universal requirement for raw starch digestion, because the majority of the  $\alpha$ -amylases that are known to degrade starch granules do not contain a linker sequence.

Despite the low sequence similarities, the crystal structures of  $\alpha$ -amylases from various organisms exhibit similar tertiary folding. The central core is an  $(\alpha/\beta)_8$  barrel (domain A), consisting of eight parallel  $\beta$  strands alternating with eight helices joined by loops (29, 30) (Fig. 2). About 10% of all known enzymes have an  $\alpha/\beta$  barrel domain, catalyzing a

wide variety of reactions. The first protein discovered to contain such folding was triose phosphate isomerase, hence the name TIM barrel (31). The evolutionary history of this  $\alpha/\beta$  barrel family of enzymes has been the subject of continuous interest. Arguments in support of convergence, as well as divergent evolution have been presented (32–35). For most  $\alpha/\beta$  barrel proteins, including the  $\alpha$ -amylase family, the active site is located at the C-terminus of the parallel  $\beta$ -strands, with the catalytic and substrate-binding residues in the loop regions.  $\alpha$ -Amylases also contain a small structural domain (domain B) inserted between  $\beta$ -strand 3 and helix 3. This protruding domain B varies both in length and sequence, and is implicated in functional diversity and stability. In the *Aspergillus oryzae* enzyme, the main feature of domain B is a short, three-stranded antiparallel  $\beta$ -sheet (36). In the *Bacillus licheniformis*  $\alpha$ -amylase, domain B possesses a  $\beta$ -sheet of six loosely connected twisted  $\beta$ -strands forming a twisted barrel with a large interior hole (37). For several  $\alpha$ -amylases with known three-dimensional structures, including *Bacillus licheniformis*, *Aspergillus oryzae*, and porcine pancreatic, domain B contains an invariant Asp residue (equivalent to

**Figure 2** A stereo view of the barley  $\alpha$ -amylase (isoform 2). The structure consists of three domains—the central  $(\alpha/\beta)_8$ -barrel (domain A), a five-stranded antiparallel  $\beta$ -sheet domain C at the bottom, and a protruding loop at the top (domain B). (From Ref. 29, PDBid: 1 amy.)

Asp175 of the *A. oryzae* enzyme) involved in calcium binding. The  $(\alpha/\beta)_8$  barrel is followed by domain C, a distinct globular unit of  $\sim 100$  amino acid residues with a folding of an antiparallel  $\beta$ -sandwich of the Greek key topology.

The three-dimensional structures of several  $\alpha$ -amylases have been solved: *Aspergillus oryzae*, *A. niger*, *Bacillus licheniformis*, *B. subtilis*, *B. stearothermophilus*, yellow mealworm, porcine pancreatic, human pancreatic, *Alteromonas haloplancis*, and barley isoform 2. The following is a functional description of the enzyme structure of barley  $\alpha$ -amylase (isoform AMY2) (29, 30, 38). AMY2 assumes the same basic features in the overall structure (Fig. 2). Domain A forms an  $(\alpha/\beta)_8$  barrel of 286 residues, with a loop of 64 residues (domain B) protruding between  $\beta$ -strand 3 and helix 3. The C-terminal 53 residues form domain C with a five-stranded antiparallel  $\beta$ -sheet. The active site is located on the C-terminal side of the  $(\alpha/\beta)_8$  barrel, with the catalytic residues Asp179, Glu204, and Asp289 positioned at A- $\beta_4$ , A- $\beta_5$ , and A- $\alpha_{7a}$ , respectively. Several invariant residues, including Tyr51, His92, Arg177, and His288, form hydrogen bonds with the substrate (39).

The  $\alpha$ -amylase contains a calcium-binding site structurally similar to that of other amyloytic enzymes (40). The calcium atom is coordinated by amino acid side chains located in both domains A and B, providing structural stability to the enzyme. Removal of calcium from the barley enzyme results in irreversible inactivation. In addition to this high-affinity binding site, two other calcium-binding sites have been located with ligands entirely in the domain B. The calcium-binding interactions seem to contribute to the folding stability of domain B.

A surface-located starch granule-binding site characteristic of cereal  $\alpha$ -amylase has been identified that interacts with starch granules. This site also binds  $\beta$ -cyclodextrin, an analog of amylose, in competition with starch granules. Chemical modification and site-directed mutagenesis suggest that two consecutive Trp residues, Trp276 and Trp277, are involved (41, 42). In a three-dimensional structure of AMY2 in complex with the inhibitor acarbose, the two Trp residues stack onto the substrate sugar rings, a typical feature of protein-carbohydrate interactions (30). However, this structural arrangement involving consecutive Trp residues protruding from the helix A- $\alpha_{6b}$  is not found in the microbial or animal  $\alpha$ -amylases that also hydrolyze raw starch granules.

## IV. REACTION MECHANISMS

$\alpha$ -Amylases hydrolyze the glucosidic bond with retention of the anomeric configuration. The retaining and inverting actions of glycosidases have been the subject of numerous investigations, and several mechanisms have been proposed to explain the stereochemistry of the catalytic process.

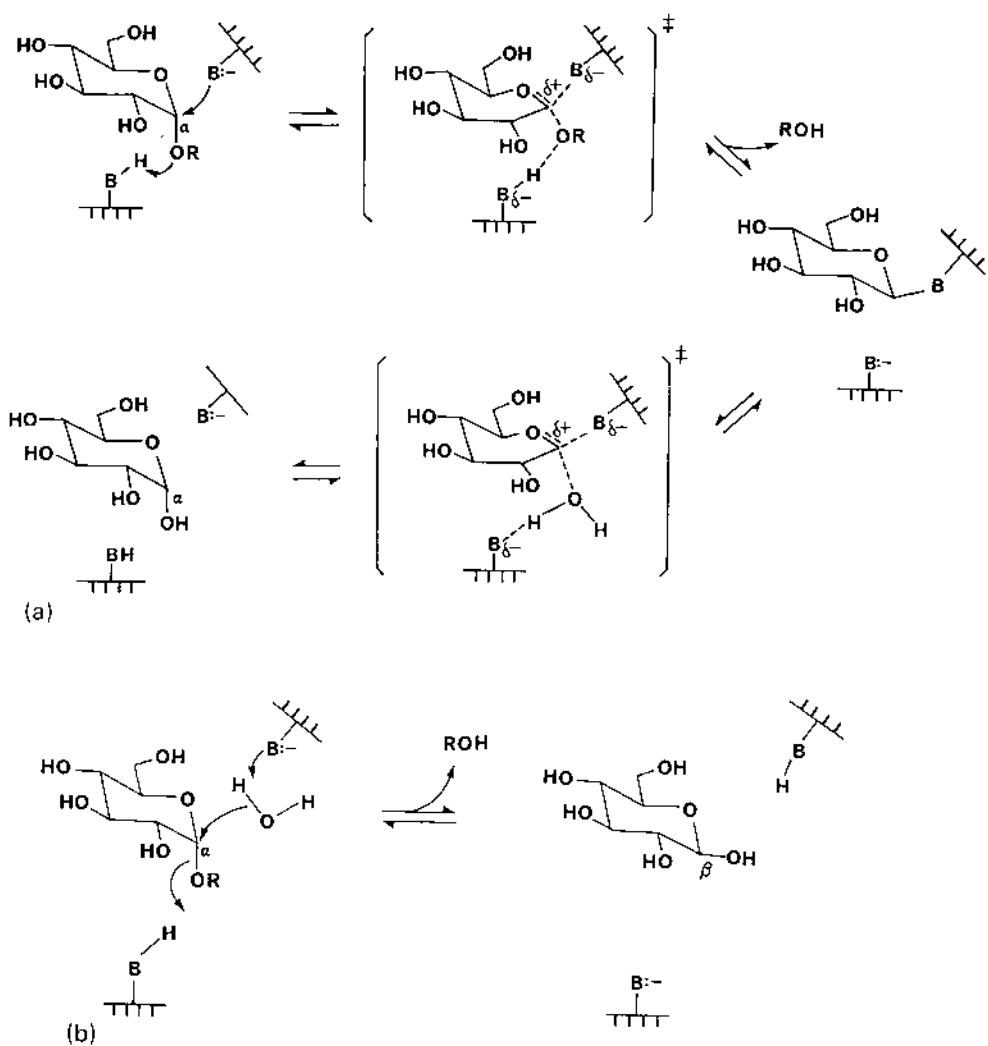

### A. Nucleophilic Displacement Mechanism

For retaining glycosidases, the reaction proceeds via a double displacement (43–45). The protonation of the glucosidic oxygen is concerted with the nucleophilic attack of a carboxylate anion at C1, resulting in the formation of a covalent glucosyl-enzyme intermediate (Fig. 3). A second displacement by a general base hydrolyzes the carboxyl-acetal bond of the glucosyl-enzyme intermediate to yield a product with  $\alpha$ -configuration.

For inverting glycosidases, the reaction involves a single displacement. The glucosidic oxygen is protonated by a general acid, resulting in a weakened maltofyl C–O bond. The attack of a water molecule occurs at the  $\beta$ -side of substrate assisted by a general base. It has been suggested that both reactions involve transition states with oxocarbonium ion character. It is interesting to note that although both reactions can be called displacement, they are obviously very different. In the single displacement, one of the carboxylic catalytic residues acts as a general acid and the other as a general base, whereas in the double displacement, one residue acts as a general acid/base, and the other acts as a nucleophile. Furthermore, the covalent enzyme-substrate intermediate invoked for the double displacement is not formed in the single displacement.

### B. Oxocarbonium Ion Mechanism

In this model, the reaction is described by S<sub>N</sub>1 substitution (Fig. 4). Protonation of the glucosidic oxygen results in bond cleavage, leading to the formation of an oxocarbonium ion intermediate that is stabilized by a carboxylate anion residue (46–48). It has also been suggested that binding of the sugar substrate to the enzyme's active site induces a distortion of the sugar ring into a half-chair conformation, thereby weakening the C1–O4 bond as shown in the case of lysozyme (49). The stereoselectivity of the reaction then depends on the direction of the nucleophilic attack of the water molecule assisted by a general base. In  $\alpha$ -amylases, the water molecule attacks from the front (original

**Figure 3** (A) A single-displacement mechanism. (B) A double-displacement mechanism with the formation of a glycosyl enzyme intermediate via oxocarbonium-like transition states.

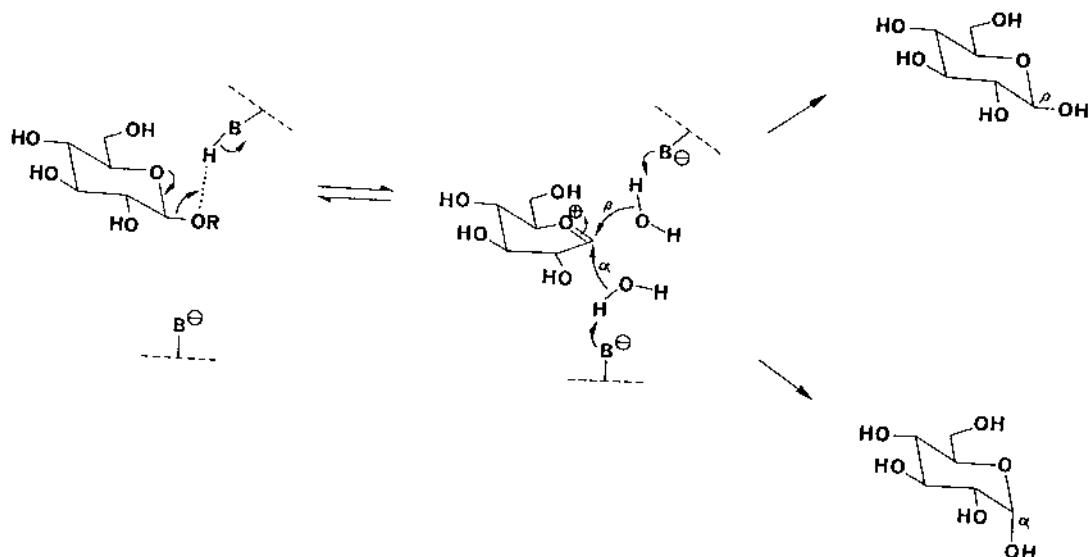

glucoside oxygen side), with the product maintaining the  $\alpha$ -configuration. In inverting glycosidases, such as  $\beta$ -amylase and glucoamylase, a back-side attack results in an inversion of the configuration. The appealing aspect of this model is that the catalytic reactions of both inverting and retaining glycosidases can be explained by a single unified mechanism (50).

The main difference between this model and the displacement mechanism lies in whether a transient or stable oxocarbonium ion intermediate exists (51, 52). The formation of a stable oxocarbonium ion intermediate is preferred if bond breaking precedes the attack of water facilitated by general base catalysis. The oxocarbonium ion is readily collapsed into a cova-

lent intermediate if nucleophilic attack occurs prior to the complete formation of the cation.

### C. Ring-Opening Reaction

An alternative mechanism that is not as well received as the above two models involves endocyclic carbon-oxygen cleavage as the rate-determining step, leading to the formation of an acyclic oxocarbonium ion intermediate (44, 53). In this model, there is no distortion of the substrate into a twist-boat conformation as shown by molecular dynamics simulation. In the chair conformation of both  $\alpha$  and  $\beta$ -anomers, the antiperiplanar orientation of the exocyclic O<sub>4</sub> lone pair fulfills the

**Figure 4** Reaction mechanism of carbohydrases involving a stabilized oxocarbonium intermediate.

stereoelectronic requirement in the fragmentation of the ring C–O bond (54). It has been also postulated that protonation occurs at the cyclic oxygen instead of the glucosidic oxygen, and the water nucleophilic attack is followed by a rotation of the hemiacetal center to position for cleavage (55).

## V. $\alpha$ -AMYLASE INHIBITORS

Two families of  $\alpha$ -amylases inhibitors ( $\alpha$ -AI), including carbohydrate- and protein-based inhibitors, have been studied in detail. The knowledge of the inhibitory action of these compounds is of great interest in medicine in the attempt to develop therapeutics for diabetes, obesity, and hyperlipemia. Proteinaceous  $\alpha$ -AIs are widespread in microorganisms and higher plants. Tendamistat, one of the most potent inhibitors of mammalian  $\alpha$ -amylases, is an acidic protein of 74 amino acids isolated from the culture medium of *Streptomyces tendae* (56, 57). This class of inhibitors also includes HAIM (*S. griseosporeus*) (58), AI-3688 (*S. aureofaciens*) (59), and PAIM (*S. griseosporeus*) (60). Tendamistat binds tightly with porcine pancreatic  $\alpha$ -amylase with a very high inhibition constant of  $9 \times 10^{-12}$  M (56). The molecular structure assumes a  $\beta$ -barrel of two  $\beta$ -sheets, each consisting of three antiparallel strands. The  $\beta$ -strands are connected by loops and turns which contain the active-site triplet Trp18–Arg19–Tyr20 characteristics of all Tendamistat-type

proteinaceous inhibitors (61, 62). Analysis of the crystal structure indicates that the head of Tendamistat containing the highly conserved triplet residues binds directly to the active site of the porcine pancreatic  $\alpha$ -amylase, blocking the five binding subsites –3 to 2, with Arg19 forming a salt bridge with the catalytic residue, Glu233 (for subsite nomenclature, refer to Ref. 62). In the formation of the enzyme–inhibitor complex, the conformation of the enzyme active site is induced to accommodate tight binding of Tendamistat and related inhibitors.

The seeds of common beans contain a family of proteins involved in a defense mechanism, composed of phytohemagglutinin, and  $\alpha$ -amylase inhibitor. The  $\alpha$ -AIs inhibit the activity of some mammalian and insect  $\alpha$ -amylases, but not of the endogenous plant enzyme. Red kidney bean  $\alpha$ -AI has a  $K_D$  of  $3.5 \times 10^{-11}$  M at pH 6.9 and 30°C (63), and black bean  $\alpha$ -AI  $4.4 \times 10^{-9}$  M at pH 6.9 at 37°C (64). There are at least five known sequences derived from  $\alpha$ -AIs of common domesticated beans, wild common bean, white kidney bean, and black bean (65). The inhibitors are glycoproteins synthesized as preproteins which require proteolytic cleavage for activation (66). Translational processes produce the active inhibitor formed by the association of two polypeptide chains,  $\alpha$ - and  $\beta$ -subunits (67). In the crystal structure of the enzyme–inhibitor complex,  $\alpha$ -AI-I exists as a dimer that binds two porcine pancreatic enzyme molecules (68). Each monomer consists of a concave

12-stranded antiparallel  $\beta$ -sandwich fold. Two hairpin loops protruding from the fold interact directly with the active-site region of the enzyme. A large conformational change occurs in the enzyme active site upon  $\alpha$ -AI-1 binding, resulting in extensive interactions with the inhibitory site of  $\alpha$ -AI. Site-directed mutagenesis studies suggest the involvement of Trp188, Arg74, and Tyr190 in  $\alpha$ AI, analogous to the Trp-Arg-Tyr motif of Tendamistat (69). X-ray structural analysis confirms that Tyr190 forms strong contacts with the catalytic residue Asp300.

A variety of  $\alpha$ -AIs, both endogenous and exogenous, occur in barley and wheat kernels. The  $\alpha$ -amylase/subtilisin inhibitor (BASI) from barley has been extensively investigated and its three-dimensional structure is known. BASI is active against the plant endogenous  $\alpha$ -amylase 2 (one of the two major barley amylase isozymes). It consists of a single polypeptide of 181 residues with a calculated MW of 19,685 daltons. Its amino acid sequence shows 26% identical residues compared to that of the soybean trypsin inhibitor (Kunitz) (70). Inhibitors with a dual function of protease and  $\alpha$ -amylase have also been identified in wheat and ragi (71, 72). BASI forms an inactive 1:1 complex with  $\alpha$ -amylase 2, with a dissociation constant of  $2.2 \times 10^{-10}$  M at pH 8 and 37°C (73) but does not inhibit  $\alpha$ -amylase 1, the other major barley isozyme. The crystal structure of BASI is composed of a 12-stranded  $\beta$ -barrel, with three sets of four sequential  $\beta$ -strands arranged in a threefold symmetry (38). The hydrophobic core is composed of six  $\beta$ -strands—S1, S4, S5, S8, S9, and S12—and one end of the barrel is closed by triangular array consisting of the remaining  $\beta$ -strands. BASI binds tightly to domains A and B of the enzyme but does not directly interact with the catalytic residues at the enzyme active site. A calcium ion is trapped at the interface of the enzyme–inhibitor complex.

The second type of inhibitors are carbohydrate-based derived from the trestatin family and are found also in *Streptomyces*. The most common inhibitor in this class is acarbose, a pseudo-tetrasaccharide with a cyclitol unit and an amino sugar unit at the nonreducing end. Cyclitol ring exists as a half-chair resembling the conformation of the oxocarbonium ion. Binding of the inhibitor to the enzyme induces structural changes at the active site, involving extensive hydrogen bonds, hydrophobic stacking, and water-bridged contacts (74). It has been shown that pancreatic  $\alpha$ -amylase can hydrolyze the reducing end glucose units, and several x-ray crystal structural analyses revealed that the original substrate acarbose is transformed into a more

potent inhibitor via transglycosylation or condensation of the cleaved products (36, 75). The additional sugar rings of the product may be stabilized by secondary binding sites on the surface of the enzyme molecule (76). Another carbohydrate inhibitor, cyclohepta-amylose (CHA), has been known to inhibit  $\alpha$ -amylase digestion of raw starch granule by interfering with  $\alpha$ -amylase adsorption to raw starch granules. Hydrolysis of starch granules by wheat  $\alpha$ -amylase is inhibited 40% by 0.88 mM CHA (41). The granular starch-binding domain of *Aspergillus niger* glucoamylase 1 binds  $\beta$ -cyclodextrin with a dissociation constant  $K_d$  of 1.68  $\mu$ M, and a competitive inhibition constant ( $K_i$ ) of 11.0  $\mu$ M for raw starch adsorption showing that  $\beta$ -cyclodextrin and granular starch bind to the same site of the enzyme molecule (28). It has been proposed that the  $\beta$  cyclodextrin seven-member ring structure mimics the helical amylose with binding in the cavity (77).

## VI. MEASUREMENT OF $\alpha$ -AMYLASE ACTIVITY

The kinetic parameters of barley  $\alpha$ -enzyme were measured using various concentrations of the substrate ET-G<sub>7</sub>PNP. A  $K_m$  of 0.45 mM and a  $k_{cat}$  of  $1.2 \times 10^2$  sec<sup>-1</sup> were obtained for the  $\alpha$ -amylase, with  $k_{cat}/K_m$  of  $2.7 \times 10^2$  mM<sup>-1</sup> · sec<sup>-1</sup>. Barley malt  $\alpha$ -amylase 1 has a  $k_{cat}/K_m$  value of  $1.75 \times 10^2$  mM<sup>-1</sup> · sec<sup>-1</sup> using *p*-nitrophenyloligosaccharide (*p*-NPGlc<sub>7</sub>) as the substrate (78). The catalytic efficiency is generally consistent with those obtained for  $\alpha$ -amylases from other organisms. For example, a  $k_{cat}/K_m$  of  $2.5 \times 10^2$  mM<sup>-1</sup> · sec<sup>-1</sup> has been reported for *Saccharomycopsis fibuligera*  $\alpha$ -amylase in the hydrolysis of malto-oligosaccharides (79), and a higher value of  $1.3 \times 10^3$  mM<sup>-1</sup> · sec<sup>-1</sup> has been observed for the same enzyme with amylose A as the substrate (80). Porcine pancreatic  $\alpha$ -amylase has a  $k_{cat}/K_m$  of  $5.8 \times 10^3$  mM<sup>-1</sup> · sec<sup>-1</sup> in the hydrolysis of *p*-NPGlc<sub>7</sub> (81). Increasing chain length of the substrate decreases the  $K_m$  value and increases the  $k_{cat}$ , as demonstrated in the *Aspergillus oryzae* enzyme:  $K_m = 9.0 \times 10^{-4}$  and  $9.5 \times 10^{-6}$  mM for maltotetraose and maltdextrin VI ( $n = 117$ ), respectively, and  $k_{cat} = 1.2 \times 10^4$  and  $9.9 \times 10^3$  min<sup>-1</sup> (82).

The method of  $\alpha$ -amylase activity measurement is characterized by the type of substrate employed in a particular procedure. All three methods described below have been used routinely by the authors for the assay of plant and recombinant  $\alpha$ -amylases.

## A. Reducing Sugar Method

Reducing sugar assays measure the increase of new reducing ends on fragments produced by the hydrolytic action of  $\alpha$ -amylase on soluble starch. In the 3,5-dinitrosalicylic acid method, the concentration of the nitroaminosalicylic acid formed at the reducing hemiacetal is measured colorimetrically (83). The measurement of  $\alpha$ -amylase activity by this method is accurate only if the sample is not contaminated with other amylolytic enzymes. A modified procedure for small-scale analysis of cereal  $\alpha$ -amylases is described: 250  $\mu$ L of enzyme in buffer (200 mM sodium acetate, pH 5.5; 10 mM CaCl<sub>2</sub>) was combined with 250  $\mu$ L of 1% soluble starch and incubated at 37°C for 10 min. To the reaction mixture 500  $\mu$ L of dinitrosalicylic acid reagent (1% nitrosalicylic acid, 30% potassium sodium tartrate, 40% 1 N NaOH) was added, heated for 5 min in a 100°C water bath, cooled to room temperature in cold water, and then clarified by centrifugation. The absorbance at 547 nm was measured, and the activity was calculated using a maltose standard curve. One enzyme unit is defined as the amount of enzyme catalyzing the release of 1  $\mu$ mole of reducing groups from soluble starch, measured as maltose, per min at 37°C. In some cases, it may be desirable to treat the starch with sodium borohydride to remove terminal reducing glucosyl residues that may interfere with the reducing sugar measurement (84). The reducing groups can also be quantitated by the alkaline ferricyanide method (85, 86), or the Nelson-Somogyi method (87, 88). Benedict's solution can detect 0.01% glucose in water.

## B. Dyed Starch Substrate Method

This procedure involves the hydrolysis of dyed starch substrate by  $\alpha$ -amylase and the measurement of absorbance at 610 nm of the soluble colored fragments released into solution from degradation of the substrate. This method is unaffected by reducing substances and is therefore particularly applicable to the measurement of  $\alpha$ -amylase activity in cell culture media containing glucose or other reducing sugars. Two types of dyed starch substrates are available commercially.

### 1. Dye-Labeled Crosslinked Starch

Dye-labeled crosslinked starch is made by crosslinking partially hydrolyzed potato starch using 1,4-butandioldiglycidether, and labeling with Cibachron Blue by

covalent bonds (89). The substrate forms an insoluble network of polymers that swells in water or buffer, resulting in a suspension. The substrate is known to be very resistant to  $\beta$ -amylase, and is particularly suitable for the analysis of  $\alpha$ -amylase in cereal grains which commonly contain considerable amounts of  $\beta$ -amylase as a common contaminant in enzyme extracts.

## 2. Dye-Labeled Non-crosslinked Starch

Dye-labeled non-crosslinked starch is made by labeling non-crosslinked starch with Remazol Brilliant Blue by covalent bonds. This is a soluble substrate (90). The substrate is also susceptible to  $\beta$ -amylase action, and therefore this assay is nonspecific for  $\alpha$ -amylase.

A microassay has been developed using dye-labeled crosslinked starch (Phadebas, Pharmacia) for rapid screening of  $\alpha$ -amylase activity (91). Linear correlation between the absorbance and enzyme concentrations in the 50-ng range was observed. The assay has been adapted for semiautomation and routinely used in monitoring the production of recombinant  $\alpha$ -amylase produced in transformed yeast cells. One unit of  $\alpha$ -amylase activity is defined as the amount of enzyme that gives an absorbance value of 0.100 (92). This definition is the most useful in the measurement of relative activities, such as monitoring chromatographic column fractions. The absorbance values obtained in the dyed-substrate-based assay can be converted to International Units using a standard curve.

## C. Defined Substrate Method

The use of low-MW synthetic oligosaccharides with a defined structure has the advantage of elimination of substrate variability. However, these are not natural substrates, and activity measurement may fail to reveal some unique enzyme properties, such as raw starch binding and hydrolysis. Defined substrates have been initially developed with a chromophore such as *p*-nitrophenol group attached to the reducing-end glucose unit. These substrates, however, are nonspecific for  $\alpha$ -amylases, since other amylases, such as  $\beta$ -amylase or glucoamylase, also can readily cleave the substrate. More recently, a specific substrate has been developed with the additional attachment of a chemical blocking group at the non-reducing-end glucose residue (93, 94). We use 4,6-ethylidene-(G<sub>7</sub>)-*p*-nitrophenyl-(G<sub>1</sub>)- $\alpha$ ,D-maltoheptaside (Sigma) as the substrate. The ethylidene group in the 4,6-position of G7 blocks the action of exoamylases.  $\alpha$ -Amylase hydrolyzes the substrate to G2-, G3-, and G4-*p*-nitrophenol

fragments, which are further hydrolyzed by  $\alpha$ -glucosidase to *p*-nitrophenol and glucose. Enzyme activity corresponds to the increase in absorbance at 405 nm owing to the liberation of *p*-nitrophenol, and the chemically blocked nonreducing end renders the substrate unsusceptible to the action of  $\beta$ -amylase and glucoamylase.

## VII. PURIFICATION OF $\alpha$ -AMYLASE

The following method, based on MacGregor and Morgan (95), has been used routinely in our lab to purify barley  $\alpha$ -amylase. Barley malt (250 g) was extracted with 500 mL of 0.2 M acetate buffer containing 1 mM CaCl<sub>2</sub>, pH 5.5. The suspension was centrifuged (8000g, 15 min) and the pellet was subjected to a second extraction using the same buffer. The combined extracts (supernatants) were heated at 70°C for 15 min, and denatured proteins, including  $\beta$ -amylase, were removed by centrifugation (8000 g, 15 min). The proteins in the supernatant were precipitated with 60% (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> at 4°C, redissolved in 200 mL of 0.02 M acetate buffer containing 1 mM CaCl<sub>2</sub>, pH 4.7, and dialyzed against the same buffer. The crude enzyme preparation was loaded onto a CM Sepharose CL-6B column equilibrated with the same buffer. Elution was performed using a linear gradient from 0.02 M to 0.06 M acetate (containing 1 mM CaCl<sub>2</sub>, pH 4.7), and active fractions were pooled to give a crude preparation of  $\alpha$ -amylase isozyme 1. A second elution was performed with a salt gradient of 0.06 M acetate buffer (containing 1 mM CaCl<sub>2</sub>, pH 4.7) and the same buffer containing 0.5 M NaCl, to give a crude preparation of  $\alpha$ -amylase 2 isozyme. The enzyme preparations are concentrated by ultrafiltration (PM10 membrane) and further purified by passing through the CHA-Sepharose affinity column (96). Bound  $\alpha$ -amylase was eluted with acetate buffer containing 8 mg/mL CHA. The CHA was removed by ion exchange chromatography as described above.

For the purification of recombinant  $\alpha$ -amylase expressed in yeast, the following method has been used in our laboratory. Yeast cells secreting recombinant  $\alpha$ -amylase were grown in 2 L YEPD medium for 36 h and centrifuged at 9000g for 20 min. The supernatant was filtered through a 0.2- $\mu$  filter, concentrated by ultrafiltration using Pellicon XL (10,000 mwco, Millipore, Bedford, MA) at a crossflow rate of 35 mL/min. The retentate was exchanged into 20 mM sodium acetate buffer, pH 5.0, containing 5 mM CaCl<sub>2</sub>. The enzyme was separated by an affinity col-

umn of cyclohepta-amylose-substituted epoxy-Sepharose 6B according to Silvanovich and Hill (96). The concentrated enzyme preparation (100 mL) was loaded onto CHA-Sepharose affinity column (1 × 8 cm), followed by successive washings with 50 mL buffer, 50 mL buffer containing 4 mM NaCl, and 100 mL buffer. The adsorbed enzyme was eluted with buffer containing 8 mg/mL CHA which was subsequently removed by dialysis in 20 mM sodium acetate, pH 5.0, buffer containing 2 mM CaCl<sub>2</sub>.

*U.S. Department of Agriculture, Albany, California, U.S.A.*

### I. INTRODUCTION

The distribution of  $\beta$ -amylase is limited to higher plants and bacteria. It is an exoenzyme that catalyzes the hydrolysis of 1,4- $\alpha$ -D-glucosidic linkages in polysaccharides to remove successively  $\beta$ -anomeric maltose units from the nonreducing end of  $\alpha$ -1,4-glucans such as starch and glycogen. Sweet potato contains an abundant  $\beta$ -amylase which accounts for 5% of the total soluble proteins in the tuber; by contrast, only a trace amount of  $\alpha$ -amylase is present. The sweetness of sweet potato is the result of the hydrolysis of starch to maltose by the endogenous  $\beta$ -amylase during cooking.  $\beta$ -Amylase is employed by the starch industry in the production of high maltose syrups. Compared with glucose syrups, maltose syrups have a higher viscosity and lower hygroscopicity, less tendency to crystallize, and more resistance to browning. These characteristics make them particularly suitable for use in the confectionery and baking industry.  $\beta$ -Amylase is highly significant in determining the fermentability of worts for brewing.

### II. CLASSIFICATION

Glycosidases are classified under hydrolases and are subdivided into those hydrolyzing *O*-glycosyl, *N*-glycosyl, and *S*-glycosyl compounds (EC 3.2.1., 3.2.2, 3.2.3).  $\beta$ -Amylase is an exoglucanase that catalyzes the hydrolysis of 1,4- $\alpha$ -D-glucosidic bonds in polysaccharides to cleave successively maltose units from the nonreducing

end. According to the IUBMB classification (1),  $\beta$ -amylase has the systematic name of 1,4- $\alpha$ -D-glucan maltohydrolase, and a code number of EC 3.2.1.2.

A classification of glycosyl hydrolases based on similarities in amino acid sequence has been proposed and yields useful information on the structure and function of these enzymes (2–4).  $\beta$ -Amylase belongs to family 14 in this scheme. This classification scheme should only be used as a supplement to the IUBMB classification.

### III. MOLECULAR STRUCTURE

Several amino acid sequences of  $\beta$ -amylases are known, primarily deduced from the gene sequences. These include (as entries are listed in Swiss-Prot): *Ipomoea batatas* (sweet potato), *Glycine max* (soybean), *Hordeum vulgare* (barley), *Triticum aestivum* (wheat), *Zea mays* (maize), *Secale cereale* (rye), *Vigna unguiculata* (cowpea), *Medicago sativa* (alfalfa), *Trifolium repens* (creeping white clover), *Arabidopsis thaliana* (mouse ear cress), *Bacillus cereus*, *B. firmus*, *B. circulans*, *B. polymyxa*, and *Thermoanaerobacter thermosulfurogenes* (*Clostridium thermosulfurogenes*). Several conserved regions exist in all  $\beta$ -amylases, although the sequences between plant and bacterial  $\beta$ -amylases show only 30% similarities (Fig. 1).

The three-dimensional structures of  $\beta$ -amylases from soybean (5–7), sweet potato (8), barley (9), and *Bacillus cereus* (10) have been reported. Soybean  $\beta$ -amylase consists of 495 amino acid resi-

**Figure 1** Comparison of regions of sequence similarities among nine  $\beta$ -amylases, including sweet potato (P10537), soybean (P10538), barley (P16098), corn (P55005), wheat (P93594), *Arabidopsis thaliana* (P25853), *Bacillus cereus* (P36924), *Bacillus circulans* (P06547), and *Bacillus polymyxa* (P21543). The catalytic Glu are marked as general acid (\*) and general base (#). Numbering of sequences starts with the N-terminus of the mature protein.

dues with a molecular weight of 56 kDa. The enzyme consists of a large  $(\alpha/\beta)_8$ -barrel core; a smaller lobe formed by three long loops (L3, L4, and L5) extending from  $\beta_3$ ,  $\beta_4$ , and  $\beta_5$  strands; and a C-terminal tail loop of  $\sim 50$  residues extending from  $\alpha_8$  and covering the entrance of the barrel. Between the surface of the lobe region and the core is a cleft that opens into a pocket  $\sim 18$  Å deep that contains the catalytic residues Glu186 and Glu380, and an essential residue Asp101. This architecture contrasts to that of  $\alpha$ -amylases which have the reactive center located in a long cleft open at both ends (11). The deep pocket conformation found in  $\beta$ -amylase is also present in glucoamylase, although the latter has an  $(\alpha/\alpha)_8$ -core domain (12). That the catalytic site is situated in a cavity allows endwise hydrolysis of the starch chain with the length of glucose units cleaved in a controlled manner. Substrate binding causes a movement of some segments in L3 (residues 96–103) to close over the bound substrate like a hinged lid. In the crystal structure of soybean  $\beta$ -amylase complexed with maltose, L3 in the closed conformation interacts with maltose forming hydrogen bonding between Asp101 and O-2 of the glucose unit 1, and Van der

Waals contacts between Val99 and the substrate. The L3 lid serves to shield the active site from being exposed to the solvent, and also positions the substrate in proximity to the two catalytic residues Glu186 (acting as a general acid) and Glu380 (acting as a general base). Glu186 has been identified as the catalytic residue by affinity labeling with 2,3-epoxy-propyl- $\alpha$ -D-glucopyranoside (13). The binding energy upon closing the lid for  $\alpha$ -maltose estimated in an automated docking experiment is 22 kcal/mol, indicating considerable enhancement of interactions between the substrate and the subsites (14, 15). The active site of soybean  $\beta$ -amylase can accommodate two maltose molecules, corresponding to a maltotetraose. The two maltose molecules bind in tandem in the active site cleft occupying subsites -1, -2 and 1, 2, respectively, with the nonreducing end at the -1 subsite and cleavage occurring between subsite -1 and +1 (for subsite nomenclature, refer to 16). Substrates with longer chain length may have the outer glucose units anchored by hydrophobic interaction with the methyl groups of Leu383 at the cleft entrance, as revealed in the crystal structure of soybean  $\beta$ -amylase complex with  $\alpha$ -cyclodextrin (6).

All plant  $\beta$ -amylases with known crystal structures have the same molecular architecture, except for the sweet potato enzyme which is a tetramer having a subunit MW of 55,800 daltons (598 amino acid residues) (8, 17). Each subunit consists of a central  $(\alpha/\beta)_8$ -barrel, a small domain formed by three long loops—L3 (residues 91–150), L4 (residues 183–258), and L5 (residues 300–327)—and a long C-terminal loop (residues 445–493). The active site is located at a deep cleft between the  $(\alpha/\beta)_8$ -barrel and the small domain  $\beta$ -amylase (Fig. 2) shows an architecture similar to that of the soybean enzyme, except that the C-terminal sequence contains Gly-rich repeats (9). Deletion of the C-terminal 45 residues led to a decrease in the thermostability of the enzyme (18). A similar extended sequence is found in endosperm-specific rye  $\beta$ -amylase (19).

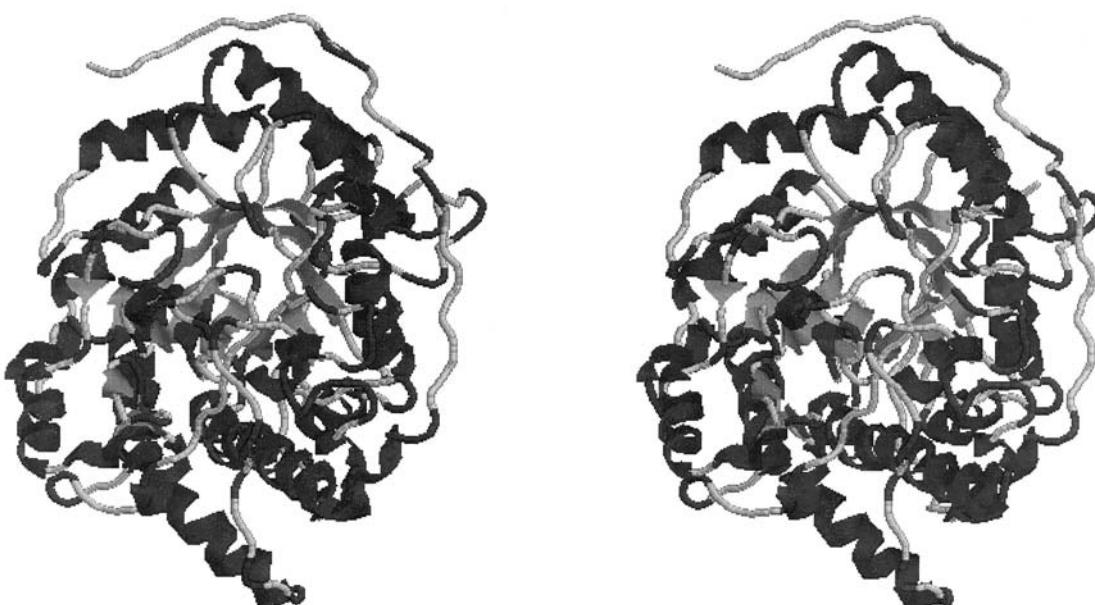

Bacterial  $\beta$ -amylases share similar tertiary structure with plant  $\beta$ -amylases, in spite of the low sequence identity ( $\sim 30\%$ ) with those of plant  $\beta$ -amylases. The crystal structure of  $\beta$ -amylase from *Bacillus cereus* var. *mycoides* reveals a C-terminal domain with two antiparallel  $\beta$ -sheets, similar to the raw starch-binding domains of glucoamylase and cyclodextrin glycosyltransferase (10, 20). The possession of this unique C-terminal domain provides bacterial  $\beta$ -amylases with the ability to bind and digest raw starch. In contrast,

plant  $\beta$ -amylases do not contain a raw starch-binding site, and are incapable of digesting raw starch.

#### IV. REACTION MECHANISMS

In a single nucleophilic displacement mechanism,  $\beta$ -amylase catalyzes hydrolysis of the glucosidic bond with inversion of the anomeric configuration (21, 22). The initial step involves protonation of the glucosidic oxygen by a general acid which weakens the maltosyl C-O bond. This is followed by a general acid catalysis with a water molecule attacking from the  $\beta$ -side of the substrate to release a maltose unit with  $\beta$ -configuration. In the soybean enzyme, the carboxylic group of Glu186 acts as a general acid, and the carboxylate anion of Glu380 serves as a general base, according to affinity labeling studies and x-ray structural analysis (7, 13).

In an equally viable mechanism, protonation of the glucosidic oxygen results in a glucosyl oxocarbonium ion intermediate with an enzyme-induced distortion of the substrate in a half-chair conformation (23–25). A backside attack by a water molecule assisted by a general base produces an inversion of the configuration. (See [Chapter 56](#), Sec. IV.)

**Figure 2** A stereo view of barley  $\beta$ -amylase (isoform 2). The structure consists of a large  $(\alpha/\beta)_8$ -barrel core, a smaller lobe formed by three long loops (L3, L4, and L5), and a C-terminal tail loop residues extending from  $\alpha_8$  and covering the entrance of the barrel (Ref. 9, PDBid: 1bly).

## V. INHIBITORS

$\alpha$ -Cyclodextrin has long been known to be a competitive inhibitor of  $\beta$ -amylase, and the enzyme-inhibitor binding has been postulated as evidence for the induced fit theory (26, 27). The observed  $K_d$  of soybean  $\beta$ -amylase for  $\alpha$ -cyclodextrin is 0.5 mM. The three-dimensional structure of soybean  $\beta$ -amylase complexed with  $\alpha$ -cyclodextrin indicates that two glucose units of the  $\alpha$ -cyclodextrin molecule interact with the enzyme at loops L5 and L6 which form the entrance of the active-site cleft (5, 6). The inhibitor forms an inclusion complex with the methyl groups of Leu383 (28). In contrast to the binding of the maltose which is positioned deep in the cleft,  $\alpha$ -cyclodextrin inhibits the catalytic function by physically blocking the entrance to the active site.

$\beta$ -Amylases contain a conserved cysteine, and its modification by various sulphydryl reagents, such as iodoacetamide, N-ethylmaleimide, *p*-chloromercuricbenzoate (PCMB), and 5,5'dithiobis-(2-nitrobenzoic acid) (DTNB), causes a decrease of the enzyme activity and a slight change in the Michaelis constant (29). Studies of the interaction of native and SH-modified  $\beta$ -amylases of soybean with  $\alpha$ -cyclodextrin and maltose suggest that the cysteine is located near the binding site of the two substrates, but is not involved in catalysis (30–32). Selective modifications of all three cysteine residues in *Bacillus polymyxa*  $\beta$ -amylase yield the same conclusion (33, 34). It is believed that the attachment of bulky alkylating agents used in chemical modification introduces steric stresses that cause a structural distortion that in turn prevents the substrates from productive binding (35). This suggestion has been confirmed by the crystal structure of soybean  $\beta$ -amylase complexed with  $\alpha$ -cyclodextrin where Cys95 and Cys343 are located in the L3 and L5 loops near the maltose and  $\alpha$ -cyclodextrin binding site, respectively (5).

## VI. PHYSIOCHEMICAL PROPERTIES

Plant  $\beta$ -amylases are  $\sim$  55 kDa, with the exception of sweet potato  $\beta$ -amylase, which is a tetramer of 215 kDa. Microbial  $\beta$ -amylases have MW of 30–160 kDa with the high value representing possible association of subunits. the tetrameric structure of the sweet potato enzyme is not essential for the catalytic function, because the monomer retains full activity (36). The pH optimum for activity ranges from 5.0 for wheat, barley malt, and sweet potato  $\beta$ -amylases, to 6.0 for

soybean and pea enzymes. In the Triticeae (barley and wheat),  $\beta$ -amylase is synthesized in the endosperm in a bound form which is posttranslationally modified by proteolytic cleavage to yield a free and more active form, during germination (37, 38). Common to all cereals is the “ubiquitous”  $\beta$ -amylase that exhibits a transitory presence in various tissues of the developing kernels and in other seedling organs (39). All known plant  $\beta$ -amylases exist in several isoforms. The barley enzyme has four isozymes with pI values of 4.65, 4.75, 4.90, and 5.20 (40). All four isoforms have been shown to be products of proteolysis of the C-terminus of the full-length enzyme (MW 57 kDa), and exhibit optimal activity between pH 4.5 and 7.5, with a  $K_m$  of 2.5 mg · mL<sup>-1</sup> (soluble starch), and  $V_{max}$  of 17  $\mu$ mol maltose · min<sup>-1</sup> (41). Soybean contains several isozymes, with isozymes 2 (pI 5.25) and 4 (pI 5.5) the most predominant. The differences between the two isozymes are due to the substitution of Glu152 and Lys399 of isozyme 2 with Lys and Arg in isozyme 4 (42). The corn enzyme consists of two isoforms with pI values of 4.25 and 4.40, with MW of 65 kDa (43). Soybean  $\beta$ -amylase has a  $K_m$  of  $4.9 \times 10^{-2}$  mM using reduced amyloextrin substrate of average degree of polymerization of 21.7 (29). Using reduced soluble starch as the substrate, Totsukan and Fukazawa (28) reported a  $K_m$  of 0.17 mM and a  $k_{cat}$  of  $410\text{ sec}^{-1}$ , with a  $k_{cat}/K_m$  value of  $2.4 \times 10^3\text{ sec}^{-1}\text{ mM}^{-1}$ . Shorter-chain maltooligosaccharides, such as G7, showed an increasing  $K_m$  value of  $1.9 \times 10^{-1}$  M, and a  $k_{cat}$  of  $610\text{ sec}^{-1}$  (44). A  $k_{cat}/K_m$  of  $1.39 \times 10^3\text{ sec}^{-1}\text{ mM}^{-1}$  has also been reported using a similar G7 substrate.

## VII. MEASUREMENT OF ACTIVITY

Several methodologies are available for the determination of  $\beta$ -amylase activity. Some are based on determination of the increase in reducing groups produced by the hydrolytic action of  $\beta$ -amylase on suitable 1,4- $\alpha$ -D-glucans, such as soluble starch. In the 3,5-dinitrosalicylic acid method, the concentration of the nitroaminosalicylic acid formed at the reducing hemiacetal is measured colorimetrically (46). The reducing groups can also be quantitated by the alkaline ferricyanide method (47) or the Nelson-Somogyi method (48, 49). The reducing sugar assay is nonspecific, and the measurement of  $\beta$ -amylase activity by these methods is accurate only if the sample is devoid of  $\alpha$ -amylase and other amylolytic enzymes. For more details, refer to Chapter 56, Sec. VI.

A specific assay for  $\beta$ -amylase in the presence of cereal  $\alpha$ -amylases has been developed using a colorimetric substrate consisting of *p*-nitrophenyl oligosaccharides (50, 51). The substrate used is *p*-nitrophenyl  $\alpha$ -maltopentaoside (PNPG<sub>5</sub>), which is too short to be effectively hydrolyzed by cereal  $\alpha$ -amylases but is readily cleaved by  $\beta$ -amylase to maltose and *p*-nitrophenyl maltotriose (PNPG<sub>3</sub>). A subsequent reaction of the product, PNPG<sub>3</sub>, with added  $\alpha$ -glucosidase produces glucose and *p*-nitrophenol. The latter product, with a molar extinction coefficient of  $1.8 \times 10^3 \text{ M}^{-1}\text{cm}^{-1}$ , can be measured at 410 nm. In a standard assay (51), the enzyme preparation or extract (0.2 mL) in a buffer containing 100 mM sodium maleate, 1 mM diNaEDTA, 1 mg/mL BSA, and 3 mM NaN<sub>3</sub>, pH 6.2, is incubated with 0.2 mL of pre-equilibrated substrate mixture containing 5 mM PNPG<sub>5</sub>, 20 units of  $\alpha$ -glucosidase, at 40°C for 10 min. The reaction is terminated and color developed by the addition of 1% w/v Tris base (3.0 mL, pH > 10). The absorbance of *p*-nitrophenol is measured at 410 nm. One enzyme unit is defined as the amount of enzyme that catalyzes the release of 1  $\mu\text{mol}$  of *p*-nitrophenol per min under the assay condition. It should be noted that although PNPG<sub>5</sub> is not an effective substrate for cereal  $\alpha$ -amylases, it has been found to be readily attacked by some other  $\alpha$ -amylases, such as *Aspergillus niger*  $\alpha$ -amylase. The procedure described above can therefore only be applied for the selective measurement of  $\beta$ -amylase in cereal flour and products. For a precise quantitation of  $\beta$ -amylase, it may be necessary to determine the degree of interference of  $\alpha$ -amylase in the sample. If necessary, the  $\alpha$ -amylase in the sample should be measured using defined substrates, such as end-blocked *p*-nitrophenol maltosaccharide, that are not susceptible to the action of  $\beta$ -amylase and glucoamylase (see Chapter 56). The  $\beta$ -amylase is then obtained by sub-

strating the  $\alpha$ -amylase activity (using defined substrates) from the total amyloytic activity.

### VIII. PURIFICATION

$\beta$ -Amylase has been prepared in a crystalline form from a variety of plant sources including germinated barley (40), sweet potato (36), and soybean (52). Purification of  $\beta$ -amylase from various sources reported in the literature mostly involves multisteps of fractionation by acetone, ethanol, or (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, followed by cation/anion exchange chromatography and gel filtration. The following describes a three-step procedure of cereal  $\beta$ -amylase purification consisting of (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> fractionation, chromatofocusing, and hydroxyapatite adsorption chromatography (Table 1) (43).

Cereal grains were sterilized for 30 min with 1% NaOCl, germinated on water-saturated cotton wool in the dark at 20–30°C for 6 days, and homogenized in 100 mM Tris buffer, pH 8.1. The extract was centrifuged at 65,000g for 20 min, to yield ~200 mL supernatant from 40 g of germinated grains. The majority of the  $\beta$ -amylase as precipitated by (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> at 40–60% saturation was redissolved in 25 mM histidine-HCl buffer, pH 6.2, and dialyzed in the same buffer. The dialyzed sample was applied to a 35-mL Polybuffer Exchanger Gel column, and eluted with polybuffer PB 74 diluted 10 $\times$  with water, pH 4. Active fractions were pooled and dialyzed in 1 mM sodium phosphate buffer, pH 6.8, and applied onto a 4.5-mL hydroxyapatite column pre-equilibrated with the same buffer. Elution was performed using a linear gradient of sodium phosphate (1–50 mM) with a flow rate of 4 mL/h. Active fractions were pooled and the purity was analyzed by SDS-PAGE and isoelectric focusing.

**Table 1** Purification of  $\beta$ -Amylase from 40-g Germinating Maize Grains

Purification steps	Total protein (mg)	Total activity (EU <sup>a</sup> )	Specific activity (EU · mg <sup>-1</sup> )	Yield (%)
Crude extract	604	397	0.66	100
(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> precipitate	110	320	2.91	81
Chromatofocusing	ND <sup>b</sup>	192	—	48
Hydroxyapatite	0.38	105	276	26

Source: Ref. 43.

<sup>a</sup> EU = one enzyme unit corresponds to the release of 1  $\mu\text{mol} \cdot \text{min}^{-1}$  of *p*-nitrophenol at pH 6 at an incubation temperature of 30°C.

<sup>b</sup> ND = Not determined because of polybuffer interference.

Although not as frequently used as in the purification of  $\alpha$ -amylases, the use of affinity chromatography for  $\beta$ -amylases has been reported. Subbaramaiah and Sharma (53) described the affinity binding of plant  $\beta$ -amylases (mustard, barley, and sweet potato) to soluble starch (amylose) or native starch (potato starch grains) and a rapid elution of the enzyme by 1% (w/v) white dextrin. Hoshino et al. (54) used raw rice starch for the adsorption, hence the purification of *Bacillus*  $\beta$ -amylases. This procedure is made possible because microbial  $\beta$ -amylases contain a raw starch-binding site as revealed by their sequences and crystal structures. Saha et al. (55) purified the *Clostridium thermosulfurogenes*  $\beta$ -amylase taking advantage of the binding of the enzyme onto raw starch granules and its desorption by soluble starch. Raw starch adsorption/desorption also provides a useful technique for separating a mixture of  $\alpha$ - and  $\beta$ -amylases of plant origins. A number of investigations employed the competitive inhibitor  $\alpha$ -cyclodextrin as a possible ligand for the affinity purification of  $\beta$ -amylases (56–58). Using an  $\alpha$ -cyclodextrin Sepharose 6B column, Totsuka and Fukazawa (59) demonstrated the increase in the specific binding of soybean and barley  $\beta$ -amylases in the presence of 1 to 2 M  $(\text{NH}_4)_2\text{SO}_4$ , resulting in a 10-fold purification.

## Glucoamylase

**Peter J. Reilly**

*Iowa State University, Ames, Iowa, U.S.A.*

### I. INTRODUCTION

Glucoamylase [ $\alpha$ -(1,4)-D-glucan glucohydrolase, EC 3.2.1.3; GA], discovered in 1951 (1) and known industrially as amyloglucosidase, attacks from the nonreducing end of starch-derived substrates to produce glucose (2). Hydrolysis is by multichain attack, different substrate molecules being more or less equally susceptible to attack after each bond cleavage (3). Although GA's natural substrates are chains of glucosyl residues linked through  $\alpha$ -(1,4) glycosidic bonds, with branch points initiated by  $\alpha$ -(1,6) glycosidic bonds, its action is more general, as it catalyzes the hydrolysis of  $\alpha$ -(1,4),  $\alpha$ ,  $\beta$ -(1,1),  $\alpha$ -(1,6),  $\alpha$ -(1,3), and  $\alpha$ -(1,2) glycosidic bonds between adjacent glucosyl residues, in order of decreasing rate (4, 5). At higher glucose concentrations, GA reforms all the glycosidic bonds that it hydrolyzes, and therefore it condenses glucose to isomaltose (6-O- $\alpha$ -D-glucopyranosyl-D-glucose), isomaltotriose (6-O- $\alpha$ -D-isomaltosyl-D-glucose), kojibiose (2-O- $\alpha$ -D-glucopyranosyl-D-glucose), nigerose (3-O- $\alpha$ -D-glucopyranosyl-D-glucose), maltose (4-O- $\alpha$ -D-glucopyranosyl-D-glucose),  $\alpha$ ,  $\beta$ -trehalose ( $\alpha$ -D-glucopyranosyl  $\beta$ -D-glucopyranoside), panose (4-O- $\alpha$ -D-isomaltosyl-D-glucose), and isomaltotetraose (6-O- $\alpha$ -D-isomaltotriosyl-D-glucose) in order of decreasing equilibrium concentration (6, 7). GA catalyzes the following reactions starting with higher concentrations of starch and related substances:

GA also can produce disaccharides of glucosyl residues linked to reducing-end arabinosyl, fructosyl, galactosyl, *myo*-inositol, lyxosyl, mannosyl, ribosyl, or xylosyl residues, as well as galactosyl-galactose, galactosyl-glucose, and mannosyl-glucose disaccharides (8). Although it was thought for many years that these so-called reversion reactions were catalyzed by glucosyltransferase impurities in GA preparations, it is now quite clear that GA itself is responsible for them (7, 8).

### II. GLUCOAMYLASE IN FOODS

GA is produced by some eubacteria, a few archaea, a number of yeasts, and many filamentous fungi. Although there are reports of animal and plant GAs, these appear to be fundamentally different enzymes with kinetic properties that overlap those of true GAs. GA is therefore not a significant factor in most unprocessed foods.

GA plays a major role in food processing. In Asia, filamentous fungi from *Aspergillus* and *Rhizopus* and filamentous yeast such as *Saccharomyces fibuligera* that secrete GA are used to saccharify steamed rice and potato, uncooked ground grains, and amylopectin-rich

rice. In addition, black koji molds from *Aspergillus* species are employed in Japan to make many traditional foods and beverages, such as soy sauce, sake, and sochu (9).

The greatest use of purified GA has been to make glucose syrups from maltodextrins produced by  $\alpha$ -amylase from purified starch. Originally *Rhizopus delemar* (now *R. oryzae*) and *R. niveus* GAs did this in Japan, but since the identical GAs from *Aspergillus awamori* and *A. niger* are more thermostable and have a wider optimal pH range, they are now used almost universally for starch saccharification. Because glucose not only is used in syrup and crystalline form in foods but also serves as a raw material for high-fructose syrups, light beer, and pure fructose, as well as for fuel ethanol, GA is one of the largest-tonnage enzymes in present use.

The standard industrial saccharification process using GA starts with dextrin of DE 10-15, with DE standing for dextrose equivalent, where DE 0 is a dextrin of zero reducing power and therefore theoretically composed of infinitely long chains, and DE 100 is glucose (dextrose in industrial usage). A DE 10 dextrin has 10% the reducing power of glucose and therefore has an average chain length of 10 glucosyl residues. A lower initial DE risks retrogradation, a pseudo-crystallization of long malto-oligosaccharide chains. On the other hand, a high initial DE leads to a lower final DE and glucose yield after GA hydrolysis, because the extended  $\alpha$ -amylase hydrolysis at pH 6–6.5 and 90–105°C required to produce high-DE starting material allows more of the glucosyl residues at the reducing ends of the malto-oligosaccharide molecules to be converted to fructosyl residues by alkaline catalysis (10).

The GA hydrolysis process is conducted batchwise in large tanks for 2 days or so at 55–60°C, a high enough temperature for microbial contamination to be insignificant but not so high that the enzyme is inactivated rapidly. The pH is 4.3–4.5, the optimal pH for GA activity and stability and, fortuitously, the pH where glucose and malto-oligosaccharides are most stable.

To reduce enzyme inactivation, microbial contamination, and the cost of boiling off large amounts of water so that the product can be economically shipped, all operations in the conversion of starch to sugars are carried out at high solids concentrations, characteristically 30–40% (w/v). This has the unwanted effect of allowing GA-catalyzed condensation reactions to proceed more rapidly and to a greater extent than at low concentrations. This occurs because the equilibrium constant of the condensation reaction

$$K_{\text{eq}} = \frac{[\text{Glc}_{n+1}]_{\text{eq}} [\text{H}_2\text{O}]_{\text{eq}}}{[\text{Glc}]_{\text{eq}} [\text{Glc}_n]_{\text{eq}}}$$

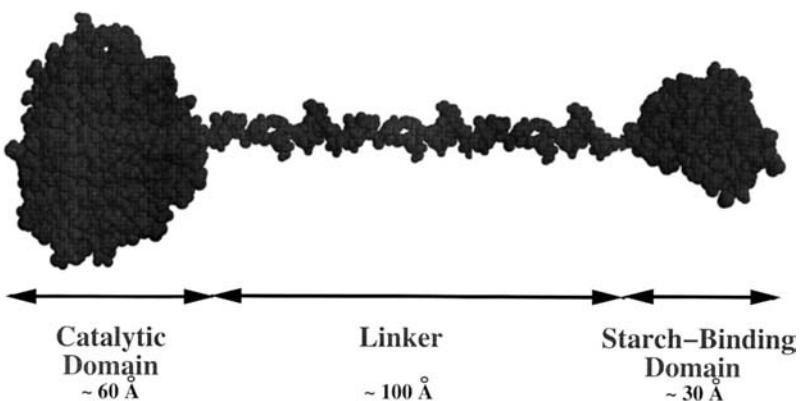

is pseudo-first order in product concentration, the water concentration being high and relatively constant during the reaction or even with substantial changes in initial reactant concentration, while the reactant concentrations are second order overall, being second order in glucose concentration if disaccharides are being produced, or first order each in glucose and oligosaccharide concentrations if higher-molecular-weight products are being formed. The reaction is stopped at peak glucose yield, when in 30% solids about 95–96% of the sugars are glucose. Glucose yield decreases thereafter because of continuing byproduct formation. It is possible to increase glucose yield slightly by adding pullulanase or isoamylase, debranching hydrolases active on  $\alpha$ -(1,6) glycosidic bonds between adjacent glucosyl residues, to the reaction mixture. These enzymes break the branch points remaining from the  $\alpha$ -amylase-catalyzed hydrolysis of amylopectin more rapidly than does GA. This allows the peak glucose yield to be reached earlier, before the byproducts have as much opportunity to be formed as when GA alone is present.

### III. PROTEIN PROPERTIES

#### A. General Properties and Isoforms

The most thoroughly studied GA, that from *A. awamori* and *A. niger*, is composed of three separate structures (11): catalytic and starch-binding domains and a rigid, highly glycosylated linker between them (Fig. 1). When produced industrially, it has two common forms, the complete 616-residue mature protein (GA I) and a proteolytically cleaved form with 512 residues (GA II), missing all but a few residues of the starch-binding domain but containing the whole catalytic domain and linker. GA II has little activity on raw starch (14) but has kinetics on smaller substrates identical to those of GA I (5). A third form of 470 residues, also formed by proteolysis (15), was the one whose crystals were used to obtain the first three-dimensional structure of the GA catalytic domain (12). Crystals of GA I and GA II have never been obtained.

When expressed by yeast, the *A. awamori/A. niger* GA catalytic domain has a molecular weight by matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy of 56.2 kDa, while those of GA II and GA I are 68.7 and 81.7 kDa, respectively

**Figure 1** Space-filling model of the *A. awamori* var. *X100* GA catalytic domain (12), the linker, and the *A. niger* GA starch-binding domain (13). A postulated structure of the *A. niger* GA linker based on scanning tunneling electro micrograph (11) is shown.

(16). These values can vary slightly because of different degrees of *O*-glycosylation produced under different culture conditions. Isoelectric focusing also indicates multiple forms of GA I and GA II (17), presumably also caused by glycosylation differences. GAs from other organisms have widely varying molecular weights, depending on their primary structures and degrees of glycosylation, and more specifically on whether they possess linkers and starch-binding domains.

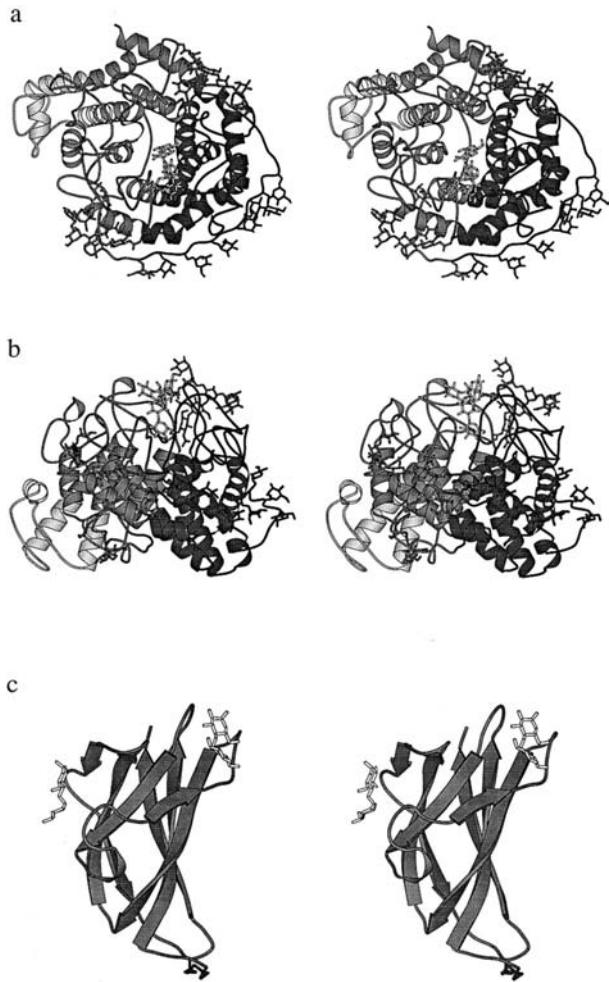

## B. Catalytic Domain

The crystal structure of the catalytic domain of GA from a strain of *A. awamori* var. *X100*, a slightly different strain from the *A. awamori/A. niger* form used industrially, was the first GA structure to be elucidated (12). The domain is an  $(\alpha, \alpha)_6$  barrel, with six interior  $\alpha$ -helices surrounded by six exterior  $\alpha$ -helices (Fig. 2), a structure found elsewhere among glycohydrolases only in *Clostridium thermocellum* endo-1,4- $\beta$ -glucanases A (22) and D (23) (CelA and CelD, respectively) and in *Thermomonospora* endo/exo-cellulase E4 (24). There are 13 helices in all, with helix 11, counting from the N-terminus of the domain, peripheral to the rest. The helices form a bed supporting a network of loops, in the center of which is found the active site. This is a well  $\sim 10$  Å deep and  $\sim 15$  Å wide at its mouth, a very primitive structure ensuring that the enzyme will have a low turnover number, since the substrate chain must penetrate the well deeply and undergo cleavage, followed by the remaining chain and then the liberated glucose molecule leaving the well before the next reaction can

occur. To overcome this handicap, many filamentous fungi have evolved the ability to produce very large amounts of extracellular GA. The placement of the active site in a well explains both the exo-acting nature of GA and its multichain attack pattern.

*A. niger* and *A. awamori* GAs were the first GAs sequenced, in 1983 and 1984, respectively (25, 26). Of the 21 archaeal, eubacterial, yeast, and filamentous fungal GAs whose full catalytic domain primary structures are known at present, computational analysis shows that all except those from *Schwanniomyces occidentalis* and *Schizosaccharomyces pombe* are substantially homologous, and have essentially the same secondary and tertiary structures as the *A. awamori* var. *X100* GA catalytic domain (18, 27, 28).  $\alpha$ -Helices 2 and 3 are shortened and fused in the GA from the filamentous fungus *Humicola grisea* var. *thermoidea*, and the peripheral  $\alpha$ -helix 11 is missing from the GAs from the eubacterium *Clostridium* var. *G0005* and the archaeon *Methanococcus jannaschii* (18). In addition, a number of loops vary in length in different GA catalytic domains.

GA is a member of family 15 of glycosyl hydrolases (29–32), the families being classified by primary sequence homology. Although nearly all the members of this family are GAs, a glucodextranase (EC 3.2.1.70) from *Arthrobacter globiformis* is also present (32). Of the other three glycosidases with  $(\alpha, \alpha)_6$  barrel structures, *C. thermocellum* endoglucanases CelA and CelD are in families 8 and 9, respectively, and *T. fusca* endo/exocellulase E4 is in family 9, so their primary structures are not closely related to that of GA. However, they may well share a distant ancestor.

**Figure 2** Stereoscopic views (18) from the front (a) and side (b) of the *A. awamori* var. *X100* GA catalytic domain and of the *A. niger* starch-binding domain (c) visualized by Molscript (19). Panels (a) and (b) show D-gluco-dihydroacarbose (20) in the active site (center and upper center, respectively). Increasing hydrophobicities of different folding units are denoted by increasingly dark shading. Panel (c) shows maltose in each of the two surface binding sites of the starch-binding domain (13), as found in a highly homologous cyclodextrin glucosyltransferase (21). (From Ref. 18.)

GAs from filamentous fungi other than *R. oryzae* have a highly *O*-glycosylated belt of ~30 amino acid residues. It extends from about residue 436 to about residue 467 (*A. awamori/A. niger* GA numbering), although it is shorter in *Corticium rolfsii* GA, and it appears to protect one side of the catalytic domain from proteolytic attack (18). When portions of this belt are deleted by site-directed mutagenesis, *A. awamori* GA thermostability and secretion from yeast are

strongly decreased (33, 34). In addition to ~10 *O*-glycosylated Ser and Thr residues in the belt, many GAs have two *N*-glycosylated residues, Asn171 and Asn395 in *A. awamori/A. niger* GA numbering (12, 25), with *N*-acetylglucosamine residues attached in five- and eight-residue chains, respectively (35). Elimination of the latter chain by mutation of Asn395 greatly reduces enzyme secretion and thermostability (36). GAs from *Neurospora crassa*, *Hormictonis resinae* P, *R. oryzae*, and two forms of *S. fibuligera* appear to have another *N*-glycosylated chain attached to Asn72 (18).

GAs from most filamentous fungi except *R. oryzae* have catalytic domains with three disulfide bridges—Cys210–213, Cys262–270, and Cys222–449 (28). The last serves to anchor the *N*-terminal end of the belt to the rest of the catalytic domain. The GAs from *C. rolfsii* and *N. crassa* have an additional Cys20–27 bridge (18).

### C. O-Glycosylated Linker

In GAs from filamentous fungi except *R. oryzae*, the *O*-glycosylated belt continues into an *O*-glycosylated linker between the catalytic domain and a starch-binding domain, longer in most *Aspergillus* GAs than in other fungi (18). In its longest form, ~40 residues to about residue 508 (*A. awamori/A. niger* GA numbering), it extends ~95 Å, as measured by scanning tunneling electron microscopy (11). Deletions of residues in this linker also decrease *A. awamori* GA secretion from yeast (34). *O*-Glycosylation of both the belt and the linker occurs on Ser and Thr residues, and in GAs secreted by *A. awamori* or *A. niger* this is composed of mannosyl residues either singly or in very short chains (37). It appears that glycosylation stiffens the linker (38, 39) and that longer linkers allow the catalytic domain in nature to attack a larger area of a starch granule while tethered to its surface by the starch-binding domain.

### D. Starch-Binding Domain

Filamentous fungi except *R. oryzae* have GAs with starch-binding domains of ~108 residues, extending to the end of the enzyme at residue 616. *O*-Glycosylation extends into the first few residues of this domain, and a disulfide bridge is found between Cys509 and Cys604 in all starch-binding domains except that from *C. rolfsii* (18). A three-dimensional structure of the *A. niger* starch-binding domain has been elucidated (13) (Fig. 2); both its sequence and structure, with its eight  $\beta$ -strands, are highly homolo-

gous with *Bacillus circulans* cyclodextrin glucosyltransferase (21, 40).

The *A. awamori/A. niger* GA starch-binding domain has two binding sites for starch and related substances such as maltose (Fig. 2). Its binding characteristics have been most completely determined by Dalmia and Nikolov (41).

In *R. oryzae* GA, a glycosylated linker and starch-binding domain are found to the *N*-terminal side of the catalytic domain (28). The yeast *Arxula adeninivorans* has a GA with an *N*-terminal region somewhat homologous to that of *R. oryzae*, but the enzyme cannot degrade raw starch (42). The GAs from the yeasts *S. fibuligera*, *Saccharomyces cerevisiae*, and *S. diastaticus*, the archaeon *M. jannaschii*, and the eubacterium *Clostridium* var. *G0005* also continue beyond the *N*-termini of GAs from most filamentous fungi (18). The functions of these regions are unknown except in the *Clostridium* GA, where it links the catalytic domain to the cell wall (43, 44).

### E. Evolution and Phylogenetic Tree

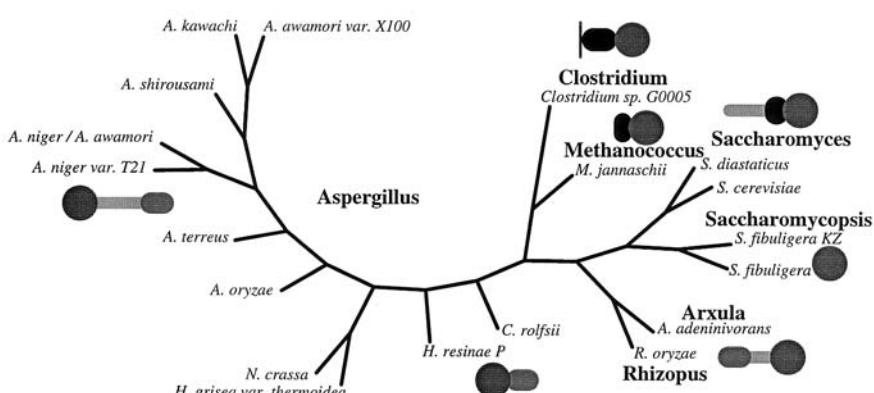

Seven subfamilies of GAs can be delineated through parsimony analysis (Fig. 3) (18). All members of each subfamily are closely related to each other by sequence homology. The *Aspergillus* subfamily has the most members, containing all the *Aspergillus* GAs along with single representatives from *N. crassa*, *H. grisea* var. *thermoidea*, *H. resinae P*, and *C. rolfsii*. The secondary and tertiary structures of these GAs are very similar, with the linker becoming progressively shorter in the order listed. The *Rhizopus* and *Arxula* subfami-

lies each have a single member. They appear somewhat closely related, even though *Rhizopus* is a basidiomycete and *Arxula* is an ascomycete. The *Saccharomycopsis* and *Saccharomyces* subfamilies, each with two representatives, are fairly homologous with each other. Finally, the *Clostridium* and *Methanococcus* subfamilies, the only ones with nonfungal members, are more closely related to each other than to any other subfamily. It does appear that GA has an ancient eubacterial origin, not only because it is found among eubacteria, archaea, and fungi, but also because it possesses a rare tertiary structure, an  $(\alpha, \alpha)_6$  barrel otherwise found at present among glycosyl hydrolases only in *C. thermocellum* and *T. fusca*, both eubacteria.

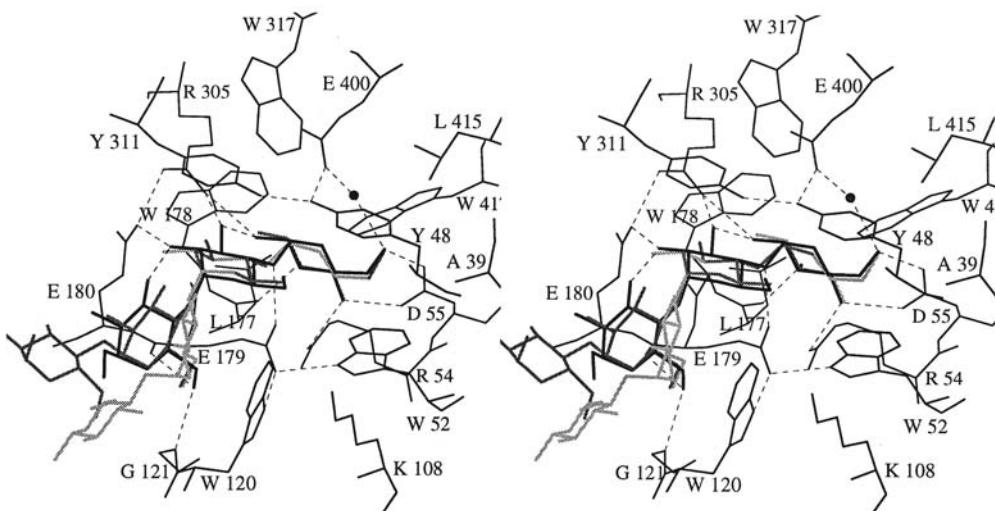

## IV. ENZYME PROPERTIES

### A. Enzyme Mechanism

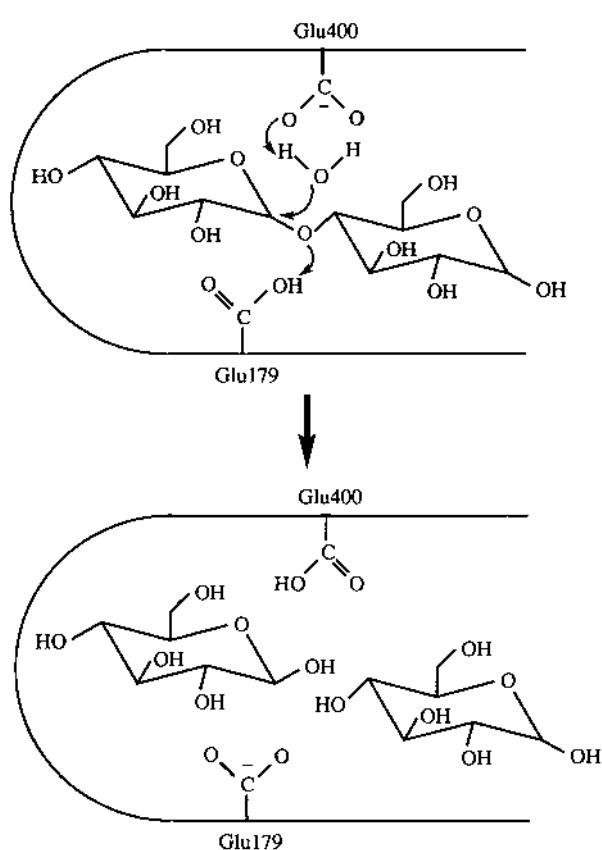

As mentioned above, the GA active site is a well, ensuring both multichain attack and exo-action. Two residues, Glu179 (45) and Glu400 (46), are the catalytic general acid and general base, respectively, and are  $\sim 10 \text{ \AA}$  apart (Fig. 4). Hydrolysis is by single-displacement mechanism, with a proton being donated to the oxygen atom of the glycosidic bond by the acid, while the hydrolytic water is coordinated by the base, which accepts the proton (48) (Fig. 5). Inversion of configuration occurs, a non-reducing-end  $\alpha$ -glycosidic bond being cleaved to yield  $\beta$ -glucose (6). The limiting step appears to be the release of the remaining substrate chain from the active site (49).

**Figure 3** Phylogenetic tree (18) showing the seven subfamilies of GAs from eubacteria (*Clostridium*), archaea (*Methanococcus*), yeast (*Saccharomyces*, *Saccharomycopsis*, and *Arxula*), and filamentous fungi (*Rhizopus* and *Aspergillus*). Dark circles: catalytic domains; medium-light ovals: starch-binding domains; light rods: *O*-glycosylated regions or linkers; black ovals: other domains; vertical bar: cell wall. (From Ref. 18.)

**Figure 4** Stereoscopic view (47) of the crystal structure of *A. awamori* var. X100 GA with D-gluco-dihydroacarbose (20) (dark gray: more abundant conformer at pH 4.0; light gray: less abundant conformer at pH 4.0) and the automated docking structure of methyl  $\alpha$ -maltotrioside (black). Also shown is the catalytic water (filled circle). The scissile glycosidic bond is immediately to the left of the rightmost glucosidic residue. (From Ref. 47.)

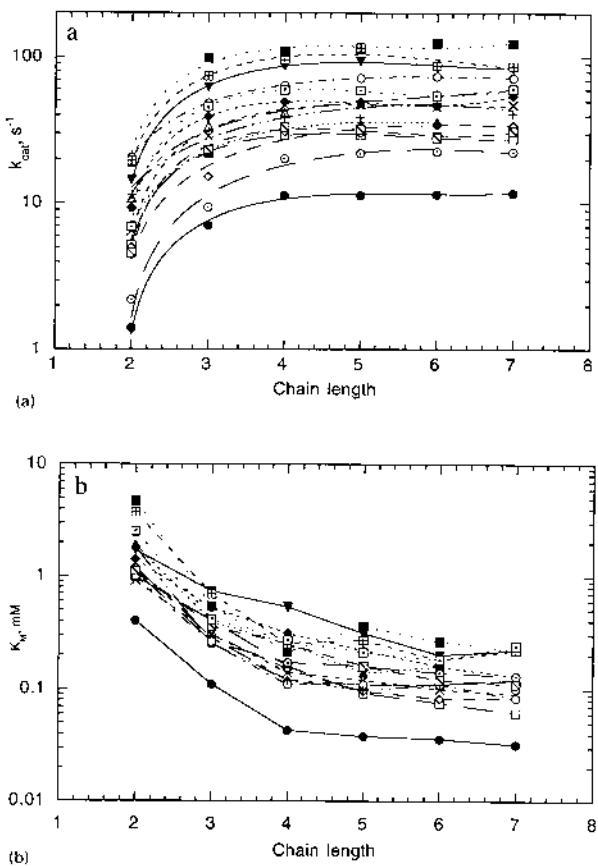

**Figure 5** Schematic of GA mechanism.

All but one of the many GAs that have been subjected to subsite mapping with various substrates appear to have six or seven subsites, with the first, binding the nonreducing glucosyl residue of the substrate, having a small negative or positive binding free energy, and the five or six subsites to the other side of the cleavage point having progressively smaller but always negative binding free energies (17, 50–64). This causes substrates with more glucosyl residues to be bound more firmly and cleaved at higher rates than those with fewer residues. With all substrates and all but one GA, values of  $K_M$  decrease essentially monotonically with increasing substrate chain length, while values of  $k_{cat}$  increase until reaching a maximum at substrates with four or five glucosyl residues (Figs. 6, 7).

The reason for the uniformity of subsite structure with different GAs has now become clear, in that all have essentially the same tertiary structure, with specifically the same active-site structure and general acidic and basic catalytic residues (18). The one exception to this uniformity is the *Swanniomyces castelli* GA, which has different kinetics (65) and which is not homologous with the other GAs.

The number of substrate-binding subsites in GA, obtained by mathematical analysis of the kinetics of the hydrolysis of oligosaccharides of different lengths, does not agree with either the crystal structures of GA with various ligands or with simulated docking studies,

which show that only two subsites are within the active-site well, with a third subsite being near the enzyme surface and being composed of different amino acid residues depending on the pH (20, 4) (Fig. 4). Furthermore, standard subsite theory is based on the assumption that the limiting reaction is the cleavage of the glycosidic bond (66), while instead the limiting reaction appears to be the release of

cleaved substrate chain from the active site (49), as mentioned above.

## B. Effect of Environmental Factors

Many studies have shown GAs from *A. awamori*, *A. niger*, and other filamentous fungi to have optimal pHs for activity and thermostability near 4.5. The optimal pH for activity is halfway between the  $pK_a$  of the catalytic acid Glu179, 6.0 in the presence of maltose and 5.8 when it is absent, and that of the catalytic base Glu400, 2.4 in the presence of maltose and 2.7 when it is absent (67). Substrates of higher chain length have slightly higher optimal pHs (67).

Activation energies for GA-catalyzed hydrolysis of many di- and trisaccharides range from 60 to 80 kJ/mol (5). Those for GA thermoinactivation in buffer are  $\sim 310$  kJ/mol (36), so increasing the temperature leads to much higher rates of enzyme inactivation but only moderate increases in enzyme activities.

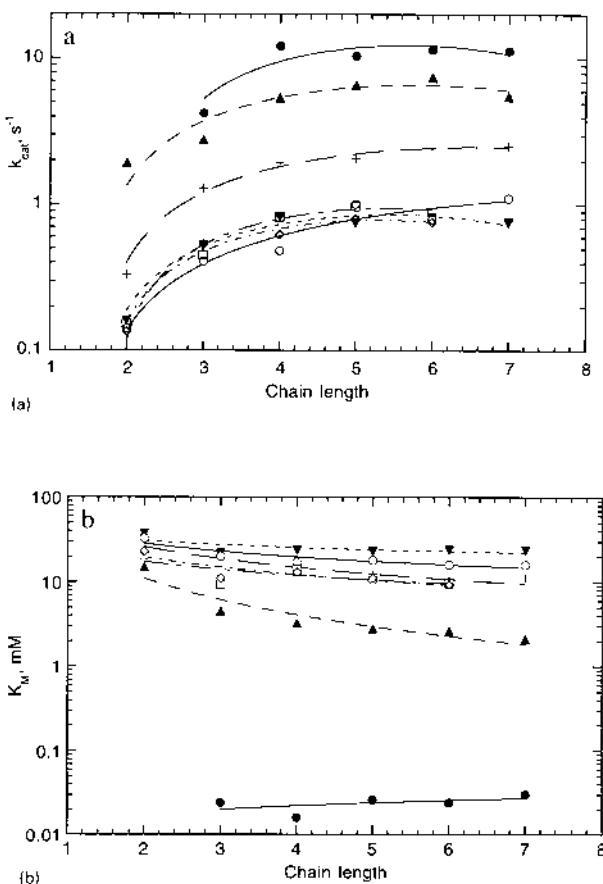

Increasing substrate and product concentrations strongly protect GA against inactivation, so that at 30% solids the optimal operating temperature of the *A. awamori/A. niger* form over 48 h is  $\sim 60^\circ\text{C}$ . With buffer rather than substrate or product, serious inactivation occurs within 30 min at  $60^\circ\text{C}$  and pH 4.5, since the first order thermoinactivation rate coefficient is  $\sim 10^{-4}\text{ sec}^{-1}$  under these conditions (36).

GA has no cofactors, nor is it stabilized by either cations or anions. It has a number of inhibitors, the most potent being the pseudo-tetrasaccharide acarbose and its various derivatives, that presumably mimic the transition-state form of the glucosyl residues about the glycosyl bond being cleaved.

## C. Kinetic Properties

An exhaustive listing of the kinetic properties of many different GAs with different substrates and inhibitors is found in the doctoral dissertation of P. M. Coutinho (68). The sheer bulk of the data set (48 pages of tables) suggests that noting many specific values here would be futile. Most data have been gathered at pHs between 4 and 5 and temperatures between 25°C and 50°C (Figs. 6, 7). Substrates range from maltose through maltodecaose to various types of starch and glycogen, but also include oligosaccharides with different glycosidic bonds. Most data are on GAs from various *Aspergillus* and *Rhizopus* spp. but there are some data from virtually every GA that has been sequenced.

To concentrate on the kinetics of *A. awamori/A. niger* GA at 45°C and pH 4.5 (68), average values of

**Figure 7** Kinetic parameters of different GAs as a function of chain length of isomalto-oligosaccharide substrates (except where noted). a: Values of  $k_{cat}$  ( $\text{sec}^{-1}$ ); b: Values of  $K_M$  (mM). Symbols: ——□——, *A. niger* G1, pH 4.5, 35°C (17); ——◇——, *A. niger* G2, pH 4.5, 35°C (17); ——▲——, *H. resinae* P, pH 4.3, 25°C (44); ——▼——, *H. resinae* S, pH 4.3, 25°C (55); —●—, p-nitrophenyl- $\alpha$ -D-malto-oligosaccharides, *A. niger* G2, pH 4.5, 25°C (57); ——+——, *A. awamori* wt, pH 4.5, 45°C (61); —○—, *R. niveus*, pH 4.5, 25°C (63). *H. resinae* S, pH 4.3, 25°C (55); —●—, p-nitrophenyl- $\alpha$ -D-malto-oligosaccharides, *A. niger* G2, pH 4.5, 25°C (57); ——+——, *A. awamori* wt, pH 4.5, 45°C (61); —○—, *R. niveus*, pH 4.5, 25°C (63).

$k_{cat}$  and  $K_M$  for maltoheptaose hydrolysis are  $60 \text{ sec}^{-1}$  and  $0.13 \text{ mM}$ , respectively, while for maltose hydrolysis they are  $10 \text{ sec}^{-1}$  and  $1.2 \text{ mM}$ , respectively. For the major byproduct isomaltose the equivalent values are  $0.37 \text{ sec}^{-1}$  and  $23 \text{ mM}$ , showing the large effect that decreasing substrate chain length and a change of glycosidic bond have in decreasing  $k_{cat}$  and increasing  $K_M$ . Fewer data are available for the primary product glucose, but it appears that  $K_i$  for GAs from filamentous

fungi is about  $\sim 100 \text{ mM}$  at pH 4.5 and a range of temperatures. Data are also rather sparse for GA kinetics on soluble starch, amylose, and amylopectin, with  $k_{cat}$  at pH 4.5 and extrapolated to 45°C being  $\sim 60 \text{ sec}^{-1}$ , the same value as for maltoheptaose. Values of  $K_M$  are too widely scattered for an average value to be reported, with most values being in weight percent, since substrate molecular weights were often not determined.

Among inhibitors, acarbose has a  $K_i$  of  $\sim 10^{-12} \text{ M}$  on *A. awamori/A. niger* GA at pH 4.5 and 27°C (68), while equivalent values for D-glucosidase, methyl  $\alpha$ -arcaviosinide, 1-deoxynojirimycin, and D-glucono-1,5-lactone are  $3 \times 10^{-8} \text{ M}$  (64),  $5 \times 10^{-8} \text{ M}$  (64),  $3 \times 10^{-5} \text{ M}$  (64), and  $1 \times 10^{-3} \text{ M}$  (68), respectively.

A general observation based on fewer kinetic and inhibition data is that values for GAs from other sources are not greatly different from those of *A. awamori/A. niger* GA, although there are a number of single values under different conditions, often at lower temperatures, that vary from the average values above.

Kinetic data for the GA-catalyzed condensation of glucose to di- and trisaccharides are available for *A. niger* GA at pHs 3.5, 4.5, and 5.5, at 25, 35, and 45°C, and at 20%, 30%, and 40% (w/v) initial glucose concentrations (7). Based on maltose formation as 100, the average initial rates of formation of  $\alpha$ ,  $\beta$ -trehalose, kojibiose, nigerose, and isomaltose across the different pHs, temperatures, and initial concentrations are 0.027, 0.010, 0.087, and 1.45, respectively, with relative rates for isomaltotriose increasing from 0.05 to 0.085 with increasing initial glucose concentrations because of their second-order dependence on solids concentration, and that of panose being too small to measure. Equilibrium constants, defined as above (Sec. I), average 0.082 for  $\alpha$ ,  $\beta$ -trehalose, 0.20 for kojibiose, 0.18 for nigerose, 0.091 for maltose, 2.2 for isomaltose, 3.3 for panose, and 2.3 for isomaltotriose; little change occurs with changes of initial glucose concentration, pH, or temperature. The last three values should be similar since  $\alpha$ -1,6 bonds are formed in each case.

## V. DETERMINATION OF GLUCOAMYLASE KINETIC PROPERTIES AND THERMOSTABILITY

GA activity is easy to determine, since the enzyme exclusively produces glucose, which can be detected with minimal interference using glucose oxidase (69,

70). Assays are conducted at pH 4.4–4.5 in 0.05 M sodium acetate buffer and at 50°C or below, where enzyme inactivation over short periods is minimal. Substrates are either 4% maltose or 2% soluble starch, both concentrations being well above their corresponding  $K_M$  values, which with *A. awamori/A. niger* GA are 1.2 mM (0.4%) for maltose, and 0.1% or less for soluble starch near pH 4.5 and 25–50°C (68). However, both values can vary when GAs from other sources or different conditions are used, so assay substrate concentrations should be modified with this in mind so that measured activities approach their maximal values. Six or more samples are taken at short time intervals to make substrate conversions sufficiently low that increase in glucose concentration is linear with time. Samples are added to pH 7 Tris at 1 M (final concentration) buffer to stop the hydrolysis reaction (14), and the quenched sample is treated with glucose oxidase, peroxidase, and one of several chromophores, the most common being *o*-dianisidine, found in different commercial kits.

If values of  $k_{cat}$  and  $K_M$  are to be determined, substrate concentrations covering at least the range from 0.2  $K_M$  to 5  $K_M$  should be used. Since GA follows Michaelis-Menten kinetics with all common pure substrates, at least six activity points should be plotted against their corresponding substrate concentrations and a hyperbolic function should be fitted through them with a nonlinear regression algorithm. This is far superior to use of various linearizing routines such as Lineweaver-Burk, Eadie-Hofstee, and Hanes plots, as the data are not distorted by algebraic manipulations.

GA thermostability in buffer without substrate can be measured by incubating samples at different temperatures or different pHs. At least six samples taken at different times are treated as above to obtain residual activities. Since GA loses activity by a first-order mechanism, the slope of a  $\ln$  (activity) vs. time curve gives the negative inactivation rate coefficient. Obtaining GA thermostability in substrate or glucose solutions is much more difficult, since glucose, the product being measured in the residual activity assay, is initially present. This problem can be ameliorated but not eliminated by using assay samples of very low residual activity and incubating for long periods.

## VI. PURIFICATION OF GLUCOAMYLASE

GA can be brought to homogeneity in several steps. Many filamentous fungi produce GA extracellularly

in high amounts, so in those cases no cell breakage is necessary unless the small amounts remaining inside the cell are to be studied. GA I and GA II can be separated from each other and from an acidic  $\alpha$ -amylase by a linear gradient from ~pH 8 to ~pH 3 by column chromatography with DEAE or another weak base on a suitable support (71, 72), the elution order being GA II,  $\alpha$ -amylase, and GA I. Meagher et al. (17) have completely described the purification of a sample containing both GA I and GA II by (a) precipitation of extraneous protein with  $(\text{NH}_4)_2\text{SO}_4$  at 80% of saturation; (b) desalting by passage through a Sephadex G-25 column; (c) separation of the two GA forms from each other and from other proteins by DEAE-cellulose chromatography using a citrate-phosphate buffer eluant whose pH decreases linearly from 7.9 to 3.6; (d) concentration by ultrafiltration; (e) desalting of each fraction with a Sephadex G-25 column; (f) rechromatography for each fraction with DEAE-cellulose; and (g) further desalting and concentration by ultrafiltration.

Protein in a 20-g sample of a commercial preparation decreased from 1.57 g to 1.19 g after step (a), to 1.02 g after step (b), to 313 mg and 217 mg in the GA I and GA II fractions, respectively, after step (c), and to 173 mg and 94 mg for the two fractions after step (f). GA specific activities increased from 7.9 U/mg for the starting material to 9.8 U/mg after the second step, to 9.8 U/mg and 12.3 U/mg for the GA I and GA II fractions, respectively, after the third step, and to 10.8 U/mg and 13.2 U/mg for the two fractions after the sixth step. One unit was the GA activity that liberated 1  $\mu\text{mol}/\text{min}$  glucose from 4% maltose at pH 4.5 and 35°C, while protein concentration was determined by UV spectroscopy using a previously measured molar extinction coefficient for GA (14).

Alternatively, complete purification of each GA form can be achieved after dialysis by acarbose-Sepharose chromatography eluted with 1.7 M Tris at pH 7.6 (73). This is especially efficient if wild-type GA containing only GA I is produced from yeast (54), but may also be used after the third step above if production is from *A. niger* or another filamentous fungus.

In some cases it is important to separately establish that seemingly homogeneous GA preparations are free of glucosyltransferase activity. This may be accomplished by measuring the conversion of panose in the presence of 0.1 g/L or more of acarbose, which completely inhibits GA but only slightly inhibits glucosyltransferase (17, 74).

## ACKNOWLEDGMENT

The author thanks Pedro Coutinho for his advice during the preparation of this manuscript and for producing Figures 1–4.

## Limit Dextrinase/Pullulanase

**E. Ann MacGregor**

*University of Manitoba, Winnipeg, Manitoba, Canada*

### I. INTRODUCTION

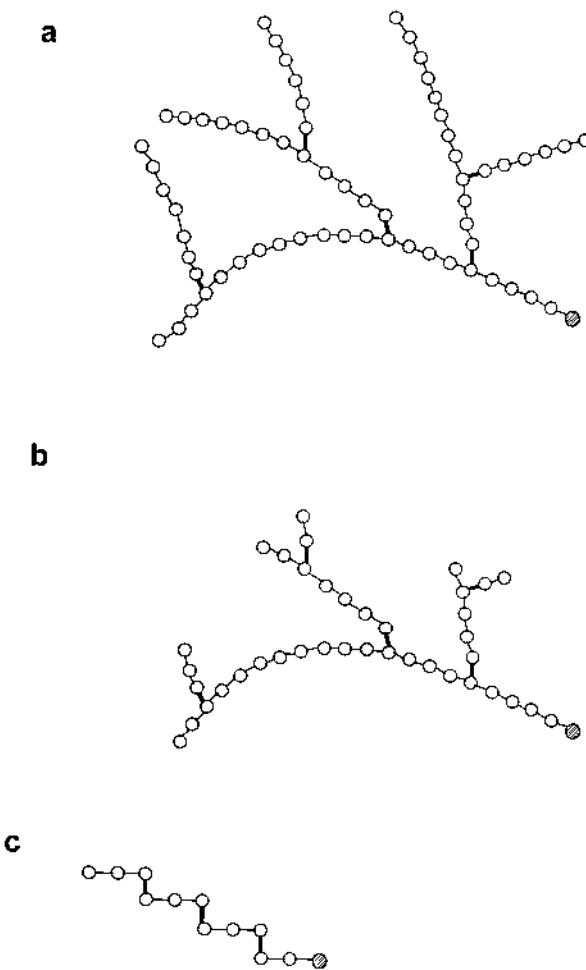

The enzymes known as pullulanase (EC 3.2.1.41) or limit dextrinase (EC 3.2.1.142) catalyze hydrolysis of  $\alpha$ -1,6-D-glucosidic linkages in pullulan, amylopectin, and the  $\alpha$ - and  $\beta$ -amylase limit dextrins of amylopectin and glycogen (Fig. 1), with limited or no action on glycogen. They are usually more active on oligosaccharide dextrins than on polysaccharide substrates—hence the systematic name  $\alpha$ -dextrin 6-glucanohydrolase. The names limit dextrinase and R-enzyme have both been applied to enzymes of plant origin; the former name is preferred since it is related to the natural substrate. In plants, the function of the enzyme is to help bring about complete degradation of starch to glucose and maltose by hydrolyzing the  $\alpha$ -1,6-glucosidic bonds of small branched dextrins resulting from the combined action of  $\alpha$ - and  $\beta$ -amylase on starch. The name pullulanase, in contrast, has been used for many years for microbial enzymes important for the breakdown of branched polysaccharides such as the amylopectin of starch. The EC recommended name is  $\alpha$ -dextrin endo-1-6- $\alpha$ -glucosidase, but it is little used.

Studies of the primary structures of limit dextrinases and pullulanases have shown appreciable sequence similarity between the plant and microbial enzymes, and it is now common to refer to plant pullulanases where the name limit dextrinase has been used in the past. There has been, however, a recommendation that “limit dextrinase” continue to be used for the plant enzymes to distinguish between these and the microbial

proteins, particularly since there are some specificity differences, with plant enzymes in general being less active on glycogen than the microbial pullulanases (1).

The minimum structural requirement for a branched oligosaccharide to be a substrate for pullulanase/limit dextrinase is a maltose residue on either side of the  $\alpha$ -1,6 linkage (Fig. 2); i.e., the enzymes cannot remove a 1,6-linked glucosyl stub from a chain of  $\alpha$ -1,4-linked glucose residues, or remove a 1,4-linked glucose chain attached to carbon 6 of a single glucose unit. The enzymes have high activity on  $6^3$ - $\alpha$ -maltosyl maltotetraose and  $6^3$ - $\alpha$ -maltotriosyl maltotetraose (2, 3) (Fig. 2).

The limited activity of pullulanase/limit dextrinase on glycogen distinguishes these enzymes from another important starch-debranching enzyme, isoamylase (EC 3.2.1.68), which brings about appreciable hydrolysis of  $\alpha$ -1,6-glucosidic bonds in glycogen but has little effect on pullulan. Furthermore pullulanase, hydrolyzing  $\alpha$ -1,6 links in pullulan to yield maltotriose, should not be confused with neopullulanase (EC 3.2.1.135) or isopullulanase (EC 3.2.1.57), which hydrolyze the  $\alpha$ -1,4-glucosidic bonds in pullulan to give panose or isopanose, respectively (Fig. 3). Enzymes known as amylopullulanases or  $\alpha$ -amylase-pullulanases can bring about hydrolysis of both  $\alpha$ -1,4 and  $\alpha$ -1,6 linkages in glucans, and therefore can be distinguished from true pullulanases, which hydrolyze  $\alpha$ -1,6-glucosidic bonds only. In some cases, however, an enzyme acting on pullulan is not always tested for activity on  $\alpha$ -1,4- and  $\alpha$ -1,6-glucosidic linkages, and confusion exists in the literature where several amylopullulanases are described as pull-

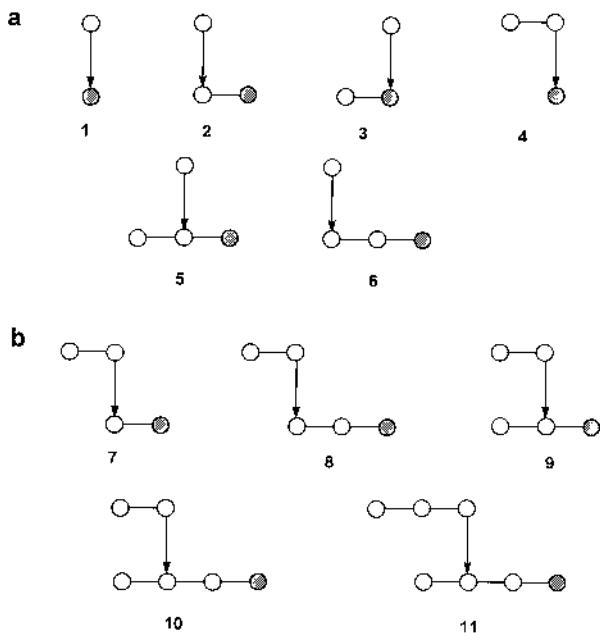

**Figure 1** (a) Representation of glycogen or amylopectin molecule. ○ = glucose residue; ● = reducing glucose residue; — =  $\alpha$ -1,4-glucosidic bond; ┃ =  $\alpha$ -1,6-glucosidic bond. In glycogen there is approximately one  $\alpha$ -1,6-linkage for every 12  $\alpha$ -1,4-linkages; in amylopectin the ratio is 1:25. (b)  $\beta$ -Limit dextrin of amylopectin or glycogen. Outer chains are trimmed to one to three glucose residues in length. (c) Pullulan.

ulanas (e.g., 4). In other cases, enzymes are described as type I or type II pullulanases. The type I enzymes are true pullulanases, specific for  $\alpha$ -1,6-glucosidic bonds, while type II pullulanases are, in fact, amylopullulanases (5).

## II. IMPORTANCE IN FOOD

Microbial pullulanases are used, as purified enzymes, in the production of glucose, fructose, and maltose syrups (see Sec. IV). The plant enzyme of greatest commercial

importance is the limit dextrinase of barley, which plays a role in the brewing and distilling industries (see Sec. IV). The enzyme is known to occur in mature barley kernels, and additional limit dextrinase is synthesized when barley seeds germinate. Much of the limit dextrinase activity of germinated barley is also found in brewers' malt, i.e., barley germinated under carefully controlled conditions and dried by kilning. During brewing, the enzyme, in theory, acts in conjunction with malt  $\alpha$ - and  $\beta$ -amylases to break down the starch from the malt itself and any added starch to glucose and maltose, prior to fermentation with yeast to produce alcohol. In practice, however, the dextrinase has very limited action, since a potent inhibitor of the enzyme (see Secs. VI and VII) also exists in malt (6).

## III. SOURCES OF PULLULANASE/LIMIT DEXTRINASE

True pullulanases have been found in, and prepared from, a variety of bacteria. The enzyme is synthesized

**a****b**

**Figure 3** (a) Hydrolysis of pullulan at 1 by neopullulanase; at 2 by pullulanase; at 3 by isopullulanase. (b) 1. Panose, product of neopullulanase action; 2. maltotriose, product of pullulanase action; 3. isopanose, product of isopullulanase action. Symbols are as in [Figure 1](#) with an arrow representing an  $\alpha$ -1,6-glucosidic bond.

intracellularly, then is usually secreted to give an extracellular pullulanase that can be purified from the supernatant of the culture.

Bacterial pullulanases that are to be used as purified enzymes in the production of glucose syrups must act in conjunction with a fungal glucoamylase, and so are used at 60°C and pH 4.5–5.0, conditions where the glucoamylase is most active (see Sec. IV). The most widely studied pullulanases, those from *Klebsiella pneumoniae*\* or related bacteria, lose activity at 60°C

\* There is confusion about the nomenclature of bacteria in which important pullulanases can be found. The first pullulanase, studied by Bender and Wallenfels (7), was said to have been prepared from *Aerobacter aerogenes*. This is now reclassified as *Klebsiella pneumoniae* (8). The bacterium *Klebsiella aerogenes*, frequently cited as a source of pullulanase, should also, more properly, be called *Klebsiella pneumoniae* (8). In 1982, however, a new species of *Klebsiella*, *K. planticola*, was distinguished from *K. pneumoniae* (8). Thus some pullulanases, prepared before 1982 and said to have originated from *K. pneumoniae*, may actually derive from *K. planticola*. Indeed the strain of “*Aerobacter aerogenes*” used by Bender and Wallenfels (7) for the original pullulanase preparation is now believed to be *K. planticola* (Culture No. 15050, American Type Culture Collection; Web site [www.atcc.org/](http://www.atcc.org/)).

(9). The enzymes from *Bacillus acidopolulyticus* and *B. deramificans* (10, 11) are efficient under the optimum conditions for glucoamylase, but are not heat stable at temperatures much above 60°C. Enzymes from thermophilic bacteria, with potentially greater heat stability, have been investigated, but most have been found to have high activity only at pH 6.0 or higher. A pullulanase from *Fervidobacterium pennavorans* is, however, very active in the pH range 4.5–5.0 and is stable at 70°C (12).

Amylopullulanases could be used in place of pullulanases if they are active under the conditions required for dextrin hydrolysis by glucoamylase; enzymes from *Clostridium thermohydrosulfuricum* and *Thermoanaerobium Tok6-B1* appear to have these properties (13, 14).

Limit dextrinases are known to occur in several plants, but only the enzyme of barley is of commercial importance. The enzyme is found in mature barley kernels, mainly in the endosperm (15), and additional limit dextrinase is synthesized in the aleurone cells during germination (16). The location of the enzyme within the seeds has been determined by dissection of the seeds and evaluation of enzyme levels within each tissue (15, 16).

#### IV. UTILIZATION OF ENZYMES IN FOODS

Before microbial pullulanases can be used in the preparation of glucose and maltose syrups, starch in a slurry must be gelatinized by heat treatment and liquefied using a heat-stable  $\alpha$ -amylase. In the liquefaction stage, the amylose and amylopectin are hydrolyzed to oligosaccharides of average chain length of 8–12 glucose units, if a glucose syrup is required, or slightly higher chain length for production of a maltose syrup (17, 18). These oligosaccharides are a mixture of linear dextrans containing  $\alpha$ -1,4-glucosidic linkages only, and branched dextrans containing all the  $\alpha$ -1,6-glucosidic bonds of the amylopectin, since such bonds are not hydrolyzed by  $\alpha$ -amylase. The second stage in glucose syrup production is saccharification, where single glucose residues are removed from the nonreducing ends of the dextrans by an exo-acting enzyme, a glucoamylase. This enzyme, however, acts slowly on  $\alpha$ -1,6 linkages and, when glucose concentrations become high, can catalyze a reverse reaction to give isomaltose. Addition of a bacterial pullulanase to hydrolyze  $\alpha$ -1,6-glucosidic bonds allows reaction times to be reduced, while higher substrate and lower glucoamylase concen-

trations can be used. This lowers isomaltose and increases glucose yields. Because the glucoamylase and pullulanase act simultaneously, the two enzymes must be compatible with respect to optimum pH and temperature. The saccharification reaction is usually carried out at 60°C and pH ~ 4.5 for maximum activity of the glucoamylase. Pullulanases active under these conditions can be obtained from *B. acidopullulyticus* (10, 17) and *B. deramificans* (11), and both are considered safe for food use (17, 19). If required, fructose syrup can subsequently be prepared from glucose syrup by isomerization with glucose isomerase.

For maltose syrups, the dextrins obtained by liquefaction of starch are treated simultaneously with  $\beta$ -amylase and pullulanase. The  $\beta$ -amylase produces maltose from the nonreducing ends of  $\alpha$ -1,4-linked glucose chains, but can neither hydrolyze nor bypass  $\alpha$ -1,6-glucosidic bonds. The pullulanase is therefore essential to convert branched dextrins in the liquefied starch mixture to linear dextrins to allow the  $\beta$ -amylase to have maximum effect (17, 20).

Although purified enzymes are usually added to the liquefied starch in a batch process, various studies have been carried out to investigate the feasibility of using immobilized pullulanase, or plant limit dextrinase, or pullulanase plus glucoamylase for hydrolysis (21–23).

Cyclodextrins can be used for flavor delivery in food, but limited solubility of the cyclodextrins can pose problems. Means of increasing the water solubility of cyclodextrins have been studied, and for this purpose glucosyl or maltosyl cyclodextrins have been prepared, where the glucose or maltose is attached by an  $\alpha$ -1,6 linkage to a glucose residue of the cyclodextrin ring. Here the reversibility of the hydrolysis reaction catalyzed by pullulanase has been employed, where the enzyme synthesizes rather than ruptures  $\alpha$ -1,6 bonds (24, 25). Such products may, in the future, acquire some commercial importance.

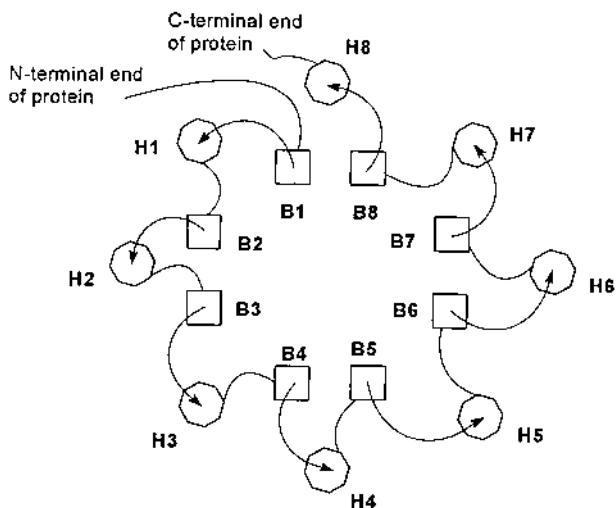

In the process of brewing beer, barley malt starch is gelatinized in warm water, and precooked adjunct starch, often from corn, may be added. The starches are broken down by the hydrolytic enzymes of the malt, principally  $\alpha$ - and  $\beta$ -amylase, to glucose and maltose plus smaller quantities of longer  $\alpha$ -1,4-linked linear maltodextrins and branched dextrins containing the  $\alpha$ -1,6 bonds of the amylopectin of the original starches, since neither  $\alpha$ - nor  $\beta$ -amylase attacks these latter bonds. In principle, the limit dextrinase of the malt is able to hydrolyze the  $\alpha$ -1,6-glucosidic linkages of the branched dextrins, but the presence of a proteinaceous inhibitor (see Secs. VI and VII) in the malt limits the efficacy of the enzyme (6). Thus

glucose, maltose, and linear and small branched dextrins are usually present in wort (aqueous extract of malt) before yeast is added, and since the yeast is able to utilize only glucose, maltose, and maltotriose for alcohol production, the larger dextrins appear in a traditional beer (26, 27). Lowering the inhibitor level, or raising limit dextrinase activity, would allow for greater breakdown of branched dextrins and greater fermentability of a wort, essential for the production of low-carbohydrate beers, but also of economic importance to the distilling industry (6, 28). Alternatively, an extraneous pullulanase or limit dextrinase could be added to increase hydrolysis of branched oligosaccharides (29).

## V. PROTEIN PROPERTIES

The molecular weight of pullulanase/limit dextrinase varies with the source of the enzyme, and discrepancies exist in the value quoted for one pullulanase, particularly the *Klebsiella* pullulanases, depending on the method used for molecular-weight determination. Calculations from amino acid sequence for the pullulanases of *B. acidopullulyticus* and *B. deramificans* suggest the molecular weights should be ~ 100,000 daltons, while experimental determinations gave values of 116,000 and 102,000, respectively (10, 11). A molecular weight of 105,000 was found experimentally for barley limit dextrinase (30), while predictions from the sequence would lead to a value ~ 97,000 (31, 32).

Polysaccharide-hydrolyzing enzymes have been classified into families, based on amino acid sequence similarities (33). It is now thought that the enzymes of one family share a common tertiary structure. The primary structures of several pullulanases/limit dextrinases are now known, including those of *B. acidopullulyticus*, *B. deramificans*, and *barley* (11, 31, 32, 34), and the enzymes are believed to belong to family 13 of the carbohydrases, which includes many other starch-degrading enzymes such as  $\alpha$ -amylase and isoamylase (35). While the three-dimensional structure of a pullulanase/limit dextrinase molecule has not been determined, it is expected to be similar to those of other family 13 enzymes for which x-ray crystallographic studies have been carried out (see, e.g., 36). The family 13 enzymes are, in general, multidomain proteins, and in pullulanase/limit dextrinase, as in isoamylase, an N-terminal domain precedes the catalytic domain. The catalytic domain itself is likely to take the form of a  $(\beta/\alpha)_8$ -barrel, i.e., a barrel of eight parallel  $\beta$ -strands, usually with at least one helix located in the primary sequence between

**Figure 4** Secondary structure of catalytic domain of a family 13 enzyme. B1–B8 represent parallel  $\beta$ -strands; H1–H8 represent helices of the  $(\beta/\alpha)_8$ -barrel. Arrows joining a  $\beta$ -strand to the following helix represent loops in the enzyme structure on which are situated amino acid residues of the active site.

each pair of adjacent  $\beta$ -strands (Fig. 4) (37). In general, the active site of family 13 enzymes is made up of amino acid residues situated on loops linking the C-terminal end of a  $\beta$ -strand to the N-terminal end of the adjacent helix (36) (Fig. 4). Amino acids on  $\beta$ -strands 3, 4, 5, and 7, or on loops immediately following these strands, are found at the active site in all family 13 enzymes. The presence and location of active-site acids on other loops vary from one enzyme to another. An obvious characteristic of this family is a long loop between the third  $\beta$ -strand of the barrel and the third helix, amino acid residues on this loop making up much of one side of the active site. In the known three-dimensional structures of family 13 enzymes, at least one domain containing a  $\beta$ -sheet structure follows the catalytic domain, and is also likely to be found in pullulanases/limit dextrinases.

There is limited sequence homology among family 13 enzymes, but all have four well-conserved short sequence segments around  $\beta$ -strands 3, 4, 5, and 7 of the barrel that contain amino acid residues thought to be critically important for the catalytic action of the enzymes (Fig. 5) (38).

The amylopullulanases tend to have larger molecules than pullulanases, with polypeptide chains of up to 1500 amino acids (39), while true pullulanases usually have 700–1100 amino acid residues. Hence the molecular weights of amylopullulanases are expected to be higher than those of pullulanases, in general

> 140,000 daltons. These enzymes, however, also belonging to family 13, are predicted to have the characteristic  $(\beta/\alpha)_8$ -barrel catalytic domain, and contain the four conserved sequence segments typical of the family (Fig. 5) (35, 37, 38).

Phylogenetic trees have been constructed for family 13 enzymes in general and starch-debranching enzymes in particular (31, 35, 38). These show that the plant limit dextrinases are closely related to one another, with the bacterial pullulanases being nearest neighbors, and isoamylases next closest in a tree of the whole family. Amylopullulanases, in contrast, are much more distantly related, and are closer to neopullulanases than pullulanases.

In neither bacteria nor plants is there evidence for more than a single gene for pullulanase/limit dextrinase in each organism. Multiple forms of an enzyme can exist, however, but these have not been well characterized. *Klebsiella* pullulanases are believed to be modified by attachment of lipid at the N-terminal end (40), while the differences between two apparent forms of *B. acidopullulyticus* pullulanase have not been explained (10). Several forms of barley limit dextrinase, separated by electrophoresis and detected using antibodies (15), possibly arise because of the presence of free limit dextrinase and limit dextrinase bound to a proteinaceous inhibitor (41). In another study, three forms of purified barley limit dextrinase have been found, but the differences among them have not been elucidated (42), although they are believed to be products of a single gene (31, 32).

## VI. ENZYME PROPERTIES

While pullulanase/limit dextrinase can degrade pullulan, the importance of these enzymes for food and beverages lies in their ability to hydrolyze the  $\alpha$ -1,6-glucosidic bonds of amylopectin and branched dextrans resulting from amylopectin breakdown. It is difficult to measure quantitatively the increase in reducing power produced by limited pullulanase action on amylopectin. It is also difficult to obtain a “standard” sample of amylopectin, or a pure, small, branched dextrin to be used as substrate. Thus, absolute values of pullulanase activity are rarely determined, and it is difficult to compare results from different laboratories, since different samples of pullulan or amylopectin may have been used. It is generally agreed, however, that pullulanase/limit dextrinase is more active on small branched dextrans than on pullulan or amylopectin (Table 1).

**Figure 5** Four short sequence segments conserved in all members of family 13 carbohydrases. Taka:  $\alpha$ -amylase from *Aspergillus oryzae*, Genbank sequence No. D00434; Kleb: pullulanase from *Klebsiella pneumoniae*, Genbank sequence No. M16187; Bacid: pullulanase from *Bacillus acidopullulyticus*, sequence from (34); Bderam: pullulanase from *B. deramificans*, sequence from (11); BLD: barley limit dextrinase, sequence from (31); Amypull: amylopullulanase from *Clostridium thermohydrosulfuricum*, sequence from (39); Isoamy: isoamylase from *Pseudomonas amyloferamosa*, Genbank sequence No. A10909. Amino acid residues are numbered from the N-terminal end of the protein. \* Indicates residues conserved in all enzymes shown. The three residues involved in catalysis are shown in bold lettering; D in sequence segment II, E in segment III, and D in segment IV.

Values of  $K_m$  for pullulan for *Klebsiella* pullulanase are given as 2.5 mM (10), 78  $\mu$ M, or 21  $\mu$ M (43) in glucose equivalents, and 70  $\mu$ M (44) in terms of concentration of hydrolyzable  $\alpha$ -1,6-glucosidic bonds. For the *B. acidopullulyticus* enzyme,  $K_m$  for pullulan is said to be 2.5 mM glucose equivalents (10), while barley limit dextrinase has a  $K_m$  for amylopectin of 26 mM glucose equivalents (3).

The turnover number ( $k_{cat}$ ) for *Klebsiella* pullulanase has been measured as 99 sec $^{-1}$  or 220 sec $^{-1}$  at 30°C (43), 53 sec $^{-1}$  at 25°C, 132 sec $^{-1}$  at 40°C (44), and 290 sec $^{-1}$  at 60°C, while measured values for the *B. acidopullulyticus* enzyme are  $2.9 \times 10^3$  or  $3.6 \times 10^3$  sec $^{-1}$  at 60°C, all on pullulan (10). For barley limit dextrinase acting on a well-defined dextrin, 6<sup>2</sup>-0- $\alpha$ -maltotriosyl maltotriose, at 40°C, the number is 90 sec $^{-1}$  (42).

The response to pH and temperature varies with the enzyme source. *Klebsiella* pullulanase is most

active between pH 5.5 and 7, and is stable in the pH range 5–12 (9); the *B. acidopullulyticus* and *B. deramificans* enzymes have maximum activity at pH 4–6 and pH 3.75–4.9, respectively, and are stable at pH 4–9 (10) and 3.5–6 (11), respectively. The limit dextrinase of barley, on the other hand, has optimum activity at pH 5.5–6.5 in the presence of bovine serum albumin, which seems to stabilize the active enzyme (30).

Temperature optima for *Klebsiella* and *B. acidopullulyticus* pullulanases are 50°C and 65°C, respectively, and both enzymes are stable at temperatures up to 55°C at pH 5 (9, 10). The enzyme from *B. deramificans* is said to retain 75% of its activity when held at 60°C for 24 h at pH 4.5, and has optimum activity at 60°C (11). The barley limit dextrinase shows maximum activity at 40–50°C (45, 46) and is stable under the mashing conditions in a brewery for at least 1 h at 60°C, but loses activity rapidly at 65°C (47).

**Table 1** Relative Activity of Pullulanase/Limit Dextrinase on Different Substrates

Source of enzyme	<i>K. pneumoniae</i> (2)	<i>B. acidopullulyticus</i> (10)	Barley (3)
Activity <sup>a</sup> on 6 <sup>3</sup> - $\alpha$ -maltotriosyl maltotetraose	146	—	250
Activity <sup>a</sup> on amylopectin	15	15–16	13

<sup>a</sup> Activity on pullulan taken as 100.

Activation energies,  $E_a$ , can be calculated from published data on the variation of activity with temperature, and are shown in **Table 2**.

Several enzymes of family 13 are known to require  $\text{Ca}^{2+}$  for activity, but although a *Klebsiella* pullulanase was found to be activated by  $\text{Ca}^{2+}$  (48), little effect was found for barley limit dextrinase (42). EDTA gave some inhibition of both *Klebsiella* and barley enzymes (42, 48). Cyclodextrins are known to be strong inhibitors of pullulanase/limit dextrinase, with  $\beta$ -cyclodextrin being the most effective.  $K_i$  for this dextrin is around 1  $\mu\text{M}$  at 25°C for a *Klebsiella* pullulanase (44) and 40  $\mu\text{M}$  at 40°C for barley limit dextrinase (42).

No investigations of subsite structure of pullulanase/limit dextrinase have been carried out because of the difficulties of obtaining well-defined substrates. In common with other family 13 enzymes, however, these enzymes would be expected to have several subsites for glucose binding at the active site. In general, family 13 enzymes are believed to operate by a mechanism involving retention of anomeric configuration. This has been demonstrated experimentally for a bacterial pullulanase (49) and barley limit dextrinase (42). Two acid groups at the active site, one to act as proton donor and the other as catalytic nucleophile, are expected to be found in family 13 enzymes. In fact, three acid groups (**Fig. 5**) are found to be essential for enzymic activity; the conserved glutamic acid is thought to be the proton donor, while the conserved aspartic acid in sequence segment II acts as the nucleophile. The role of the second aspartic acid residue in sequence segment IV is not clear.

In barley, germinated barley, and malt, a proteinaceous inhibitor of barley limit dextrinase has been found. The inhibitor levels decrease at later stages of germination (6), and it therefore appears likely that the uninhibited limit dextrinase can then continue the degradation of barley starch begun by the  $\alpha$ - and  $\beta$ -amylases of the grain. The resulting small linear maltooligosans can be further hydrolyzed by  $\alpha$ -glucosidases to provide glucose for the growth of a new barley plant. Under the conditions used for brewing beer, this inhibitor severely restricts the action of limit dex-

trinase, since germination for malt production is stopped before inhibitor disappears (6).

## VII. DETERMINATION OF ACTIVITY

Well-defined substrates for pullulanase/limit dextrinase, particularly small branched dextrans, are not readily available, and so activity is usually determined on pullulan or a commercially available modified pullulan.

There seems to be no generally accepted standard procedure for measurement of activity on pullulan. Temperature and pH conditions are usually chosen to suit the particular enzyme under study. Pullulan concentration is usually in the range 2.5–5 mg/mL in buffer, often acetate of concentration 20–100 mM and a pH in the range 5.0–5.6 (10, 44, 50). Enzyme is added to the pullulan and after a set time a sample is withdrawn and may be added to 0.1 M NaOH to stop the reaction, and reducing power in the sample is determined by the Nelson-Sömogyi method (51). Calculation of activity depends on the assumption that pullulanase/limit dextrinase converts pullulan mainly to maltotriose (**Fig. 3**) and that measurement of reducing power gives an indication of the amount of maltotriose present. If the pullulanase is not pure, however, and contains a glucosidase, then reducing power determination may seriously overestimate maltotriose concentration and activity of the pullulanase.

In plants,  $\beta$ -amylase may be present in impure samples of limit dextrinase, and in high enough concentration,  $\beta$ -amylase also can hydrolyze maltotriose. Methods of determining limit dextrinase activity in plant extracts have been developed based on the use of modified pullulans (50). In one method, a soluble red-dyed pullulan (Red Pullulan, Megazyme, Bray, Ireland) is dissolved in 0.5 M KCl solution to a concentration of 20 mg/mL. Enzyme solution in acetate buffer (0.2 M, pH 5.0) containing 20 mM cysteine and 0.02% sodium azide is added to substrate solution and incubated at 40°C for a set time. High-molecular-weight substrate is then precipitated by addition of

**Table 2** Activation Energies

Enzyme source	<i>K. pneumoniae</i> (9)	<i>B. acidopullulyticus</i> (10)	<i>B. deramificans</i> (11)	Barley (46)
Activation energy (kJ)	33	45	23	37
Calculated over temperature range (°C)	30–50	40–55	55–60	30–50

ethanol (95% v/v), the mixture is left at room temperature for 10 min, and centrifuged at 1000g for 10 min. Small fragments of dyed pullulan, hydrolyzed by the enzyme from the original high-molecular-weight pullulan, remain in the supernatant giving a colored solution. Absorbance of this solution is measured at 510 nm against distilled water. A blank without enzyme must also be prepared. Absorbance can then be related to pullulanase activity in terms of  $\mu$ moles of glucose reducing sugar equivalents released per min, using a standard curve. The standard curve is prepared by measuring reducing sugar released from pullulan by purified enzyme in acetate buffer (0.2 M, pH 5.0) at 40°C over a set time period. The Nelson-Sömogyi (51) method is used for reducing sugar determination.

In a second method involving a modified pullulan (50), enzyme solution in sodium maleate buffer (0.1 M, pH 5.5) containing 25 mM dithiothreitol and 0.02% sodium azide is incubated at 40°C for 5 min. A tablet of insoluble blue-dyed pullulan (Limit Dextri-Zyme tablet, Megazyme, Bray, Ireland) is added and the mixture is incubated for a set time. The reaction is terminated by stirring with Tris base solution (1% w/v), and the mixture is left at room temperature for  $\sim$  5 min, then stirred and filtered. In this case, the enzyme hydrolyzes some of the insoluble substrate to give soluble blue-dyed fragments that remain in the filtrate, and measurement of absorbance of the filtrate at 590 nm gives a measure of pullulanase activity. Again, a suitable blank must be prepared by adding Tris base solution to enzyme solution before addition of substrate. Limit dextrinase activity in terms of absorbance at 590 nm must be converted to glucose reducing power equivalents using a standard graph. Preparation of the standard graph differs from the method given for the red pullulan graph only in that buffer at pH 5.5 must be used.

Once standard graphs have been prepared, both methods using modified pullulan have the advantage that the assays are not affected by other enzymes such as  $\alpha$ -amylase,  $\beta$ -amylase, or  $\alpha$ -glucosidase that could be present in impure preparations of plant limit dextrinase. (Both modified pullulans are available commercially, and detailed instructions for their use are provided by the supplier.) It has been found, however, that the presence of maltodextrins in a limit dextrinase assay system (such as would occur in a malt extract) interferes with activity determinations using the dyed pullulans as substrate (52). In such cases, pretreatment of extracts with amyloglucosidase gives a more accurate estimate of limit dextrinase activity.

Screening for pullulanase/limit dextrinase activity in the presence of other starch-degrading enzymes is diffi-

cult, unless polyacrylamide gel electrophoresis is used (53). Red Pullulan (Megazyme, Bray, Ireland) can be incorporated into a gel, and after electrophoresis in e.g., Tris-HCl buffer (pH 7.4), the gel should be immersed in acetate buffer (0.2 M, pH 5.5) at 40°C to allow the enzyme to hydrolyze the pullulan and leave a yellow band on the red background. Amylopullulanase may also give a yellow band, but enzymes such as  $\alpha$ -amylase,  $\beta$ -amylase, and  $\alpha$ -glucosidase should have no effect on the red pullulan substrate.

A major problem in determining the activity of limit dextrinase in a plant extract is the possible presence of strong inhibitors. This has been demonstrated to be the case for germinated barley, for example, and it has been found that prolonged incubation (16 h) at 40°C in the presence of 25 mM dithiothreitol (30) or treatment overnight at 4°C with 5 mM ascorbic acid (42) is necessary to disrupt completely the inhibitor-limit dextrinase complex. If the complex is not destroyed, then any measure of limit dextrinase activity gives an underestimate of the amount of enzyme actually present.

## VIII. PURIFICATION

Details of the method used for purification of a pullulanase/limit dextrinase depend on the source of the enzyme and the response of the enzyme to pH and temperature.

*B. acidopullulyticus* pullulanase, for example, can be purified from Promozyme (Novozymes North America, Inc., Franklinton, NC, U.S.A.), a commercially available source of the enzyme (10). After dialysis of Promozyme overnight against acetate buffer (50 mM, pH 5.0), the pullulanase can be precipitated by addition of cold acetone ( $-20^{\circ}\text{C}$ ) to a final concentration of 50% (v/v). The precipitate is collected by centrifugation at 10,000g for 30 min and dried in vacuo. The powder is dissolved in acetate buffer (20 mM, pH 5.0) and applied to a CM-Toyopearl 650 S column equilibrated with the same buffer. The enzyme is eluted with the acetate buffer containing a linear gradient of 0–0.5 M NaCl. Active fractions are pooled and concentrated, then applied to a Toyopearl HW-55S column equilibrated with acetate buffer (20 mM, pH 6.0) containing 0.8 M NaCl. Enzyme is eluted from the column using this buffer, and active fractions are pooled and concentrated, then dialyzed against phosphate buffer (20 mM, pH 7.0). Solid ammonium sulfate is added to 25% saturation, the precipitate is removed by centrifugation at 10,000g for 20 min, and the supernatant is applied to a Butyl Toyopearl 650 S

column equilibrated with phosphate buffer (20 mM, pH 7.0) containing ammonium sulfate at 25% saturation. The column is eluted with the same buffer using a linear gradient of 25% to 0% saturation of ammonium sulfate. Two active fractions are obtained from the column, but the properties of the two fractions are very similar, and apparently there is no gain in purity by use of the Butyl Toyopearl column (10). Yield of active enzyme decreases appreciably, however, when the latter column is used (10).

Barley limit dextrinase is most easily prepared from green malt, and two slightly different methods have been published (30, 42). In the procedure of MacGregor et al. (30), ground green malt is extracted with acetate buffer (0.1 M, pH 5.5) containing 25 mM dithiothreitol at 40°C for 16 h. The slurry is centrifuged at 9000g for 15 min and the supernatant collected. The pellet is re-extracted for 1 h at 40°C with buffer and re-centrifuged, and the supernatants are combined. Limit dextrinase is precipitated overnight at 4°C by addition of ammonium sulfate to 80% saturation. The precipitate is obtained by centrifugation at 9000g for 15 min and dissolved in phosphate-citrate buffer (0.02 M, pH 6.0) containing 1 mM monothioglycerol. The solution is dialyzed at 4°C against the same buffer to remove ammonium sulfate and centrifuged at 8000g for 15 min, and the supernatant is filtered through glass wool. The dialyzed extract is then loaded onto a diethylaminoethyl cellulose ion exchange column (Whatman DE52) equilibrated with the phosphate-citrate buffer containing 1 mM monothioglycerol. The column is washed with this buffer until the absorbance of the eluate at 280 nm returns to baseline. The column is then eluted with the same buffer using a linear gradient of 0–0.5 M NaCl. Active fractions are pooled, concentrated, and dialyzed against acetate buffer (0.02 M, pH 5.5) containing 1 mM monothioglycerol. A  $\beta$ -cyclodextrin affinity

column [Sephadex CL6B covalently linked to  $\beta$ -cyclodextrin (54)] is prepared and equilibrated with acetate buffer (0.02 M, pH 4.0) containing 1 mM monothioglycerol. The dialyzed enzyme solution is adjusted to pH 4.0 with acetic acid, centrifuged at 10,000g for 10 min, and loaded onto the affinity column. The column is washed with acetate buffer (0.02 M, pH 5.5) containing 1 mM monothioglycerol, and enzyme is eluted with the buffer using a linear gradient of 0–0.5 mg/mL  $\beta$ -cyclodextrin. Fractions are collected into tubes containing acetate buffer (0.02 M, pH 5.5) containing 1 mM monothioglycerol to minimize time spent by the enzyme at pH 4.0. Active fractions are pooled, concentrated, and dialyzed overnight at 4°C against the 0.02 M acetate buffer. The enzyme solution is then further concentrated and applied to a Sephadex S-200 gel permeation column equilibrated with the same acetate buffer. The column is eluted with the buffer, and active enzyme fractions are pooled and concentrated. Typical recovery of protein and activity during the purification are given in Table 3.

In a second method (42), green malt flour is extracted with acetate buffer (0.2 M, pH 5.0) containing 5 mM ascorbic acid for 2–4 h at room temperature and allowed to settle overnight at 4°C. The supernatant is concentrated and ammonium sulfate is added to 20% saturation. The precipitate is discarded after centrifugation, and ammonium sulfate is added to the supernatant to 70% saturation. The precipitate is collected and dissolved in acetate buffer (50 mM, pH 5.0) containing 0.5 M CaCl<sub>2</sub>. The solution is desalting by diafiltration and applied to a DEAE-Fractogel 650S column equilibrated in acetate buffer (20 mM, pH 5.0). The column is washed with this buffer and eluted using a linear gradient of 0–1 M NaCl. Active fractions are pooled and ammonium sulfate is added to 1.5–2 M. The solution is applied to a  $\beta$ -cyclodextrin Sephadex column equilibrated in

**Table 3** Purification of Limit Dextrinase

Stage of purification	Total activity (mU) <sup>a</sup>	Total protein (mg)	Specific activity (mU/mg)	Purification (fold)
Extract	412,000	50,200	8.21	1
Ammonium sulfate precipitate	230,000	7,740	29.7	3.6
After ion exchange chromatography	161,000	144	1,120	136
After affinity chromatography	116,000	13.1	8,860	1080
After gel permeation chromatography	70,400	8.32	8,460	1030

<sup>a</sup> Activity was measured using Limit DextriZyme tablets and converted to glucose reducing power equivalents using a standard graph supplied with the substrate (see Sec. VII).

acetate buffer (50 mM, pH 5.0) containing 2 M ammonium sulfate. The column is washed with this buffer and then with acetate buffer without the ammonium sulfate until the absorbance of the eluate at 280 nm is < 0.05. Limit dextrinase is then eluted with the acetate buffer containing 7 mM  $\beta$ -cyclodextrin. Active enzyme fractions are pooled and applied to a DEAE-Fractogel 650S column in acetate buffer (20 mM, pH 5.5). The column is washed with the 20 mM acetate buffer, and enzyme is eluted using this buffer with a linear gradient of 0–0.5 M NaCl. Active fractions are pooled and may be stored at –18°C.

In each preparation, the initial presence of dithiothreitol or ascorbic acid is necessary to disrupt limit dextrinase–inhibitor complexes and release free, active limit dextrinase.

## Limit Dextrinase

**James Hutchison Bryce**

*Heriot-Watt University, Edinburgh, Scotland*

### I. INTRODUCTION

My aim is to provide an outline of the reactions of limit dextrinase and consider how our present knowledge about limit dextrinase will affect its use during the processing of starch in the food industry. My focus will be upon the effect of limit dextrinase in the production of alcoholic beverages from malted barley. However, my comments are relevant to anybody involved in processing starch from any cereal to produce alcoholic beverages or syrups. Furthermore, an understanding of the properties and regulation of limit dextrinase is essential to any project where the aim is to produce a genetically modified organism with altered limit dextrinase activity.

A plant with genetically modified limit dextrinase activity may have altered starch degradation and/or modified starch synthesis. Such genetically modified plants would be an important source of material for studying starch metabolism. Also, such plants have the potential to be the breeding material for new varieties of crops which could produce products with improved yields or processing properties.

Limit dextrinase ( $\alpha$ -1,6-glucanohydrolase, EC 3.2.1.142) is a debranching enzyme which selectively catalyzes the hydrolysis of  $\alpha$ -1,6-glucosidic linkages and has no action on  $\alpha$ -1,4-glucosidic linkages (1). Limit dextrinase is the name commonly used for the debranching enzyme derived from plants, whereas the bacterial enzyme is known as pullulanase (EC 3.2.1.41). Both these enzymes degrade pullulan, amy-

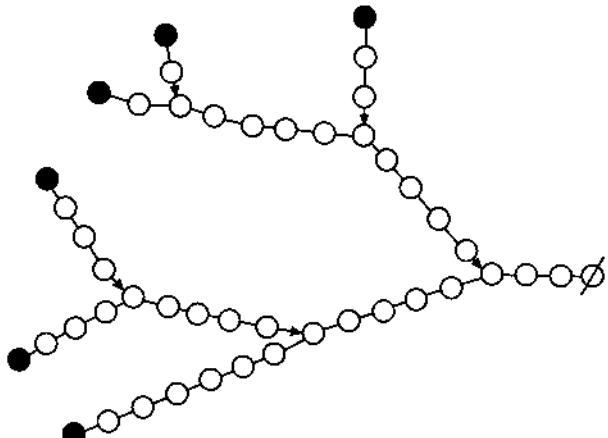

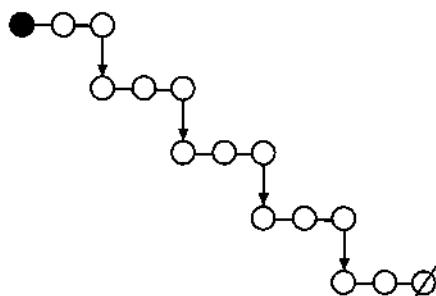

lopectin, and  $\alpha$ -1,6-glucosidic bonds in branched dextrans derived from amylopectin (2). The structures of pullulan and amylopectin are shown in Figure 1.

### II. IMPORTANCE TO QUALITY AND EFFICIENCY OF ALCOHOLIC BEVERAGE PRODUCTION

Limit dextrinase is necessary for complete starch breakdown because starch consists not only of amylose, linear chains of glucose, but also of amylopectin, which contains  $\sim$  4–5% of  $\alpha$ -1,6-glucosidic linkages (3). The precise proportion of amylose to amylopectin varies with the source of the starch, but generally is in the range of 20–30% for normal cereal starches (4).

In processing cereals to produce alcoholic beverages, a wort is normally produced by mixing the ground cereal with hot water ( $\sim$  65°C) for at least 1 h. The temperature is selected to achieve gelatinization of starch granules while maintaining, at least briefly, some activity of the hydrolytic enzymes that will degrade carbohydrate and protein (5). In a wort produced entirely from malted barley, a typical carbohydrate profile following starch degradation is 75% glucose, maltose, and maltotriose, and 25% dextrans, about half of which have multiple branches (6, 7).

Limit dextrinase activity, or indeed lack of activity, is of fundamental importance in the production of wort from cereals in the brewing and distilling industries. Dextrans with  $\alpha$ -1,6-glucosidic bonds are not fer-

**Amylopectin****Pullulan**

**Figure 1** Representations of the structures of amylopectin and pullulan. Circular symbols denote glucose residues. A line (—) denotes an  $\alpha$ -1,4-glucosidic bond, and line with an arrow ( $\rightarrow$ ) denotes an  $\alpha$ -1,6-glucosidic bond. All glucose residues are linked via their hemiacetyl hydroxyl groups at carbon 1 except for the residues shown with a diagonal line through them ( $\emptyset$ ) (the reducing end of each molecule). The residues shown in black contain hydroxyl groups at carbon 4 which are not linked to other residues.

mented by yeast, except in the rare cases of yeast strains that secrete enzymes capable of hydrolyzing  $\alpha$ -1,6-glucosidic bonds. Normally, therefore, if branched dextrins are present in brewer's wort, they will be found in the final beer. In beer, dextrins contribute to calorific value and may also impart fullness or body (8). In contrast, during fermentation of distiller's wort, dextrin degradation may continue because the wort is not boiled and therefore malt enzymes that survive mashing temperatures can remain active. However, dextrins remaining after fermentation will contribute nothing to the new make distilled spirit. Therefore, the requirements for limit dextrinase activity differ between brewers and distillers. A brewer may desire only limited activity of limit dextrinase to ensure that adequate fermentable sugars are produced during mashing (but sufficient branched dextrins remain), whereas a distiller would wish for complete hydrolysis of  $\alpha$ -1,6-glucosidic bonds so that the greatest possible amount of fermentable sugar is available to yeast (9).

### III. PROPERTIES OF LIMIT DEXTRINASE PROTEIN

The properties of limit dextrinase have been thoroughly reviewed by Stenholm (10). In summary, the enzyme from malted barley is reported to have a mole-

cular weight of 103–105 kDa with a pH optimum of 5.0–5.5 (5.5–6.5 in the presence of bovine serum albumin [BSA]). The pI values reported in the literature vary from 4.2 to 4.6.

The gene-encoding limit dextrinase has been isolated (11). In an independent study, the cDNA isolated by Burton et al. (11) has been used to show that there is only one limit dextrinase gene in barley and that the gene is located on the long arm of chromosome 4H, where it has now been mapped [C-D Li, X-Q Zhang, RCM Lance, LC MacLeod, GB Fincher, P Langridge, unpublished data; cited by Burton et al. (11)].

Molecular techniques have been used to establish a clear distinction between strictly  $\alpha$ -1,6-specific debranching enzymes, such as limit dextrinase, and dual-bond type enzymes that attack  $\alpha$ -1,4-glucosidic and  $\alpha$ -1,6-glucosidic bonds (12).

When amino acid sequences of debranching enzymes were examined for phylogenetic relatedness using the PileUp program (13), two distinct groups were distinguished (11). Debranching enzymes that attacked pullulan were grouped together, whereas the isoamylase type fell into a second group.

Partial amino acid sequence analysis provides evidence that barley limit dextrinase belongs to the  $\alpha$ -amylase family of multidomain amylolytic enzymes with a characteristic  $(\beta/\alpha)_8$ -barrel catalytic domain (12, 14, 15).

#### IV. SUBSTRATES, SPECIFICITY, AND ROLE OF DEBRANCHING ENZYME IN BARLEY

The specificity and nomenclature of debranching enzymes have been clarified by Manners (16). Enzymes formerly classified as EC 3.2.1.41 included limit dextrinase (from plants) which does not act on glycogen, and pullulanase of microbial origin which attacks both amylopectin and glycogen. "Isoamylase" enzymes (EC 3.2.1.68) hydrolyze inter-chain linkages in glycogen, amylopectin, and certain derived dextrans, but have no action on pullulan.

Barley limit dextrinase has ~ 50% and 85% sequence identity to bacterial pullulanases and rice starch debranching enzyme, respectively (17). This sequence similarity between barley limit dextrinase and bacterial pullulanases and the similarity of their action (18–21) added weight to the appropriateness of the former classification of barley limit dextrinase with pullulanases (EC 3.2.1.41).

It was believed in the early 1970s that there were two plant debranching enzymes, limit dextrinase and R-enzyme. R-enzyme has been found to act on amylopectin and its  $\beta$ -limit dextrin, and to act on  $\alpha$ -dextrans from both amylopectin and glycogen, but it did not act on undegraded glycogen. Thus, the substrates of limit dextrinase and R-enzyme are identical. Indeed, it is now well established that limit dextrinase and R-enzyme are the same enzymes, and the name limit dextrinase is preferred since this name relates to its natural substrate (16). In the context of starch breakdown to fermentable sugars, it is important to note that the smallest substrate for limit dextrinase is  $6^2\text{-}\alpha\text{-maltosyl-maltose}$  (Fig. 2) (20). Limit dextrinase requires at least one  $\alpha$ -1,4-glucosidic bond on either

side of the  $\alpha$ -1,6-glucosidic bond if it is to hydrolyze the  $\alpha$ -1,6-bond.

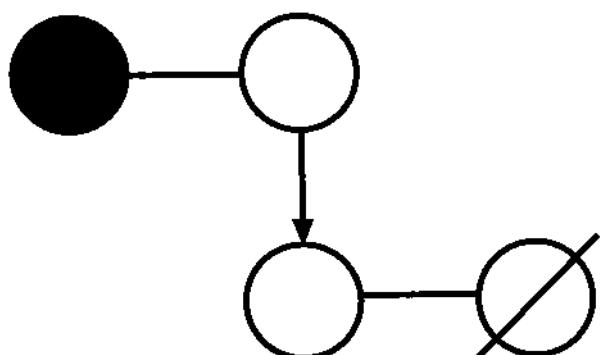

The question arises as to why enzymes formerly classified as EC 3.2.1.41 should have had two names, limit dextrinase (EC 3.2.1.142) (from plants) and pullulanase (EC 3.2.1.41) (from microbes). Manners (16) suggested that the two different names were appropriate because pullulanase is capable of attacking both amylopectin and glycogen whereas limit dextrinase has very limited activity, if any, with glycogen. Furthermore, the nomenclature maintained the subgroups of enzymes that attack pullulan in different ways, namely pullulanase that produces maltotriose, and isopullulanase and neopullulanase that act on  $\alpha$ -1,4-linkages to produce isopanose (22) and panose (23), respectively. However, a distinction has now been drawn between these enzymes with their allocation of separate EC numbers.

Although the debranching enzyme from germinating barley grain falls into the pullulanase group of debranching enzymes; it should be emphasized that the natural substrates of the enzyme are amylopectin or oligomeric limit dextrans rather than pullulan. In vivo, the debranched oligosaccharides are susceptible to further hydrolysis by amylases and  $\alpha$ -glucosidases (24).

In addition to a role in hydrolysis of starch degradation products during germination, limit dextrinase has been implicated in starch synthesis where it is proposed that an appropriate balance between branching and debranching enzymes is required to achieve the final degree of branching in amylopectin (25–30). Furthermore, a debranching enzyme would also be capable of producing primers for the starch synthase reaction (31), a function that could explain the presence of limit dextrinase in developing rice grain (32).

Burton et al. (11) have obtained mRNA encoding barley limit dextrinase from overlapping cDNA clones from PCR amplification. The cDNA sequence has an open reading frame that encodes a putative transit peptide of 78 amino acid residues and a mature polypeptide of 884 amino acid residues. The calculated molecular weight of the mature polypeptide is 97.4 kDa and the calculated pI is 5.0 (assuming all the acidic and basic groups are on the surface in the tertiary structure). These are values comparable to the molecular weight of 105 kDa and pI values of 4.2–4.6 reported for purified limit dextrinase (17, 33, 34). The discrepancy between the deduced and measured values of molecular weight could be due to glycosylation of the enzyme; seven potential N-glycosylation sites are present in the deduced amino acid sequence.

A number of features relating to the function of the gene stand out. First, limit dextrinase mRNA is abun-

**Figure 2** Structure of  $6^2\text{-}\alpha\text{-maltosyl-maltose}$ . (Symbols are as for Figure 1.)

dant in gibberellic acid (GA)-treated aleurone layers and in germinated grain. Furthermore, abscisic acid (ABA) abolishes the GA induction of limit dextrinase mRNA in isolated aleurone cells. This would be expected since ABA often acts as an antagonist to GA in plant tissues. These observations would tend to confirm that limit dextrinase should participate in starch degradation during endosperm mobilization in germinating grains. However, if this is so, then it would be expected that limit dextrinase would carry a signal peptide to target the nascent polypeptide to the endoplasmic reticulum for eventual secretion from the aleurone to the endosperm. No such signal peptide has been identified (11). Therefore, since there is no evidence that aleurone cells become leaky to metabolites as they senesce, the mechanism of limit dextrinase release into the endosperm, if it does occur, remains to be established.

The question of the potential role of limit dextrinase in starch synthesis also arises. Low levels of limit dextrinase mRNA were detected in the developing endosperm of barley until  $\sim$  20 days post anthesis (DPA), after which time the levels rapidly declined. Limit dextrinase activity was detected in the developing grain. This expression pattern corresponds closely to the timing of starch synthesis in developing barley grains, although the precise timing in any give grain is dependent to some extent on growth temperatures (35).

Starch synthesis occurs in an organelle known as an amyloplast and limit dextrinase has a presequence typical of transit peptides that target nascent polypeptides to amyloplasts (11). In the developing endosperm of barley, limit dextrinase is thus targeted to the organelle in cells whose primary role is to synthesize starch and is expressed at a time coinciding with starch synthesis. This suggests a role for limit dextrinase in starch synthesis in the developing endosperm.

While the above molecular evidence points to a role for limit dextrinase in starch synthesis, the biochemical evidence is much less convincing. In the model of amylopectin biosynthesis involving debranching enzyme activity (28), it is proposed that there is intensive branching generating phyto-glycogenlike structures. These structures are then trimmed by debranching enzymes. This requires very precise regulation of the activities of the enzymes involved. The lack of evidence for such precise regulation of these enzymes, plus the lack of limit dextrinase activity with phyto-glycogen (16), means that a role of limit dextrinase in starch synthesis is as yet unresolved.

## V. MEASUREMENT OF LIMIT DEXTRINASE ACTIVITY

### A. Assay

The extraction and measurement of limit dextrinase have advanced recently with analytical procedures employing pullulan reacted with dye molecules (36, 37). The sensitivity of these methods is better than that of methods based on measurement of reducing sugars (10). Two commercial products, Red-Pullulan (soluble Reactive Red 120-labeled pullulan, Megazyme Ltd) and Limit DextriZyme tablets (insoluble cross-linked azurine-pullulan, Megazyme Ltd), are now widely used for assay of limit dextrinase activity in barley and malt extracts. The Limit-DextriZyme tablets have the advantage of greater sensitivity (10- to 15-fold), lower blank values, greater ease of use, and greater stability than Red-Pullulan (37).

There are other potential methods for the measurement of limit dextrinase. Sissons et al. (38) developed a rapid enzyme-linked immunosorbant assay (ELISA) for measuring limit dextrinase. The assay was supposed to be specific and sensitive and to recognize the active enzyme, but values do not correlate with the Red Pullulan assay (10).

Earlier assays were based on the measurement of maltotriose released from pullulan by limit dextrinase (24, 39). The drawback of this procedure was the production of additional reducing groups if the sample to be analyzed contained  $\alpha$ -glucosidase. Thus, for crude extracts containing endogenous  $\alpha$ -glucosidase, Lee and Pyler (40) developed a two-step assay method in which the limit dextrinase reaction products from pullulan were hydrolyzed to glucose by added yeast  $\alpha$ -glucosidase, and the glucose was then assayed. Problems with this approach included (a) the fact that  $\alpha$ -glucosidase does not hydrolyze the higher oligosaccharides, which are initial hydrolysis products of pullulan (37), and (b) the requirement to remove endogenous reducing sugars by dialysis (41).

### B. Extraction

From the foregoing discussion, it should be evident that while the assay of limit dextrinase can be difficult, the use of dyed pullulan has been a significant advance. However, just as important as assaying the enzyme correctly is the correct extraction of the enzyme. It is thought that in vivo in germinating barley, the enzyme exists in three forms—bound and inactive, soluble and active (known as “free”), and soluble and inactive (42,

43). Furthermore, limit dextrinase inhibitors have been detected in barley grain extracts (44). While barley grains at maturity have a high level of limit dextrinase inhibitor, the level is lower in wheat, and the inhibitor is absent in rice and maize (45). All these factors complicate the interpretation of limit dextrinase activity measurements. However, it is currently believed that the “total” activity of limit dextrinase in germinating barley grain can be determined by extraction for 5 h with a reducing agent, whereas extraction for 5 h without a reducing agent provides a measure of the “free” activity (soluble and active).

## C. Properties

### 1. Inhibitors and Activators

The effect of inhibitors and activators of limit dextrinase is reviewed by Stenholm (10). One potentially important feature to emerge is the inhibition of rice limit dextrinase by maltose, maltotriose, and a number of small maltosaccharides. This suggests that rice limit dextrinase contains binding sites for at least two, and probably more, adjacent  $\alpha$ -1,4-linked glucose residues (19). If barley limit dextrinase were inhibited by these low-molecular-weight oligosaccharides during mashing in the brewing process, then it could reduce the conversion of nonfermentable branched dextrins to fermentable sugars.

Cyclodextrins inhibit limit dextrinase, with  $\beta$ -cyclodextrin being very significantly more inhibitory than  $\alpha$ -cyclodextrin or  $\gamma$ -cyclodextrin (21, 34, 46, 47). Purified limit dextrinase (200 mU/mL) was inhibited 50% by 75  $\mu$ g/mL  $\beta$ -cyclodextrin (34). All three cyclodextrins are competitive inhibitors of limit dextrinase.

The properties of limit dextrinase differ significantly from those of  $\alpha$ -amylase. There is no effect of  $\text{Ca}^{2+}$  (1–100 mM) on activity and EDTA (10 mM) causes only a 15% decrease in activity. Also, the pseudo-tetrasacharide acarbose, a potent inhibitor of  $\alpha$ -1,4-specific amylolytic enzymes such as  $\alpha$ -amylase and glucoamylase, reduces the activity of limit dextrinase by only 30% at a high concentration of 10 mM (34).

### 2. Temperature Stability

In the past, there have been major differences in the reported heat stability of limit dextrinase (10). If limit dextrinase is to be active in mashing, then it must survive kilning of the grain where temperatures will normally exceed 60°C and may even exceed 80°C—for example, if an ale malt is being produced. At present, it is generally agreed that barley limit dextrinase has

thermostability properties during kilning that are intermediate between  $\alpha$ -amylase (heat stable) and  $\beta$ -glucanase (relatively heat labile and inactivated by kilning) (37). However, whereas in the past it was thought that limit dextrinase was denatured during mashing, there is now good evidence that limit dextrinase survives mashing temperatures of 63–65°C.

### 3. Measurement in Crude Extracts

The measurement of limit dextrinase is most simply done by determining the “total” activity of the enzyme (extraction with a reducing agent) and activity of the “free” enzyme (extraction without a reducing agent). In the recommended procedures, limit dextrinase is extracted from ground grain for 5 h at 40°C in 0.1–0.2 M NaOAc (pH 5.0–5.5). This extracts the “free” enzyme (soluble-active) (37), whereas “total” activity is obtained after similar extraction with a reducing agent, e.g., 25 mM dithiothreitol (DTT). Soluble-inactive enzyme is the total activity minus the free activity. Excessive extraction of limit dextrinase in the presence of DTT can start to lead to a decline in the apparent total activity of limit dextrinase, a decline that is probably due to the activation of nonspecific proteases that start to degrade limit dextrinase.

Sjöholm et al. (48) measured limit dextrinase activity during mashing. In a 1 h mash, limit dextrinase activity remained stable at 60°C, declined by 55% at 62.5°C, and declined by 65% at 65°C. Limit dextrinase was only fully inactivated in 1 h by temperatures > 65°C. Similar evidence for the stability of limit dextrinase at mashing temperatures was obtained by MacGregor et al. (45) and Bryce et al. (49). Furthermore, when MacGregor et al. (45) collected samples mashed at 63°C and incubated the sample supernatants at 40°C with 25 mM DTT (dithiolthreitol) the measured activity of limit dextrinase increased dramatically. This shows that a large portion of the limit dextrinase in the malt was solubilized during mashing but had remained in the wort as inactive enzyme.

In some of the experiments just described (45, 48, 49), samples were taken directly from wort for measurement of limit dextrinase activity using dyed pullulan as substrate. The aim of this was to provide a measure of limit dextrinase activity in the wort rather than its potential activity. MacGregor et al. (45) were able to obtain much higher activities when the sample was extracted with DTT prior to assay. This makes an important point; if limit dextrinase is to be assayed, the researcher must decide whether to determine the activ-

ity present or the potential “free” or “total” activity. Potential free activity would be that obtained by further extraction in the absence of a reducing agent.

Furthermore, the presence of limit dextrinase inhibitor in certain cereals means that in any process to which limit dextrinase or pullulanase is being added, it is necessary to determine whether or not the enzyme will be inhibited upon addition to the process. Bryce et al. (49) produced a lactic malt with a “free” limit dextrinase activity of 800 mU/g. A recombination experiment was carried out in which an extract from this malt with high free activity was mixed with an equal proportion of a more typical malt where a high percentage of limit dextrinase is in the soluble but inactive form. The result was an inhibition of the free limit dextrinase from the lactic malt > 50%. This shows that the typical malt contains inhibitor capable of inhibiting free limit dextrinase. It also suggests that supposedly free activity in malt could be activity of the soluble and “inactive” enzyme. However, pullulanase from *Bacillus acidopullulyticus* (Promozyme 200 L, Novo Nordisk, Denmark) was not inhibited by malt extracts (49). Therefore, it appears that pullulanase is not inhibited by limit dextrinase inhibitor.

McCafferty and Bryce (unpublished) have found activities of limit dextrinase from malted barley substantially higher than those of “free” limit dextrinase by rapid extraction (a few minutes) and assay at pH 4.4. Therefore, any analysis of limit dextrinase activities of crude extracts should be accompanied by careful checking of the optimum pH and time for extraction and assay.

#### 4. Measurement of Purified Enzyme Activity

A further factor that should be taken into account in assaying limit dextrinase is the presence of protein. BSA (0.05 mg/mL) increased the activity of purified limit dextrinase threefold (34). This stabilization or activation effect was not specific to BSA; proteins from crude barley extracts had the same effect of boosting the activity of purified limit dextrinase (provided endogenous inhibitor was first removed from the extracts). To avoid any apparent loss of activity of limit dextrinase following purification 0.5 mg/mL BSA was added routinely to assay buffers to overcome any effects that could arise owing to variable protein levels (34).

#### 5. Measurement in Food and Food Processing—Summary

From the above discussion, it should be apparent that there is an incomplete understanding of how limit dex-

trinase activity is regulated. However, present knowledge should make it possible to measure limit dextrinase activity and how it changes either during the processing of food, for example, cereal grains or following the production of genetically modified plants with altered limit dextrinase expression.

#### 6. Extraction and Purification of Limit Dextrinase

The key to extraction of limit dextrinase from germinating barley is to do it in the presence of a reducing agent such as DTT; also, if a good yield of enzyme is desirable, it should be done after at least 8–10 days of germination. There is evidence that sulphydryl proteases, activated by a reducing agent, are necessary during extraction to activate limit dextrinase solubilized from germinating barley grains (50), and such proteases are also necessary to solubilize bound limit dextrinase associated with the insoluble fraction of germinating barley grains (43).

The extraction process should also aim to minimize the effect of heat-stable endogenous inhibitor(s) of ~15 kDa (44) that are reported to form soluble but inactive complexes with limit dextrinase (51). Two factors could reduce the effect of these inhibitors. First, activity of sulphydryl proteases could “upset” the enzyme–inhibitor complex, and second, an extended period of germination could lead to breakdown of the inhibitor. MacGregor et al. (45) showed a very low level of inhibitor to be present after 6 days of germination. The problem of the inhibitor will only occur in extracts from cereal grains of barley, triticale, durum, wheat, and oats, since the inhibitor has been detected in these grains. The inhibitor has not been detected in rice, sorghum, millet, or maize.

Homogeneous barley limit dextrinase has been isolated on a large scale with a yield of 9 mg/kg from 10-day germinated green (unkilned) malt (17). This represented a 9400-fold purification with a 29% recovery of activity compared to that of a flour extracted in 0.2 M NaOAc (pH 5.0) containing 5 mM ascorbic acid. The purification protocol consisted of precipitation of limit dextrinase from an extract at 20–70% saturated ammonium sulfate (AMS), followed by diethylaminoethyl (DEAE) 650S Fractogel anion exchange chromatography, and affinity chromatography on  $\beta$ -cyclodextrin-Sepharose in the presence of 2 M AMS. Limit dextrinase was eluted by 7 mM  $\beta$ -cyclodextrin and contained a single polypeptide chain of 105 kDa (SDS-PAGE) and pI of 4.3.

MacGregor et al. (34) purified limit dextrinase by extraction of grist in 0.1 M NaOAc, pH 5.5 at 40°C for 16 h with 25 mM DTT, followed by ammonium sulfate precipitation, and chromatography on ion exchange (DEAE, pH 6.0), affinity ( $\beta$ -cyclodextrin Sepharose with pH 4.0 for loading and pH 5.5 for elution), and gel filtration (Sephacryl S-200, pH 5.5) columns. The enzyme had high specific activity, was homogeneous, and gave single bands of protein when examined by SDS-PAGE (~ 105 kDa) and IEF (pI 4.6).

Binding of limit dextrinase to the  $\beta$ -cyclodextrin column was improved in two ways. First, the affinity column was equilibrated to pH 4.0, and the pH of the DEAE purified pool was adjusted to pH 4.0 just before loading to the column. Seventy percent of the limit dextrinase applied to the column was recovered in the postaffinity pool. This degree of binding was similar to that reported by Maeda et al. (52) but higher than that reported by researchers who used a higher pH (5.5 or 6.0) for  $\beta$ -cyclodextrin columns (33, 43, 53). Limit dextrinase activity is lost quickly at pH 4.0; therefore it was necessary to bring the pH of the eluted enzyme back to pH 5.5 as quickly as possible by collecting column effluent into tubes containing a small volume of strong pH 5.5 buffer.

Binding of dextrins to the affinity column was also improved by first removing from the preparation, by DEAE chromatography, other  $\beta$ -cyclodextrin-binding enzymes, such as  $\alpha$ -amylase.  $\alpha$ -Amylase binds to  $\beta$ -cyclodextrin columns much more tightly than limit dextrinase (53), and would be eluted after limit dextrinase in the  $\beta$ -cyclodextrin gradient.

Limit dextrinase was eluted from the column by a low concentration of  $\beta$ -cyclodextrin. This step achieved a large increase in the specific activity of the enzyme, confirming the effectiveness of an appropriate affinity chromatography method of protein purification. Gel permeation chromatography on Sephadryl S-200 was used as the final step in the purification of the enzyme to remove  $\beta$ -cyclodextrin, as well as a small amount of a low-molecular-weight contaminant.

## Methodologies for Assaying the Hydrolysis of Cellulose by Cellulases

**David Johnston**

*U.S. Department of Agriculture, Wyndmoor, Pennsylvania, U.S.A.*

### I. INTRODUCTION

This chapter does not intend to be a complete description of all cellulase assays available. The methods described here are generally regarded as the most useful or commonly employed assays. Many of the assays are useful from an empirical standpoint, but they cannot be used to compare results among laboratories. An attempt has been made to include methods applicable to a variety of research interests.

The analysis of cellulase activity presents a number of unique problems that are not typically observed in the study of other enzymes. Cellulose, the native substrate for cellulases, is insoluble and varies significantly in its structure. This complexity makes the kinetic analyses difficult since concentration and form of substrate are variable. Additionally, the presence of trace amounts of other cellulases may enhance hydrolysis in a synergistic fashion, altering experimental results. Enzymes such as  $\beta$ -glucosidase or cellobiose phosphorylase, which are not strictly cellulases, can also enhance cellulose hydrolysis by the removal of products that cause inhibition.

The unifying characteristic of all cellulases is their ability to hydrolyze the  $\beta$ -1,4-glucosidic linkage in cellulose. Cellulases are classified into four separate

Mention of brand or firm name does not constitute an endorsement by the U.S. Department of Agriculture above others of a similar nature not mentioned.

classes, based on their positions of hydrolysis and the products they produce.

The first class comprises the endoglucanases, which are enzymes that hydrolyze the internal bonds of the cellulose chain (endo-1,4[1,3;1,4]- $\beta$ -D-glucan 4-glucanohydrolases, EC 3.2.1.4). The second class is the exocellobiohydrolases (1,4- $\beta$ -D-glucan cellobiohydrolyases, EC 3.2.1.91). This class of enzymes releases predominately cellobiose from cellulose molecules. Previously this group consisted of enzymes that released cellobiose from the nonreducing end; however, the class is now being subdivided into two separate groups of enzymes that release cellobiose from either the reducing or the non-reducing end of the cellulose molecule. The third class is the exoglucanohydrolases (1,4- $\beta$ -D-glucan glucanohydrolase, EC 3.2.1.74). This group is composed of enzymes that release predominantly glucose from the nonreducing end of the cellulose molecule. There are some researchers who dispute the existence of these enzymes, with the contention that they are actually cellobiohydrolases contaminated with  $\beta$ -glucosidase or cellobiohydrolases that have some ability to hydrolyze cellobiose. The fourth class is the  $\beta$ -glucosidases ( $\beta$ -glucoside glucohydrolase, EC 3.2.1.21). This group hydrolyzes cellobiose, and to a much lesser extent cellotriose, to produce glucose. Technically these enzymes may not be considered cellulases (since they do not hydrolyze cellulose); they are included with the cellulases because they hydrolyze a  $\beta$ -1,4-

glucosidic linkage and their action is important for complete hydrolysis of cellulose to glucose.

The classification above is currently under revision as increased information about cellulase specificity, hydrolytic activity, products formation, hydrolytic stereochemistry, and structural similarities is gathered. The current trend in the literature is to classify cellulases based on the comparison of their deduced amino acid sequences. In 1993 the comparison of 120 primary sequences of cellulases and xylanases defined a total of 11 families (designated A–K) (1).

Cellulases have a variety of commercial applications and many potential applications. In the food industry, cellulases are used in the processing of some fruits to aid in peeling or to increase juice yield. In the textile industry, cellulases are used to treat dyed fabrics to give a look similar to stone washing and to alter the properties of some regenerated fibers. One of the more exciting potential uses of cellulases is in the conversion of cellulosic waste material to glucose for fermentation into fuel ethanol. While cellulases are currently used in the detergent and textile industries, their application for waste conversion is still not considered economically viable because of the large quantities of enzymes necessary for the complete conversion of cellulosic material to glucose.

## II. SUBSTRATE PREPARATION

### A. Carboxymethyl Cellulose (CMC) and Hydroxyethyl Cellulose (HEC) (2)

Many different procedures are cited for preparation of substrates for viscosity determinations; however, most do not yield a substrate with a stable viscosity. The procedure described here is a slight modification from Garcia et al. (2) and does yield a solution with stable viscosity for several weeks. CMC or HEC can be used interchangeably without modification. Higher-molecular-weight substrates permit greater sensitivity in viscosity methods. CMC is the preferred choice when using capillary viscometry since HEC tends to form bubbles.

The substrate solution is prepared by slow addition of CMC 7H3SF from Aqualon to water heated to 80°C and stirred for 1 h to completely dissolve the substrate. After completing the addition, the solution is filtered through a sintered glass funnel (coarse) into a vacuum filtering flask and then allowed to cool to room temperature. Equal weights of the substrate and a 0.1 M sodium acetate buffer (pH 5.0) are

weighed into a vacuum flask and degased with stirring for 1 h.

### B. Phosphoric Acid Swollen Cellulose (4)

Phosphoric acid swollen cellulose (PSC) is commonly used as an example of an amorphous cellulose substrate in cellulase hydrolysis experiments. This procedure is a slight modification of Ställberg et al. (3) producing a more uniform substrate than by other methods, without requiring blending or filtering (3, 4).

A suspension of cellulose is prepared by addition of 3.00 g Sigmacell 20 to 5 mL deionized water. The cellulose suspension is then added slowly to 300 mL of cold 85% (w/v) phosphoric acid with stirring in an ice bath. The container of the cellulose suspension is rinsed with an additional 5 mL water to remove all of the cellulose. The cellulose solution is stirred on ice for 2 h. No undissolved cellulose should be visible to the naked eye. The solution is then slowly added to 4 L cold water with constant stirring on a magnetic stir plate. The precipitated cellulose is allowed to settle and the supernatant is removed by vacuum aspiration. An additional 4 L water is added with mixing, the suspension is allowed to settle, and the supernatant is removed by vacuum aspiration. This procedure is repeated a total of 10 times. After the final settling of the suspension, the cellulose is transferred to 1-L graduated cylinder. The supernatant is removed, and 500 mL of 0.10 M acetate buffer, pH 5.0, is added and the volume adjusted to 1 L. The final substrate concentration is determined using the Dubois method (5) for total carbohydrate.

### C. Dyed Avicel (6)

Dyed Avicel is a convenient substrate for many applications. It is particularly useful for assays where reducing group measurements give excessively high blank values (e.g., inhibition by glucose or cellobiose).

A suspension of 100 g of Avicel is prepared in 1 L water. The suspension is heated to 50°C with vigorous stirring. One liter of 1% (w/v) Remazol Brilliant Blue dye is prepared in water and added to the Avicel suspension. Vigorous stirring is continued for 45 min, followed by addition of 200 g Na<sub>2</sub>SO<sub>4</sub> in several portions. Following the Na<sub>2</sub>SO<sub>4</sub> addition, 100 mL of a 100% solution of Na<sub>3</sub>PO<sub>4</sub> is added (pH should now be 12) and the mixing continued for an additional 75 min. The suspension is now filtered through a sintered glass funnel (porosity 1) and washed with 60°C distilled water until the filtrate is colorless. While still in

the funnel, the dyed Avicel is washed with acetone and then ether. The prepared substrate is then vacuum dried.

### III. METHOD TYPES

#### A. Viscosity (2)

##### 1. Capillary

A 22-mL (22.00 g) aliquot (delivered by weight) of 0.5% CMC solution (prepared as described in Sec. II.A) is placed in a screw-cap tube in a 40°C water bath and preequilibrated for 15 min. After equilibration, 220  $\mu$ L enzyme solution is added and the reaction timer activated. The cap is secured and the tube inverted gently 10 times. The solution is removed from the tube using a syringe, and  $\sim$  20 mL is injected into the capillary tube (Ubelode type). The reaction mixture is drawn up into the capillary using suction, and the drain time measured. This is repeated consecutively over the desired time frame. The viscosity is then calculated using the capillary tube calibration constant. The reaction time used for each measurement is the time at one-half of the drain time (reaction time at beginning of measurement plus 0.5 the drain time).

##### 2. Rotational

A rotating spindle viscometer (Brookfield DV-III rheometer) is used to measure viscosity. Eight milliliters (8.00 g) of 0.5% CMC solution (prepared as described in Sec. II.A) is weighed into a chamber for small sample volumes (Brookfield spindle model SC4-18) and preequilibrated with the spindle at 40°C for 15 min. After equilibration, an 80  $\mu$ L aliquot of CMC solution is removed and 80  $\mu$ L enzyme solution is added. The sample is mixed for 1 min by moving the chamber up and down in the thermostated jacket. The spindle is then started at 60 rpm; after 2 min the first reading is taken, and subsequently each minute thereafter, in order to follow the rate of CMC hydrolysis.

#### B. Reducing-Group Methods

Reducing-group measurements are the best methods for general cellulase activity determinations. One of the greatest difficulties with this type of method is the nonuniform response between oligosaccharides with different degrees of polymerization (DP). Another difficulty is the incompatibility of some methods with certain substrates. Among the three reducing-

group methods described here for measurement of cellulase activity, the disodium 2,2'-bicinchoninate (BCA) method gives the greatest sensitivity and little or no difference in response among different DPs.

##### 1. BCA Method

*Reagent A.* The reagent is prepared by dissolving 54.28 g/L (512 mM) of Na<sub>2</sub>CO<sub>3</sub>, 24.2 g/L (288 mM) of NaHCO<sub>3</sub> and 1.942 g/L (5 mM) of disodium 2,2'-bicinchoninate. The solution is stored in a foil-covered bottle at room temperature. It is stable for several months.

*Reagent B.* The reagent is prepared by dissolving 1.248 g/L (5 mM) of CuSO<sub>4</sub> · 5H<sub>2</sub>O and 1.262 g/L (12 mM) of L-serine. Solution is stored in a foil-covered bottle at 4°C. The solution is stable for up to 2 months. A new solution should be made when reagent blank value increases.

*Sodium carbonate/bicarbonate solution.* The solution is prepared by dissolving 54.28 g/L (512 mM) of Na<sub>2</sub>CO<sub>3</sub>, and 24.2 g/L (288 mM) of NaHCO<sub>3</sub> in the same solution. Final pH of the solution is 10.

*BCA Working Reagent.* Equal volumes of reagents A and B are mixed. The BCA Working Reagent solution should be prepared daily.

a. *Sampling Using CMC (2).* Twenty milliliters (20.00 g) of CMC solution is transferred to a 50-mL screw-cap tube gravimetrically and incubated at 40°C. Two 1-mL aliquots are taken as controls after 15 min and transferred to 13 × 100 mm test tubes containing 2 50  $\mu$ L Na<sub>2</sub>CO<sub>3</sub>/NaHCO<sub>3</sub> solution. The enzyme reaction is initiated by addition of 180  $\mu$ L enzyme solution to the 50-mL tube and mixed by gently inverting several times. One-milliliter aliquots are removed at timed intervals and transferred to tubes containing 250  $\mu$ L of the Na<sub>2</sub>CO<sub>3</sub>/NaHCO<sub>3</sub> solution to inactivate the enzyme.

b. *Sampling Using PSC (4).* One milliliter of PSC suspension is transferred into a microcentrifuge tube from a flask mixing on a magnetic stir plate. The tubes are preequilibrated to 40°C for 10 min. The enzyme reaction is initiated by addition of 5–40  $\mu$ L enzyme plus buffer followed by thorough mixing. The mixture is incubated at 40°C for a specified time and then inactivated by addition of 250  $\mu$ L Na<sub>2</sub>CO<sub>3</sub>/NaHCO<sub>3</sub> solution followed by mixing.

To determine the total reducing groups formed during the enzymatic reaction, the inactivated sample is vortexed (< 5 min before sampling) and hand-mixed immediately before removing a 100  $\mu$ L sample. The sample is added to 900  $\mu$ L of water in a 13 × 100

mm test tube. Soluble reducing groups can be determined after centrifuging for 5 min prior to removing the 100- $\mu$ L sample to pellet the insoluble cellulose. Total and soluble reducing groups can be determined on the same sample by first sampling for total reducing groups followed by sampling of soluble reducing groups.

c. *Determination of Reducing Group (4).* Reducing groups are determined by addition of 1 mL of BCA Working Reagent to each tube containing 1 mL of sample or standard and incubated in a water bath at 80°C for 30 min. Tubes are mixed before incubation and covered with marbles to minimize evaporation. A standard curve of glucose (0–55 nmoles/mL) is prepared and incubated at the same time as the samples. Following heating, the tubes are cooled to room temperature in a water bath, sealed with Parafilm, and mixed by inverting several times. The absorbance values are measured in a spectrophotometer at 560 nm against a buffer blank. The number of glucose equivalents (nmoles of reducing groups/mL) is calculated by comparison to the standard curve. To prevent variation due to turbidity, samples using PSC as the substrate should be allowed to settle and the supernate removed for absorbance measurements using a Pasteur pipette.

## 2. Nelson-Somögyi Method (7, 8)

a. *Somögyi Reagent.* The reagent is prepared by dissolving 12.0 g KNaC<sub>4</sub>H<sub>4</sub>O<sub>6</sub> (potassium sodium tartrate) and 24.0 g anhydrous Na<sub>2</sub>CO<sub>3</sub> in 250 mL deionized water. In a separate container, 4.0 g of CuSO<sub>4</sub> · 5H<sub>2</sub>O is then dissolved in minimal water and added to the mixture. Sixteen grams of NaHCO<sub>3</sub> is then added and dissolved. Deionized water (500 mL) is boiled for 10 min with 180 g Na<sub>2</sub>SO<sub>4</sub> to expel air and then added to the mixture. The final volume is then diluted to 1.0 L and the solution aged 1 week. The aged solution is filtered before using.

b. *Nelson Reagent.* The reagent is prepared by dissolving 50.0 g ammonium heptamolybdate [(NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub> · 4H<sub>2</sub>O] in 900 mL deionized water. Concentrated H<sub>2</sub>SO<sub>4</sub> (42.0 mL) is then added slowly with mixing. In a separate container, 6.0 g Na<sub>2</sub>HAsO<sub>4</sub> · H<sub>2</sub>O is dissolved in 50 mL deionized water and added to the mixture. The final volume is adjusted to 1.0 L and aged 24 h at 37°C in the dark before use.

c. *Procedure.* Sampling using CMC and PSC is done as described under the BCA-reducing group assay with the modification of enzyme inactivation by heating in a boiling water bath for 5 min prior to reducing group determination.

Somögyi reagent (0.5 mL) is added to 0.5 mL of sample or standard in a 16 × 100 mm test tube. The tubes are mixed by vortexing, covered with marbles to prevent evaporation, and placed in a boiling water bath for 10 min. The tubes are removed and cooled to room temperature. After cooling, 0.5 mL of the Nelson reagent is added to each tube followed by mixing using a vortex mixer until no bubbles remain. A standard curve using glucose from 0 to 180  $\mu$ g/mL is prepared and heated at the same time as the samples. The absorbance values are measured at 560 nm in a spectrophotometer, and the number of glucose equivalents ( $\mu$ moles of reducing groups/mL) is calculated by comparison to the standard curve.

## 3. DNS Method (9)

The 3,5-dinitrosalicylic acid reagent is prepared by dissolving 1.0 g of 3,5-dinitrosalicylic acid (DNS) in 50 mL water followed by addition of 20 mL of 2 N NaOH. After all the material is dissolved, 30 g of sodium potassium tartrate (KNaC<sub>4</sub>H<sub>4</sub>O<sub>6</sub>) is added and dissolved. The solution is diluted to 100 mL with water. The solution is stable for several weeks when stored in an amber bottle protected from CO<sub>2</sub>.

Sampling using CMC and PSC is done as described under the BCA reducing group assay (Sec. III.B.1) with the modification of enzyme inactivation by heating in a boiling water bath for 5 min prior to reducing group determination.

DNS reagent (1.00 mL) is added to 1.00 mL of sample or standard in a 18 × 150 mm test tube. The tubes are heated for 5 min in a boiling water bath and then cooled in a water bath to room temperature. The solutions are diluted to 3 mL with water and read in a spectrophotometer at 540 nm against a blank in which 1.00 mL water is used in place of the sample. The concentration of reducing groups is determined from a standard curve of glucose (0–1 mg).

## 4. Filter Paper Method

While this method is considered standard, many researchers have made extensive modifications to meet various needs. The method described here is based on the standard method of Mandelis et al. (10) as described by Ghose (11).

To a 25-mL or larger test tube is added 1.0 mL of 0.05 M sodium citrate buffer, pH 4.8. A 0.5-mL aliquot of enzyme diluted in sodium citrate buffer is added and the tube equilibrated at 50°C. (A minimum of two different dilutions is necessary for each enzyme to be tested. One dilution should produce slightly > 2 mg of glucose and the other slightly less.) A 1.0 × 6.0 cm (~ 50 mg) Whatman No. 1 filter paper strip is rolled around a glass rod and added to the test tube and incubated at 50°C for 60 min. The reaction is stopped by the addition of 3 mL DNS mixture. All tubes are then boiled together (including standards and blanks) for 5 min and cooled in a cold-water bath. The reactions are then diluted with 20 mL water, mixed by inverting several times, read in a spectrophotometer at 540 nm, and compared with a standard curve of glucose (1–3.35 mg).

The absolute amount of glucose released is determined after subtraction of the appropriate enzyme blank. A semilog plot (to improve linearity) of the glucose released against the fold enzyme dilution is made and the amount of enzyme necessary to release exactly 2.0 mg of glucose is determined. The filter paper units (FPU) in U/mL are calculated by dividing 0.37 by the determined enzyme concentration necessary to release 2.0 mg glucose. [Note: The FPU is derived from the International Unit (IU). When the product is glucose, 1 IU is equal to 0.18 mg min<sup>-1</sup>. At the defined dilution (4% hydrolysis), 2 mg of glucose is produced from 0.5 mL of enzyme in 60 min. Therefore, the enzyme necessary to release 2.0 mg of glucose in the reaction contains 0.37 units (IU mL<sup>-1</sup>).]

### C. Chromophore and Fluorescent Group Release Methods

#### 1. Dye Release—Cellulose Azure Method (12)

Cellulose azure (commercially available) is weighed into a test tube (100 mg), and 3 mL of 0.05 M sodium citrate buffer, pH 4.8, is added. The tube is equilibrated to 50°C and a stirring bar is added. Two milliliters of enzyme (equilibrated to 50°C) is added and incubated with stirring for 10 min. After incubation, the suspension is filtered through Whatman No. 1 filter paper and the OD at 595 nm is measured in a spectrophotometer.

#### 2. Dye Release—Avicel Method (12)

A substrate suspension is prepared in 50 mM sodium citrate buffer, pH 4.8, using 50–100 mg/mL dyed Avicel (prepared as described in Sec.IIC). Enzyme

solution 2 mL is pipetted into a test tube and equilibrated to 50°C. Three milliliters of the substrate suspension (equilibrated to 50°C) is added. The enzyme-substrate mixture is incubated for 1–2 h with or without stirring using a magnetic stirrer at 400 rpm. Following incubation, the suspension is heated in a boiling water bath for 5 min and then filtered through Whatman No. 1 filter paper. The filtrate is allowed to cool to room temperature, and the absorbance at 595 nm is determined. Activity is expressed in arbitrary units of absorbance.

### 3. MeUmb Method (13, 14)

The use of 4-methylumbelliferyl β-D-glycosides as substrates can be used to monitor cellulase activities. The cellobiose and cellotriose derivatives are commercially available or can be prepared according to Tilbeurgh et al. (14).

a. *Continuous Method, OD.* At pH 5.0, the release of 4-methylumbelliferone (MeUmb) can be followed continuously by difference absorption spectrophotometry at 347 nm. Enzyme assays are done at 25°C in 50 mM sodium acetate buffer, pH 5.0, using substrate concentration of 10–2000 μM. Concentrations of MeUmb glycosides can be determined using the molar absorption coefficient at 316 nm;  $\epsilon_m = 13,600 M^{-1} \text{cm}^{-1}$ .

b. *Fixed-Point Method, Fluorescent.* Using a discontinuous method, taking samples, and adjusting the pH to 10.0, the release of MeUmb can be monitored fluorometrically. The sensitivity of the discontinuous fluorometric method is significantly greater (< 1 μM of MeUmb) than the continuous method at pH 5.0. The reaction conditions used are the same as in the continuous assay, but the reaction is stopped by the addition of an equal volume of 50 mM Na glycine, pH 10, in 50% ethanol. The relative fluorescence is then measured (excitation 366 nm, emission > 400 nm). A calibration curve is made using standard solutions of MeUmb (recrystallized from ethanol).

### D. Chromatographic Methods

#### 1. HPLC Method

Separation of substrates and products by HPLC can be used to analyze product distribution of individual cellulases for classification and to determine specificity of cellulases when using cello-oligosaccharides. Several different procedures have been used successfully with a variety of different separation procedures. Labeled

and unlabeled substrates and products have also been used.

a. *Unlabeled Sugar Substrates* (15). Separation of unlabeled sugars using Aminex columns with detection by refractive index is one of the more common procedures used. These columns have the distinct advantage that they use water, or in some applications, dilute sulfuric acid as the eluent. In application to cellulases analysis, the HPX-87P (Pb form) and the HPX-42A (Ag form) for monosaccharides and oligosaccharides analyses, respectively, are used most frequently.

An HPLC system using an Aminex column (ideally with a deashing guard column), a column heater, and a refractive index detector is required. Samples are prepared using an appropriate hydrolysis system followed by inactivation of the enzyme by heating (5 min in boiling water). If the final pH is not between 5 and 9 for the HPX-87P or between 6 and 8 for the HPX-42A, the pH should be adjusted to prevent loss of column performance. Samples are then filtered through 0.45- $\mu$ m filters and injected (10–20  $\mu$ L) into the HPLC system. Flow rates of 0.4–0.8 mL/min are used with column temperatures of 60–85°C. Quantification of results is accomplished by running external standards and constructing response factors for each sugar.

b. *MeUmb-Labeled Substrates* (13). MeUmb-labeled cello-oligosaccharides are prepared according to Tilbeurgh et al. (14), or they are available commercially. Enzymes are mixed with substrates in 0.05 M acetate buffer, pH 5.0, with substrate concentration from 300–500  $\mu$ M and incubated at 25°C. Samples are taken from the reaction mixture (at 5 to 10-min intervals for 30–60 min) and diluted 1:3 in acetonitrile to stop the reaction. Inactivated samples (20  $\mu$ L) are injected into an HPLC system consisting of a 25  $\times$  0.46 cm Rasil-Polyol 5- $\mu$ m particle-size column from Alltech and a UV detector monitoring at 313 nm. The eluent is a mixture of acetonitrile and water (39:11, v/v) at a flow rate of 1.5 mL/min. Quantification of results is accomplished by running external standards and constructing response factors for each sugar using integrated peak areas. Using the same column and eluent, the unmodified cello-oligosaccharides can be analyzed using a refractive index detector.

## 2. Enzyme Detection in Polyacrylamide Gels (16)

The detection of cellulases in polyacrylamide gels is based on the hydrolysis of 5-bromoindoxyl- $\beta$ -D-cellobioside by endo-1,4- $\beta$ -D-glucanases to produce 5-bromoindoxyl. The product 5-bromoindoxyl is then

oxidized with nitroblue monotetrazolium (NBMT) producing an insoluble blue precipitate.

Standard gel electrophoresis is carried out using nondenaturing PAGE or isoelectric focusing systems. The incubation solution is prepared by first dissolving 5 mg of 5-bromoindoxyl- $\beta$ -D-cellobioside and 20 mg NBMT in 0.5 mL dimethylformamide followed by mixing with 20 mL of 0.1 M sodium acetate buffer, pH 5.0. The gel is added to the solution and incubated in the dark at 40°C until dark blue bands appear. The development time is 2–15 h and is dependent on the concentration of active enzyme in the gel. Gels can be scanned or photographed for preservation. The staining solution can be used many times before discarding.

## 3. Gel Electrophoresis of Products (17–19)

a. *ANTS Reagents*. A 0.2-M solution is prepared by dissolving 0.086 g of 8-aminonaphthyl-1,3,6-trisulfonate (ANTS) in 5 mL of a solution of glacial acetic acid/water (3:17; v/v).

b. *Reducing Agent*. A 1.0-M solution of sodium cyanoborohydride (NaCNBH<sub>4</sub>) is prepared in HPLC-grade dimethylsulfoxide (DMSO) by the addition of 2.5 mL DMSO to 0.25 g NaCNBH<sub>4</sub>.

c. *Procedure*. Enzymatic hydrolysis reactions are carried out using 0.05 M ammonium acetate buffer, pH 5.0, and inactivated by a change in pH using ammonium hydroxide. The use of this volatile buffer system prevents high salt concentrations and allows samples to be dried before labeling with the ANTS reagent. Following hydrolysis, the inactivated reaction is centrifuged and the necessary volume (10–50 nmoles reducing sugar) is transferred to a microcentrifuge tube and dried using a vacuum centrifuge.

The dried sample containing 10–50 nmoles of reducing sugar is labeled by adding 5–10  $\mu$ L of the ANTS reagent and 5–10  $\mu$ L of the reducing agent. This mixture is vortexed for 10 sec and centrifuged briefly to bring reagents together. The reaction is incubated at 40°C for 15 h.

Electrophoresis is done using a 5–36% gradient acrylamide gel with a Tris-glycine buffer system, pH 8.3, and a 5% stacking gel, pH 6.8 (no SDS is incorporated). [The acrylamide stock solution used to prepare gels is acrylamide/bis-acrylamide (39:2 w/w).] The labeled sample is diluted with four times loading buffer (40% glycerol in 0.2 M Tris-HCl buffer, pH 6.8) and applied to sample wells. Current is applied and the migration monitored by use of a hand-held UV moni-

tor. The gel is removed when the fluorescent dye front reaches the bottom of the gel. Gels are documented by photography on a UV gel box. A Polaroid camera is used with a  $4 \times 5$  film holder model 545, type 55 film, which gives a negative and a positive image, and a No. 8 filter.

#### 4. Capillary Electrophoresis of Products (17, 19)

a. *Saturated Trisodium Phosphate (TSP).* An excess of TSP is added to water and mixed. Solution is kept at room temperature.

b. *Phosphoric Acid.* Commercial 85% phosphoric acid ( $8.67\text{ M}$ ) is diluted to  $1\text{ M}$  with deionized water.

c. *Running Buffer.* Phosphoric acid  $100\text{ mM}$  is titrated to pH 2.5 using triethylamine (TEA). The final solution is  $\sim 100\text{ mM}$  phosphate,  $36\text{ mM}$  TEA.

d. *Procedure.* Hydrolysis samples are labeled as above for gel electrophoresis but diluted with water (1:10) rather than loading buffer. A capillary electrophoresis system with an inactivated capillary column ( $60\text{ cm} \times 50\text{ }\mu\text{m}$ ) and phosphate-TEA buffer, pH 2.5, is used. Injection is done using pressure at  $20\text{ psi} * \text{sec}$ . Separation is monitored at  $235\text{ nm}$  and samples are run at  $20\text{ kV}$  with the polarity  $(-)$  to  $(+)$ . Capillary and sample chamber temperatures are set at  $35^\circ\text{C}$ . Run times are  $\sim 15\text{ min}$ . The column is flushed with fresh buffer between runs.

The capillary is conditioned and cleaned before separation by sequentially flushing the column with saturated TSP, deionized water,  $1\text{ M}$  phosphoric acid, deionized water, and running buffer for 5 min each. When the column performance decreases, as indicated by a change in elution times, the column is again cleaned.

### E. Coupled Enzyme Methods

#### 1. Glucose Oxidase/Peroxidase Method (20)

The enzymatic determination of glucose concentrations for estimating cellulase activity is a useful method when reducing group determinations are not possible or when total cellulose conversion determinations are required. Several variations of the glucose oxidase/peroxidase assay for the determination of glucose concentration have been published. The primary difference is the particular compound used as the indicator. Kits are available from some chemical supply companies (Sigma).

a. *Glucose Reagent.* Dissolve  $1.5\text{ U/mL}$  peroxidase,  $9\text{ U/mL}$  glucose oxidase, and  $0.5\text{ mg/mL}$  of 2,2'-azino-di-(3-ethylbenzthiazoline)-6-sulfonate (ABTS) in  $0.12\text{ M}$  phosphate buffer, pH 7.0. A few drops of chloroform can be added to avoid bacterial growth. When stored at  $4^\circ\text{C}$  the solution is stable for several weeks.

b. *Procedure.* Glucose reagent ( $3\text{ mL}$ ) is added to  $1.0\text{ mL}$  of sample or standard in a  $16 \times 100\text{ mm}$  test tube. The tubes are incubated for 30 min at room temperature and the absorbance measured at  $450\text{ nm}$ . A standard curve of glucose ( $0\text{--}75\text{ }\mu\text{g}$ ) is used to determine the concentration in unknown samples.

#### 2. Cellobiose Dehydrogenase (Discussion Only)

Coupled enzyme methods using cellobiose dehydrogenase for determining cellulase activity have been published (21, 22). The methods require the use of enzymes from *Phanerochaeta chrysosporium* or *Humicola insolens* that are not commercially available and therefore their purifications will be required to use this method. These are among the few methods permitting a continuous measurement of cellulase activity and could prove extremely valuable in kinetic comparison between purified cellulases.

### F. Special Methods

In a detailed study of a purified cellulase, additional details about the enzyme activity can contribute to the characterization and classification of the enzyme. Several techniques will be discussed that have been developed for determination of some important factors.

#### 1. Inverting or Retaining—NMR Method (22, 23)

During the course of hydrolysis, the stereochemistry of the anomeric carbon formed is dependent on the structure and topology of the enzyme active site. Utilizing proton NMR, the hydrolysis of reduced cellooligosaccharides (i.e., cellobiohexaitol) can be monitored for the formation of  $\alpha$ - or  $\beta$ -anomers. The enzymes can then be classified as inverting or retaining based on the product stereochemistry. Dividing cellulases based on the primary sequences into families shows that there is very strong relationship between the family and the stereochemical course of hydrolysis.

## 2. Cellulose Chain End Determination Method (24)

Until recently it was believed that the mechanism of hydrolysis for exocellulases (cellobiohydrolases) was solely from the nonreducing end of the cellulose molecule. In 1996, Barr et al. (24) used  $^{18}\text{O}$  and  $^{14}\text{C}$  labeling of celooligosaccharides in conjunction with ion-spray mass spectrometry to determine the precise position and direction of hydrolysis of five different exocellulases from *Thermonospora fusca* and *Trichoderma reesei*. Their results support the conclusion that there are two different classes of exocellulases each working from different ends of the cellulose molecules.

## 3. Dialysis Reactor Cell Method (25)

Synergism is an interesting observation shown with cellulases and with other enzymes, such as amylase, that have insoluble substrates and multiple types of enzymes working on the same substrate. Determination of synergism is difficult, especially using a native substrate. Baker et al. (25) developed a microdialysis device for studying synergism using native or pretreated substrates, under conditions in which product inhibition is minimized. The reactor cell is loaded with substrate and enzymes and held under constant temperature. The cell is continually flushed with fresh buffer, and the eluent is collected and assayed using HPLC sugar analysis.

## Cellulases in Food Processing

**Maija Tenkanen, Marja-Leena Niku-Paavola, Markus Linder, and Liisa Viikari**

*VTT Biotechnology, Espoo, Finland*

### I. INTRODUCTION

Plant materials contain different  $\beta$ -glucans, mainly celluloses and mixed 1,3-1,4- $\beta$ -glucans. Cellulases belong to the group of  $\beta$ -glucan hydrolases that have the ability to degrade cellulose. Enzymes often called  $\beta$ -glucanases that are able to hydrolyze  $\beta$ -1,4-linkages in other materials, such as in water-soluble  $\beta$ -glucans, but not in cellulose, are not covered in this chapter. Cellulases are not among the main enzymes used in the food industry. They are, however, applied in processing of cereal-based beverages and foods such as beer and bread. Cellulases are used in rather large amounts in animal feed. As a consequence of modern enzyme production technologies, which enable the production of more selective, tailor-made enzyme products, and owing to the increased knowledge of the structure-function relationship of food components, the use of cellulases may increase in the future in food processing.

### II. CELLULOSE: A CHEMICALLY SIMPLE BUT STRUCTURALLY COMPLEX SUBSTRATE

Cellulose is the most abundant biopolymer on earth. It is mainly produced in higher plants, e.g., woods as well as annual plants in which it forms the rigid skeleton of the plant. In addition, all algae produce highly crystal-

line cellulose. Some bacteria, especially *Acetobacter xylinum*, are also able to synthesize cellulose.

Cellulose is chemically a very simple polymer. It is a homopolymer consisting of up to 1000  $\beta$ -1,4-linked anhydroglucopyranoside units. However, its physical state makes it a very challenging substrate for enzymes. Single glucose polymers are packed onto each other to form a highly crystalline fibrillar material in which the individual cellulose chains are held together by hydrogen bonds. Cellulose microfibrils also contain some amorphous regions, the amount of which depends on the source. The most crystalline cellulose is produced by algae, and the least crystalline by plants.

Animals do not possess digestive enzymes able to degrade crystalline cellulose. However, several microorganisms, including filamentous fungi, yeast, and bacteria, existing in the intestine and colon of monogastric animals are able to hydrolyze cellulose to oligosaccharides and eventually to glucose, which they can then use as a carbon source. Ruminants, particularly, are able to fully degrade cellulose in their rumen by the wide spectrum of microorganisms present. To meet the challenge of degradation of crystalline and water-insoluble cellulose, microorganisms produce a complex mixture of several enzymes, which act synergistically. There are also several reports on plant cellulases, which are involved in plant cell expansion for loosening the cell walls during the growth of cell (1). Cellulase from different microorganisms have been thoroughly reviewed during the last decade (2–7).

### III. CLASSIFICATION OF CELLULASES

All cellulases act on the chemically identical bond, i.e., the  $\beta$ -1,4-linkage between two anhydroglucose units. However, they differ in terms of their site of attack on the cellulose chain. Enzymes acting on cellulose have traditionally been classified by the International Union of Biochemistry (IUB) ([www.expasy.ch/cg1-bin/enzyme-search-cl](http://www.expasy.ch/cg1-bin/enzyme-search-cl)) into two distinct groups, endoglucanases and exoglucanases, which act in the middle of the cellulose chain or at either end of the cellulose chain, respectively (Fig. 1; Table 1). However, this classification is not very satisfactory, as some exoglucanases have also been claimed to possess endoactivity (8, 9). The classification of cellulases becomes even more complicated as some also have activity on other polysaccharides, such as xylan (10). Therefore, a new classification of these enzymes, as well as of other glycosyl hydrolases, have been suggested based on their structural similarities (11). This, however, requires information on their amino acid sequence which is not always available.

At present, the different glycosyl hydrolases are grouped according to the structures of their catalytic domains into more than 70 families ([afmb.cnrs-mrs.fr/~cazy/CAZY/index.html](http://afmb.cnrs-mrs.fr/~cazy/CAZY/index.html)). In addition, some of the families have further subfamilies. The classification is based on sequence alignments and hydrophobic cluster analysis (HCA) (12), but it has been proven to correlate well with the three-dimensional structures and

reaction mechanisms. So far, some families contain only enzymes with the same catalytic activity, but most contain both endo- and exoglycanases being able to act on different polymers. For example, family 5 contains endoglucanases, exoglucanases, endomannanases, and endoxylanases. Currently, there are cellulases in 11 glycosyl hydrolase families (families 5–10, 12, 26, 44, 45, and 48).

The new suggestion for the naming of different cellulases is based purely on their assignment to these glycosyl hydrolase families (11). If there is more than one enzyme belonging to the same family from one organism, the enzymes are further named with running alphabets in the order that they have been classified. For example *Trichoderma reesei* Cel7A (CBH I) and Cel7B (EG I) are two cellulose degrading enzymes in the glycosyl hydrolase family 7. In this chapter, the old naming system using endoglucanases and cellobiohydrolases is used since most publications still use this nomenclature.

The endoglucanases (EG) (1,4- $\beta$ -D-glucan-4-glucanohydrolase, EC 3.2.1.4) catalyse random cuts in cellulose chains, thereby producing shorter and shorter cello-oligomers, which can be further degraded by exoglucanases. The trivial name given by the IUB for endoglucanases is cellulases, which is very misleading as cellobiohydrolases (CBH) (1,4- $\beta$ -D-glucan cellobiohydrolase, EC 3.2.1.91) also act on cellulose and are actually the main enzymes responsible for the degradation of crystalline cellulose. Therefore, in this chapter the name cellulase covers all enzymes that are able to degrade polymeric celluloses, i.e., both EGs and CBHs. The final degradation of cello-oligomers produced by EGs and CBHs to glucose is accomplished by  $\beta$ -glucosidases (BGL) (EC 3.2.1.21). In addition to  $\beta$ -1,4-linkages, the latter enzymes are often also able to hydrolyze other  $\beta$ -glucosidic linkages, and although they are not able to hydrolyze polymeric cellulose they are, owing to their action on cello-oligosaccharides, usually considered as part of cellulolytic enzyme system.

CBHs cleave predominantly cellobiose units from either the reducing or nonreducing ends of cellulose chains and cello-oligosaccharides (Table 1). CBHs normally produce a small amount of celotriose when acting on cello-oligosaccharides. Substitution of cellulose chains blocks the action of CBHs, but most of them are able to hydrolyze 1,4- $\beta$ -linkages in mixed 1,3-1,4- $\beta$ -glucans, which exist in high quantities in the cell walls of grains (Table 2).

EGs are mainly active on amorphous cellulose, thus breaking down the less ordered amorphous parts of

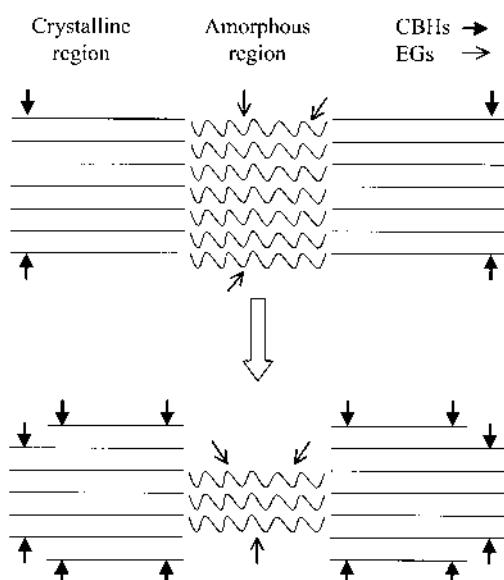

Figure 1 Hypothetical picture of cellulose degradation.

**Table 1** Classification of Enzymes Acting on 1,4- $\beta$ -Glucans

Action	Systematic name	Trivial name(s)	EC No.	Substrate specificity	Linkage hydrolyzed	Main products formed
Endo	1,4- $\beta$ -D-glucan-4-glucanohydrolase	Cellulase, endoglucanase (EG)	3.2.1.4	Cellulose, 1,3-1,4- $\beta$ -glucans	1,4- $\beta$	1,4- $\beta$ -dextrans, mixed 1,3-1,4- $\beta$ -dextrans
	1,3-1,4- $\beta$ -D-glucan-4-glucanohydrolase	Lichenase, $\beta$ -glucanase	3.2.1.73	Lichenin, 1,3-1,4- $\beta$ -glucans	Next 1,4- $\beta$ after 1,3- $\beta$ -linkage	Mixed 1,3-1,4- $\beta$ -dextrans
	1,3- $\beta$ -D-glucan-3/4-glucanohydrolase	Laminarinase	3.2.1.6	Laminarin, 1,3-1,4- $\beta$ -glucans	Next 1,4- $\beta$ - or 1,3- $\beta$ -after 1,3- $\beta$ -linkage	Mixed 1,3-1,4- $\beta$ -dextrans
	1,3- $\beta$ -D-glucan-3-glucanohydrolase	Laminarinase	3.2.1.39	Laminarin, pachyman, (1,3-1,4- $\beta$ -glucans)	1,3- $\beta$	1,3- $\beta$ -dextrans (1,4- $\beta$ -dextrans)
Exo	1,4- $\beta$ -D-glucan-cellulohydrolase	Cellobiohydrolase (CBH)	3.2.1.91	Cellulose, 1,3-1,4- $\beta$ -glucans	1,4- $\beta$	Cellobiose
	1,4- $\beta$ -D-glucan-glucohydrolase	Exoglucanase	3.2.1.74	1,4- $\beta$ -glucans	1,4- $\beta$	Glucose
	$\beta$ -Glucosidase	Cellobiase	3.2.1.21	Wide variety of $\beta$ -D-glucosides	1,4- $\beta$ 1,3- $\beta$ 1,6- $\beta$	Glucose

**Table 2** Specific Activities of the Major *T. reesei* Cellulases Against Different Substrates

Enzyme	Specific activity <sup>a</sup> (nkat/mg)			
	HEC	$\beta$ -GLC	XYL	MUC
EG I	540	3920	550	60
EG II	1170	6850	3	3.4
CBH I	2	12	3	3.2
CBH II	2	72	2	0

<sup>a</sup> Substrates used in the measurement: HEC = hydroxyethylcellulose;  $\beta$ -GLC =  $\beta$ -glucan from barley; XYL = birch xylan; MUC = methylumbelliferyl cellobiose.

cellulose fibers (13). Some bacterial EGs are also claimed to be able to degrade crystalline parts of cellulose microfibrils (14). EGs are highly active on various water-soluble cellulose derivatives such as carboxymethyl cellulose (CMC) and hydroxyethyl cellulose (HEC), which are often used as substrates for determination of the endoglucanase activity (see Chapter 61). In addition, EGs hydrolyze  $\beta$ -1,4 linkages in mixed 1,3-1,4- $\beta$  glucans. There are also other enzymes, which are able to hydrolyze  $\beta$ -1,4-glycosidic linkages in soluble  $\beta$ -glucans (Table 1) (Fig. 2). However, as they are not able to hydrolyze cellulose, these enzymes are not discussed here (see Chapter 74).

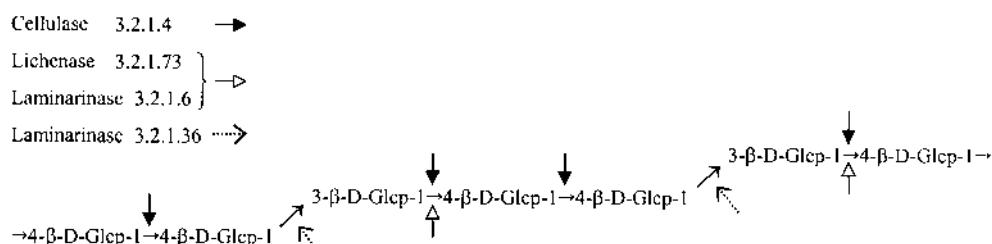

EGs are basically able to hydrolyze all polysaccharides containing  $\beta$ -1,4-linked glucopyranosyl units, such as xyloglucans (1,4- $\beta$ -glucan backbone with side chains made up of xylose, galactose, and occasionally fucose) (see Chapter 73). These are present in small quantities in plants but are the predominant polysaccharides in tamarind seeds. Many EGs are also able to hydrolyze polymers in which glucose is  $\beta$ -1,4-linked to other glycosyl units. Thus, for example, the  $\beta$ -1,4-linkages between glucose and mannose units in glucomannans are cleaved by EGs (see Chapter 75). Glucomannans are interesting food hydrocolloids and they exist in

high quantities in some plants, such as in konjac tubers. Some EGs act also on other  $\beta$ -1,4-glycosidic linkages. One example of this lack of specificity is the EG I from *T. reesei* which is also able to hydrolyze  $\beta$ -1,4-xylosidic linkages in xylans (Table 2) (see Chapter 71).

#### IV. METHODS TO ASSAY CELLULASES

The determination of cellulase activities is not a very easy task, as the degradation of the water-insoluble, highly crystalline cellulose is not linear with time and different enzyme dosages. Therefore, several "nonnatural" substrates are normally used. As mentioned earlier, soluble cellulose derivatives are often used to assay EG activity. These are rather specific to EGs, as CBHs are not generally able to degrade substituted celluloses (Table 2). The international standard assay for measuring EGs is based on the hydrolysis of HEC (15). Soluble cereal, 1,3-1,4- $\beta$ -glucans can also be used as substrates. They are degraded by EGs and by many CBHs. However, 1,3-1,4- $\beta$ -glucans are not a specific substrate for cellulases as other  $\beta$ -glucanases are also able to degrade it. Amorphous cellulose has been used as a substrate mainly for EGs, but in many cases the enzymatic reaction is not linear or is linear only at the short initial reaction stage. Recently, a novel method for the preparation of totally amorphous cellulose beads has been developed (Pettersson, unpublished). These beads can also be made from dyed cellulose and were shown to be excellent substrates for EGs.

There are several ways to analyze the degree of degradation of the substrate. It can be based on the reduction in viscosity, on the formation of new reducing groups, or on the liberation of dyed oligosaccharides from chromophoric polymers. The viscosity method is the most sensitive one and can be used to measure very low levels of EGs, for example, from plant extracts. It is also highly specific to EGs, as exo-glycanases do not affect the viscosity of the polymer.

**Figure 2** Endoglucanases acting on 1,3-1,4- $\beta$ -glucans.

The action of EGs and CBHs is difficult to differentiate in the methods based on the formation of reducing groups.

The activity of CBHs is often measured by using small fluorogenic substrates such as methylumbelliferyl cellobioside or methylumbelliferyl lactoside. However, these substrates are specific not only to CBHs as some EGs also degrade them (Table 2). The activity of  $\beta$ -glucosidases is in most cases determined using *p*-nitrophenyl- $\beta$ -D-glucopyranoside as a substrate and measuring the color formed by the liberated *p*-nitrophenol. EGs and CBHs do not hydrolyze this substrate.

Naturally soluble oligosaccharides up to DP 6 can be used as substrates for all cellulases, and the formed degradation products are normally analyzed by HPLC. In some cases it is important to know the overall cellulolytic capacity of the sample, i.e., how well real cellulose is degraded by a mixture of different cellulases. This is normally measured by the international standard method using filter paper as a substrate and the activity is expressed as filter paper units (FPU) (15). The different methods used for assaying the hydrolysis of cellulose by cellulases are covered in more detail in a separate chapter (see Chapter 61).

## V. STRUCTURE-FUNCTION RELATIONSHIPS IN CELLULASES

A two-domain structure consisting of a catalytic domain and a separate substrate-binding domain is typical for cellulose-degrading enzymes from both bacteria and fungi. The existence of substrate-binding domains is also common in other enzymes which degrade solid substrates. In fungal enzymes the cellulose-binding domains (CBDs) are typically linked to the catalytic domain (catalytic core) by linkers which clearly separate the two domains (Fig. 3). The CBDs can be found in either the C or N terminus of the enzyme. In some cases, such as in the bacterium *Thermomonospora fusca* enzyme E4, the CBD forms a more integral part of the enzyme (16). Some bacteria have been reported to produce multidomain proteins which contain different, covalently linked catalytic domains hydrolyzing cellulose and hemicelluloses as well as several binding domains (17).

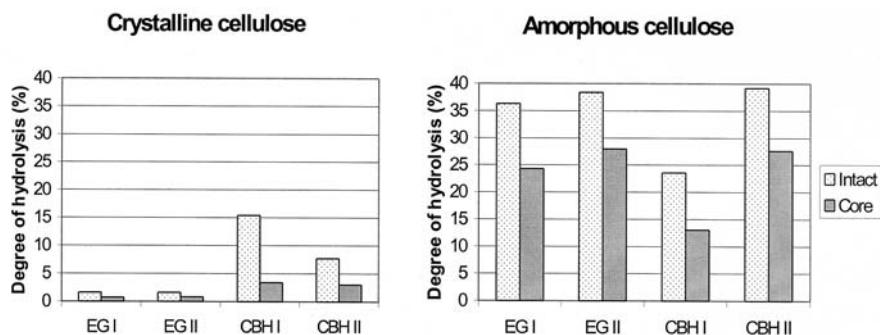

Many aerobic organisms produce large complexes called cellulosomes, which are clusters of different non-covalently linked proteins (18, 19). The assembly and action of cellulosomes have been studied by cloning the genes of the different subunits. Cellulosomes may consist of several EGs, CBHs, and other glycanases, but

**Figure 3** Model showing the two-domain structure of CBH from *T. reesei*. The larger catalytic domain is connected by the linker to the smaller cellulose-binding domain (CBD). Model coordinates provided by Christina Divne, Uppsala University.

also proteins involved in binding and targeting the cellulosome to the substrate. The individual enzymes alone in the complex normally have no significant activity against crystalline cellulose, but the cellulosome hydrolyzes it actively. Each enzyme component is attached to a nonenzymatic protein called scaffoldin, via a conserved docker sequence. The scaffoldin polypeptide contains a CBD and internal repeats (cohesins) which interact with enzymes. The molecular weight of cellulosomes can be as high as 2000 kDa.

Although 13 families of CBDs have been identified based on sequence homology, only one of them (family 1) occurs in fungi (20). The fungal CBDs are distinguished by their small size (< 40 amino acid residues). Like most other carbohydrate-binding proteins, the binding to cellulose has been shown to be largely dominated by interactions from aromatic amino acid residues. The CBDs have been shown to be important for the function of cellulases on solid substrates (Fig. 4). If they are removed either by proteolysis or protein engineering, both activity and binding to solid substrates are greatly decreased (21, 22). In many experiments the binding of cellulases to cellulose has been seen to be irreversible, which has sometimes been ascribed to the CBD. The interaction is complex, however, and is seen as interplay between the catalytic and binding domains which results in a synergistic binding to cellulose (23). At least in the case of fungal enzymes, no evidence has

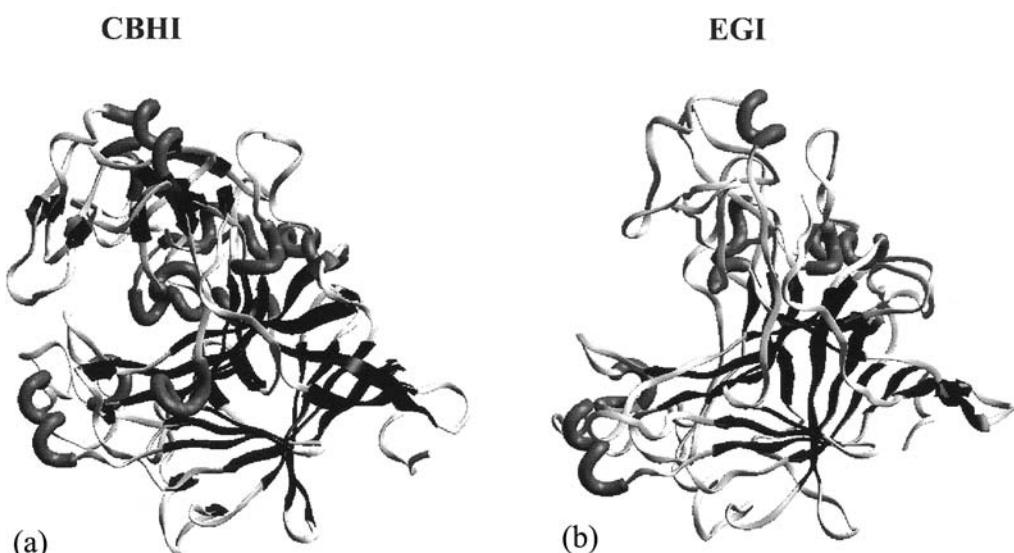

**Figure 4** Hydrolysis of bacterial crystalline cellulose and amorphous cellulose by *T. reesei* cellulases and the corresponding core proteins (300 nmol/g, pH 5, 50°C, 20 h).

been presented which would show that CBDs have one active role in hydrolysis of the crystalline cellulose, e.g., breaking down the hydrogen bonds. CBDs have been reported to lower the apparent  $K_m$ , but also to reduce the apparent  $k_{cat}$  probably by slowing down the mobility of the enzyme (24).

Owing to several three-dimensional protein structures of cellulases that are available together with detailed biochemical characterization, many special structural features of cellulases have been revealed. For example the EG I and the CBH I of *T. reesei* have a sequence identity of ~45%. Comparison of their structures shows that the active site of CBH I is located in a tunnel formed by surface loops, while many of these loops are missing in EG I, which gives

this enzyme a much more open active site (Fig. 5). The tunnel shape of the active site in the CBH I, as well as that found in other CBHs, gives a structural explanation for the action of the enzyme. It is thought that the long tunnel keeps the enzyme bound to the same cellulose chain by multiple interactions as it progressively moves along the chain hydrolyzing cellobiose units. The open active site groove found in EGs allows them to hydrolyze in the middle of cellulose chains (25–27). It has been speculated that cellulases can display more or less a continuum of structures with active sites covered to different degrees, giving more “endo-like” or “exo-like” enzymes, making the division unclear as mentioned earlier. The degree of endo- or exo-character can be determined by either the pre-

**Figure 5** Comparison of the structure of endo- and exoglucanases. (A) Core domain from CBH I; (B) core domain of EG I from *T. reesei*.

sence/absence of the loops, or their flexibility. An issue, which is still not understood for CBHs is how the cellulose chain is picked up from the crystalline cellulose and how it is targeted to the tunnel. In the case for CBH II from *T. reesei*, a region on the outer side of the tunnel has been shown to be important for the hydrolysis of crystalline cellulose, but not for soluble substrates or amorphous cellulose (28).

Cellulases, like all glycosidases, catalyze the hydrolysis of the glycosidic bonds by general acid catalysis (29). The reaction involves two essential catalytic carboxylates, the proton donor and the nucleophile, which are generally located on opposite sides of the scissile bond. Depending on the structure of the active site, the cleavage proceeds by either retention or inversion of the configuration of the ( $\beta$ ) anomeric carbon (29). Based on the structure of the active-site tunnel, some cellulases are proposed to twist the cellulose chain at the active site in order to expose the scissile bond better (25). The active sites have been shown to bind up to 10 glucose units. Since the active sites contain several sugar binding sites, it is convenient to have a common nomenclature for them. The bond cleavage occurs at the bond between the  $-1$  and  $+1$  sites so that the + direction is toward the reducing end of the sugar chain and the - direction is toward the nonreducing end.

## VI. FUNGAL CELLULASES

Cellulolytic fungi occur in all major taxa (30, 31), but the current knowledge of fungal cellulases has been obtained mainly by studying deuteromycetes *Trichoderma* (21), *Penicillium* (13), and *Humicola* (24). Other significant fungi-producing cellulase are the plant pathogen *Fusarium solani* (32), *Aspergillus aculeatus* (33), and the ascomycete *Neurospora crassa* (34). Cellulase producers have also been found among anaerobic rumen fungi, the first example of which was *Neocallimastix frontalis* (35). Studies on the white rot fungi *Sporotrichum pulverulentum* (anamorph of *Phanerochaete chrysosporium*) (36) and *Phanerochaete chrysosporium* (37) have revealed that lignin-degrading fungi are also able to produce a complete set of cellulolytic enzymes depending on the culture conditions. The studies on brown rot fungi suggest that these organisms produce only EGs and  $\beta$ -glucosidases (38).

Most cellulolytic fungi produce a mixture of several EGs, CBHs, and  $\beta$ -glucosidases to be able to degrade crystalline cellulose into glucose (Table 3). Fungal enzymes are normally glycosylated, and the isoforms, having different isoelectric points, make the purification and characterization of individual enzymes difficult. In addition, the culture filtrates often contain the catalytic core domains of cellulases as the native

**Table 3** *T. reesei* and *H. insolens* Cellulases

Fungi	Enzyme	New name	Size (kDa)	pI	Remarks	Optimal pH	Reference

enzymes are sometimes cleaved at the linker region by secreted proteases. Therefore, confusing literature exists on the number of individual enzymes produced by different fungi. After cloning the genes encoding the corresponding cellulases, the picture will become clearer.

The commercial cellulases are mainly produced with *T. reesei* and *H. insolens*. In addition, individual *H. insolens* genes have been cloned into a noncellulolytic *Aspergillus* strain and produced as monocomponent enzymes. However, these enzymes are not yet available for food use. The current *T. reesei* strains, which have been developed by classical mutagenesis from the native strain, are among the most powerful producers of extracellular proteins (39, 40). When grown on cellulose, ~90% of the extracellular protein consists of four major cellulases (~50% CBH I, 20% CBH II, 10% EG I, and 10% EG II). Several tailor-made *T. reesei* strains have been recently developed by deleting the genes encoding unwanted enzymes, thus leaving for example only one of the four major cellulases (40). *T. reesei* is also nowadays used as a host organism for the production of other glycosyl hydrolases (41, 42).

#### A. Cellulases from *T. reesei*

*T. reesei* is the most thoroughly studied cellulolytic organism. It is reported to produce at least five different endoglucanases (EG I through EG V), two cellobiohydrolases (CBH I and CBH II) and two  $\beta$ -glucanases (BGL I and BGL II) (Table 3). All EGs, except EG III, and both CBHs have a modular structure with a separate catalytic core domain and a CBD. EG I differs from the other EGs in being able to also hydrolyze xylan (10). Its specific activity on the water-soluble xylan is about the same as the activity on the soluble cellulose derivative HEC (Table 2). All EGs act mainly on amorphous cellulose (Fig. 4). However, EG II has been shown to reduce the degree of polymerization much faster than EG I (43).

CBH I and CBH II from *T. reesei* both act on the cellulose chain ends, but they clearly have different substrate specificities. CBH I acts from the reducing end of the cellulose chain whereas CBH II starts the action from the nonreducing end (7, 44). Thus, all these cellulases act on different parts of the cellulose chain and complement each other in the total hydrolysis of cellulose. CBH I has a rather unique action as most exoglycanases act from the nonreducing end. CBH I, which is clearly the major enzyme produced by *T. reesei*, has been found to be the key enzyme in the degradation of crystalline cellulose. Deletion of the

gene encoding CBH I has resulted in >70% reduction in the filter paper degrading activity, whereas deletion of other cellulases had only a minor effect (45).

Electron microscopy studies have shown that CBH I causes lateral thinning of cellulose microfibrils, whereas CBH II has been reported to sharpen the crystal ends (46, 47). CBH I seems to be a more processive enzyme than CBH II. This might be due to a longer tunnel in CBH I having 10 glucose binding sites (25). However, the action of CBHs on crystalline cellulose is at least 10 times slower than their action on soluble cellulose derivatives (28). Thus, it seems that stripping the cellulose chain from the crystal and targeting the chain end to the active site is the rate-limiting step. It might also be that the transfer of the cellulose chain along the active site for the next cut is a slow process compared to the actual hydrolytic action. *T. reesei* CBH I is also very sensitive to end-product inhibition (48). The *Trichoderma* enzymes usually exhibit the highest activity at acid pH (~5) and at temperatures <55°C.

#### B. Cellulases from *H. insolens*

The other commercially interesting fungus, *H. insolens*, produces an almost identical pattern of cellulases to *T. reesei*, having at least five EGs, two CBHs, and several  $\beta$ -glucosidases. These enzymes are also structurally similar, thus belonging to same glycosyl hydrolase families (Table 3). In addition, there exists remarkable homology (>50%) in the amino acid sequences between the corresponding cellulase component of *T. reesei* and *H. insolens*. However, several *H. insolens* cellulases work at higher pH and higher temperatures than *T. reesei* enzymes and have therefore found commercial applications, especially in textile treatments (49).

Two *H. insolens* cellulases, EG I and EG III, are lacking the CBD. EGs I–III show similar activity toward CMC and amorphous cellulose, while EGs V–VI have the highest catalytic activity on amorphous cellulose. None of them has been reported to be active in hydrolyzing xylan. *H. insolens* CBH I degrades crystalline cellulose, but it is clearly less sensitive to end product inhibition than CBH I from *T. reesei*.

#### C. Other Fungal Cellulases

Many *Aspergillus* spp. produce cellulases. *A. aculeatus* produces several cellulases (33) of which EG V, EG I, and CBH I have clear similarities to EG II, EG III, and CBH I from *T. reesei*, respectively (afmb.cnrs-mrs.fr/

[~cazy/CAZY/index.html](http://afmb.cnrs-mrs.fr/~cazy/CAZY/index.html)). Noncellulolytic *Aspergillus* spp., mainly *A. oryzae*, are often used as hosts for transformed cellulase genes from other fungi (50). *Penicillium* strains are also good cellulase producers. *P. pinophilum* produces an extensive set of endoglucanases (13). EG II and CBH I of *P. janthinellum* are homologous to EG II and CBH I of *T. reesei* (51).

Among anaerobic cellulolytic rumen fungi, *Neocallimastix frontalis* has been studied most extensively (35). It is reported to produce a cellulosome-like protein complex containing EG, CBH, and xylanase (52, 53). Other rumen fungi, e.g., *Piromyces* sp., produce similar cellulase complexes. It has been speculated that cellulases from anaerobic rumen fungi would hydrolyze crystalline cellulose more actively than enzymes from aerobic fungi (35).

Studies on the white rot fungi *Sporotrichum pulverulentum* (anamorph of *Phanerochaete chrysosporium*) and *Phanerochaete chrysosporium* have revealed that lignin-degrading fungi are able to produce a complete set of cellulolytic enzymes (36, 37). Four *P. chrysosporium* CBH Is are classified into family 7 and CBH II into family 6 ([afmb.cnrs-mrs.fr/~cazy/CAZY/index.html](http://afmb.cnrs-mrs.fr/~cazy/CAZY/index.html)). Interestingly one of the CBH Is is lacking the CBD.

The studies on the brown rot fungi suggest that these fungi possess both an oxidative and hydrolytic pathway in cellulose degradation. The initial step in the hydrolysis of crystalline cellulose is speculated to be nonenzymatic. Brown rot fungi have been reported to produce only EGs and  $\beta$ -glucosidases (38). The degradation of cellulose by white rot and brown rot fungi is different. The action of brown rot fungi is directed toward the whole cellulose microfibrils, whereas white rot fungi attack the surfaces of the microfibril, producing progressive erosion (54).

## VII. BACTERIAL CELLULASES

Bacteria harbor several systems for cellulose degradation. They can produce extracellular EGs and CBHs, cell-bound enzymes, or powerful enzyme complexes. For example, the following bacterial species secrete low amounts of EGs and CBHs: *Clostridium*, *Acetovibrio*, *Ruminococcus*, *Streptomyces*, *Microspora*, and *Cellulomonas* (55). *Cellulomonas fimi* cellulases are among the most extensively studied bacterial cellulases. Four secreted EGs (CenA, -B, -C, -D), one CBH (CbhA), and one cellulase-xylanase (Cex) have been characterized both at the biochemical and genetic levels (56). The cellulases of *Actinomycetes*, *Corynebacteria*, *Thermomonospora fusca*, and *Microbispora bispora*

have also been studied in detail (57, 58). Several *Streptomyces* spp. have been reported to produce cellulases. These filamentous bacteria are able to secrete both EGs and CBHs.

Some bacteria do not produce cellulolytic enzymes separately but rather as large cellulosomes (18). The most thoroughly studied cellulosome is from *Clostridium thermocellum*. The individual cellulase components cloned from *C. thermocellum* are three CBHs, 21 EGs, six xylanases, two  $\beta$ -glucosidases, and two lichenases (59). The main cellulase component is the exoglucanase CelS, which alone is able to slowly hydrolyze microcrystalline cellulose, but when linked to the anchoring protein containing the CBD it hydrolyzes this substrate extensively (60). However, none of the bacterial CBHs characterized until now belong to the family 7, but several are in the family 6 ([afmb.cnrs-mrs.fr/~cazy/CAZY/index.html](http://afmb.cnrs-mrs.fr/~cazy/CAZY/index.html)). Cellulosomes are also formed by the following bacteria: *Bacteroides*, *Acetivibrio*, *Bacillus*, *Butyrivibrio*, *Cellulomonas*, *Fibrobacter*, and *Thermomonospora* (18). Thermophilic bacterium *Caldocellulosiruptor saccharolyticus* produces an interesting multidomain enzyme that contains two catalytic domains, EG and mannanase, and two substrate-binding domains (17).

Bacterial cellulases have in many cases been reported to have much higher specific activities than fungal cellulases. However, bacteria generally produce extracellular cellulases in much lower quantities than fungi. In addition, several bacterial cellulases exist as part of a cellulosome. Therefore, their production, especially by using native strains, is difficult and uneconomic at large scale compared to the production of fungal cellulases. Individual bacterial cellulases have, however, been cloned and produced at an industrial scale in more suitable host organisms. These types of products are entering the markets, but they are still used only in nonfood applications.

## VIII. ENDOGENOUS CELLULASES IN PLANTS

Several plants, for example cereals, produce endogenous enzymes acting on  $\beta$ -1,4-glucosyl linkages (see Chapter 74). However, these enzymes are reported to be mainly active on mixed-linked 1,3-1,4- $\beta$ -glucans and do not possess activity on cellulose. There are also several reports on true cellulases in plants (1, 61). So far only EGs have been found in plants; there are no reports on CBHs. In contrast to fungal and bacterial EGs, plant enzymes lack the CBD. Plant EGs have

been found to degrade only amorphous cellulose in vitro. The exact substrate in vivo is not known, but it is thought to be xyloglucan (1). Endogenous plant EGs have been suggested to play a role in plant development, e.g., in fruit ripening and leaf abscission, or in the rearrangement of polysaccharides in growing cells. The mode of action of EGs in cell expansion could be either to promote wall loosening or to contribute to the incorporation of new microfibrils in the growing wall (61). There are several projects ongoing around the world screening different plant genomes. Owing to fast, modern screening techniques, several new enzymes, which are able to hydrolyze cellulose, will almost surely be found in the near future.

One interesting group of proteins is the expansins, which have been found in several plants (62). The action of these proteins is not well understood, but they are believed to break down the hydrogen bonds between individual cellulose chains during growth of the plant cells. Expansins are currently not classified as enzymes as they seem not to act on any covalent linkages. One study has been carried out on the production of an expansins type protein by the fungus *T. reesei* (Markku Saloheimo, unpublished).

## IX. ROLE OF DIFFERENT CELLULASES IN THE HYDROLYSIS OF CELLULOSE

To study the biochemical properties of cellulases, absolutely pure enzymes are needed. The purification of individual cellulases from the mixture is often very difficult even using specific affinity chromatography techniques (63). It has been shown that minor (0.4%) contamination of an EG makes a significant difference in the action of a CBH (64). Cross-contamination can be avoided by gene cloning and expressing the individual cellulases in noncellulolytic hosts (65). Another possibility is to delete most of the cellulase genes from the cellulolytic organism and leave only the one encoding the acceptable activity (66). The enzyme preparation used in the studies must also carefully be characterized and confirmed to be a whole, intact protein since core parts are produced by proteolysis during cultivation. It has clearly been demonstrated that CBDs are necessary in the hydrolysis of both crystalline and amorphous cellulose (Fig. 4) (67). However, the hydrolysis of soluble substrates, which are often used in the activity assays, is not dependent on the presence of CBDs.

For complete hydrolysis of crystalline cellulose an effective mixture of different cellulases is needed. The

key enzymes are CBHs possessing activity on crystalline cellulose. These enzymes are sometimes even able to degrade crystalline cellulose totally on their own, but the hydrolysis is very slow (60, 68). CBHs are thought to be processive enzymes, remaining bound to the substrate until it is totally degraded (69). They start their action from the ends of the cellulose chain, liberate cellobiose, and decrease the degree of polymerization (DP) of the substrate very slowly. EGs cleave bonds along the length of the cellulose chains, resulting in a faster decrease in DP of the substrate. Most EGs attack only the amorphous regions of cellulose and have different specificities toward the oligosaccharides liberated during hydrolysis. They are, however, highly active on polymeric water-soluble  $\beta$ -glucans such as carboxymethyl cellulose and cereal  $\beta$ -glucans, and even very low dosages of EGs reduce the DP rapidly.

Conventional kinetic parameters for cellulase reactions are not obtained while the substrate is changing during hydrolysis, and thus, only apparent values can be measured. Furthermore, the degradation of cellulose by individual cellulases is seldom linear, making kinetic measurements difficult. Therefore, water-soluble cellulose derivatives and cello-oligosaccharides up to DP 6 are normally used in kinetic studies for EGs and CBHs, respectively.

Cellulases have not been reported to have any specific inhibitors. Hg compounds, which inactive many glycosyl hydrolases, have been reported to affect the activity of CBH I more than EGI from *T. reesei* (70). End-product inhibition has often been considered as one reason for inefficient hydrolysis. The  $K_i$  values of cellobiose for different CBHs cannot be strictly compared because they have been estimated using different substrates. A very low  $K_i$  value (0.02 M) has been reported for *T. reesei* CBH I in the hydrolysis of methylumbelliferyl  $\beta$ -glucosides (48), whereas the  $K_i$  was 0.4 mM in the hydrolysis of celodextrins (71). CBH I from *H. insolens* is less sensitive to the end-product inhibition, having a  $K_i$  value of 0.65 mM in the hydrolysis of celotriose (24).

When the cellulase components act together in the hydrolysis of cellulose, they enhance the efficiency of each other significantly (72, 73). EGs assist the action of CBHs by liberating new chain ends from which CBHs can continue the hydrolysis towards more crystalline parts of the cellulose (Fig. 1). In general, only a small amount of EG is needed to improve the hydrolysis rate significantly. For example, the optimal mixture of *T. reesei* EG I and CBH II in the hydrolysis of crystalline cellulose is 2:8 (74). The synergism is com-

pleted by  $\beta$ -glucosidase, which is needed for the final step in the hydrolysis of cello-oligosaccharides to glucose. The presence of  $\beta$ -glucosidase also enhances the action of other enzymes by diminishing the end-product inhibition through the hydrolysis of cellobiose, which is a strong inhibitor especially for CBHs. Cooperative action is mainly found between EGs and CBHs, but also exo-exo synergism has been reported (75). The degree of synergism is dependent on the relative amounts of the enzymes and on the substrate used. The synergy is greatest on crystalline cellulose (76). The synergy in general can be explained when differently acting enzymes provide good substrates and binding sites for each other by degrading different parts of cellulose crystals. EGs and CBHs also assist each other in the hydrolysis of soluble 1,3-1,4- $\beta$ -glucans. However, the synergism is much smaller than in the case of cellulose as EGs are alone very effective in the degradation of water-soluble  $\beta$ -glucans (see Chapter 73).

Cross-synergism between cellulases from different organisms has also been demonstrated (76). This makes it possible to optimize the mixture of supercellulase components originating from different sources. In fact, the degradation of cellulose in nature obviously proceeds by mixed microbial populations.

## X. APPLICATION OF CELLULASES IN FOOD PROCESSING

Cellulases are not among the major enzymes used in food production (Table 4). In many food applications cellulases are not used alone but are added to boost the action of other enzymes, mainly pectinases and/or xylanases. As all EGs are active on 1,3-1,4- $\beta$ -glucans, they can be used in the same applications as the more specific 1,3-1,4- $\beta$ -glucanases e.g., lichenases and laminarinases (Table 1; Fig. 2). 1,3-1,4- $\beta$ -Glucans and arabinoxylans are the main components in cereal cell walls (see Chapter 74) and 1,3-1,4- $\beta$ -glucans exist in high quantities especially in barley and oat (Table 5). Thus, cellulases are useful enzymes in the processing of cereals. Most mixed-linked  $\beta$ -glucans are water soluble and form viscous solutions. In some cases this is desired—for example, as soluble nondigestible fiber within the food—but in other cases they create problems during processing of cereal materials.

### A. Brewing

Brewing is largely based on the action of endogenous barley and yeast enzymes which are activated during malting, mashing, and fermentation. During malting,

**Table 4** Possible Uses of Cellulases in Food and Feed

	Process	Action	Benefits
Food	Baking	Degradation of cell walls	Softer dough Shorter fermentation time Increased loaf volume
	Brewing	Degradation of soluble $\beta$ -glucan	Better filterability Higher production efficiency
	Wine and juice production	Degradation of cell walls	Better extraction Higher yield Enhanced color and/or aroma
	Extraction of oils	Degradation of cell walls	Better extraction Higher yield Enhanced color and/or aroma
	Extraction of starch and other polysaccharides	Degradation of cell walls	Better extraction Higher yield Enhanced color and/or aroma
	Upgrading agricultural residues	Degradation of cellulose to glucose	Better economics Less waste production Utilization of renewable materials
Feed	Animal farming	Degradation of cell walls	Better release of nutrients Enhanced feed conversion rate Less waste
	Pet animals	Degradation of cell walls	Better release of nutrients Healthier animals

**Table 5** Chemical Composition of Cereal Grains

Grain	Starch (%)	$\beta$ -Glucan (%)	Xylan (%)	Protein (%)	Fat (%)
Wheat	60–73	0.5–3.8	5.5–7.8	9–17	2.1–3.8
Barley	53–67	3.0–10.6	4.0–11.0	8–13	0.9–4.6
Oat	39–55	2.2–5.4	3.2–12.6	11–15	5.0–9.0
Rye	50–63	1.0–3.5	8.0–10.0	8–12	2.0–3.5

the grain polymers are mainly degraded to smaller fragments by amylases, proteases, and  $\beta$ -glucanases. The main separation problems during brewing processes are connected to the water-soluble cell wall polysaccharides, i.e.,  $\beta$ -glucan and xylan. They both may increase viscosity, form gels, and cause serious problems including poor filtration of the wort, slow runoff times, low extract yields, or the development of haze in the final product. Mashing performance is determined largely by the raw materials used. In addition to malt, alternative sources of fermentable carbohydrates, such as corn, rice, and wheat starch from various origins and syrups, are used in many breweries depending on the beer type, availability of starchy raw material, and the price of the extract. There is natural seasonal variation in the quality of barley and malt, due to variations in weather conditions during growth and storage. Barley cultivars also differ from each other in the potential to produce endogenous enzymes during germination.

Plant enzymes are not very heat stable and are mostly inactivated in kilning after germination, whereas most microbial enzymes can tolerate much higher temperatures. Thus, exogenous microbial enzymes are often used in brewing.  $\beta$ -Glucanases (cellulases) are mainly added in the mashing (77), but they can also be used during malting (78) or after mashing in primary fermentation (77). *T. reesei* cellulases have been found to be better than other commercial  $\beta$ -glucanases in both pilot and industrial-scale trials in terms of higher filtration rate and overall brewhouse efficiency (79).

The other option to increase the level of  $\beta$ -glucanases is to enhance the level of endogenous plant enzymes by genetic engineering (see also Chapter 75) or by cloning a microbial enzyme to barley. The first enzyme to be successfully cloned into barley was the EG I from *T. reesei* (80, 81). An even more thermostable bacterial  $\beta$ -glucanase has later been expressed in barley (82). Another sophisticated option is to construct a glucanolytic brewer's yeast strain. *T. reesei*

EG I was cloned > 15 years ago into an industrial brewer's yeast strain (83). The EG I secreted during fermentation decreased the viscosity of beer, which resulted in a markedly improved filterability with unaltered quality (84).

## B. Wine and Juice Production

Even though the amount of  $\beta$ -glucans in grapes and fruits is significantly lower than in cereals, cellulases have also found applications in the production of wines and fruit juices where they are used in combination with pectinases and hemicellulases. In wine making, the enzymes are generally used for better skin maceration, improved color extraction, easier must clarification and filtration, and increased wine quality and stability (85). The use of  $\beta$ -glucosidases for aroma development from naturally present glucosylated precursors has also been described (86). Macerating enzyme cocktails with cellulases are also used in fruit juice production. In addition, the use of these enzymes offers advantages in the treatment of by products of the fruit industry by improving the extraction yield and the overall process efficiency. Cellulases and hemicellulases can be used for the isolation of pectin from citrus fruits to break down the cell walls, increasing the pectin yield. Cellulases can be used alone or in combination with other cell wall degrading enzymes in all processes in which valuable compounds such as juice, oil, polysaccharides, protein, etc., are extracted from the plant material.

## C. Baking

Added enzymes are used increasingly in baking for improved processing and product quality. Traditionally, the main enzymes used in wheat baking are amylases and xylanases.  $\beta$ -Glucanases (cellulases) have gained less attention. Enzymes acting on cell walls are used especially in the manufacture of high-fiber bread to overcome processing problems caused by the high content of cell wall material in the dough. Addition of cell wall components decreases the bread volume, and the breadcrumb loses its elasticity. Soluble, nondigestible polysaccharides, which are often called dietary fiber, are believed to be beneficial for human health by lowering cholesterol levels (especially soluble  $\beta$ -glucan), preventing colon cancer, and acting as specific growth substrates (prebiotics) for beneficial intestinal bacteria (probiotics, mainly lactic acid bacteria and bifidobacteria) (87). Thus, breads with a high fiber content are gaining growing interest.

In wheat baking, the addition of water-soluble  $\beta$ -glucans has shown to improve breadcrumb grain (88). Treatment of the  $\beta$ -glucans with  $\beta$ -glucanase before their addition to the bread dough resulted in bread with poor crumb grain. In wheat dough supplemented with rye bran, xylanases and cellulases have been shown to make the cell wall polysaccharides more soluble and functional (89). The added enzymes made the dough softer, specific volume of the bread and crumb structure were improved, and the staling rate was reduced. Enzyme mixtures were found to be more efficient than individual enzymes.

Wholemeal rye baking differs significantly from wheat baking as rye proteins do not form a gluten matrix. Instead of gluten, the amounts of soluble xylans and endogenous enzymes are very important for the baking quality of rye since the gums in the rye dough have an important role in stabilizing the gas cells. The water-extractable xylans improve the baking quality by increasing dough viscosity. In rye meal slurries  $\beta$ -glucan and xylan extractability was increased by 90% and 40%, respectively, by EG II of *T. reesei* (90). Both xylanase and EG II from *T. reesei* are reported to make the rye dough softer, increase dough volume, and shorten fermentation time (91). The most marked effect of the enzymes was the reduction of proofing time. Cell wall-degrading enzymes softened the bread crumb and reduced the staling rate, but had a negative effect on oven rise. From the published reports on  $\beta$ -glucanases in baking it appears that the enzymes, including EGs, are useful especially when used in combination with other baking enzymes.

#### D. Isolation of Starch and Other Polysaccharides

The major application of food enzymes is in starch processing, i.e., hydrolysis of starch to glucose by amylolytic enzymes (see Chapters 56 and 57) and in the further isomerization of glucose to high-fructose syrup by glucose isomerase. The starch is mainly isolated from wheat or corn by milling and extraction. The isolation procedure can be further improved by cell wall degrading enzymes, i.e., by  $\beta$ -glucanases (cellulases), xylanases, or their mixture (92).

Several food hydrocolloids, mainly carrageenan, alginate, and agar, are isolated from algae. After initial isolation steps, the products often contain some contaminating cellulose from algae cell walls that impairs the functional properties of these polysaccharides. Cellulases are in some cases used in further purification steps to degrade the residual cellulose, after which the

target polysaccharide can be further isolated. Cellulases can also be used for controlled degradation of some water-adsorbing polysaccharides used in food processing, e.g., CMC, konjac glucomannan, and some bacterial exopolysaccharides, such as xanthan, which contain  $\beta$ -1,4-glucosidic linkages.

#### E. Animal Feed Production

A large quantity of cereals or various side fractions of grains from food processing are used as animal feed. In many cereals, part of their energy content is locked up in the form of nonstarch polysaccharides, undigestible for several animals. Therefore, selected enzymes, such as cellulases and hemicellulases, can be added to break down the cell walls leading to increased metabolizable energy (93). The viscous arabinoxylan and 1,3-1,4- $\beta$ -glucan also creates difficulties in the adsorption and digestion of nutrients, especially by monogastric animals such as chicken and pig. The viscosity is considered to be an important constraint to animal digestion by interfering with the diffusion of pancreatic enzymes, substrates, and reaction products (94). As a consequence, the presence of high levels of these components in feed causes poor feed conversion rates, slow weight gain, and wet droppings, particularly with poultry. The addition of enzymes, mainly xylanases and  $\beta$ -glucanases (cellulases), in feed enhances the breakdown of the corresponding polysaccharides and helps the adsorption of all feed components including proteins and fats, thereby improving feed conversion and weight gain. It is assumed that the beneficial effects of enzyme addition are due to both reduced intestinal viscosity and release of nutrients from grain cells. Other benefits of the cell wall-degrading enzymes are greater flexibility of diet formulations, the possibility of using cheaper raw materials, and production of less waste. In addition, with chickens the color of egg yolk is better and cleaner eggs are produced.

The liquid enzyme preparations are normally mixed in feed before pelleting. However, the current trend is to use higher pelleting temperatures to eliminate *Salmonella* contamination. Thus, normal fungal cellulases, such as those from *T. reesei*, may not survive the high temperature (95). The other option is to use granulated enzymes or to spray liquid enzyme preparations on the pellets at the cooling phase. The most advanced option is to clone new enzymes directly into animals. A transgenic mouse expressing a microbial cellulase in the exocrine pancreas has been constructed (96). The enzyme was secreted into the small intestine, demonstrating the feasibility of generating

nonruminant animals with a capacity to utilize cell wall polysaccharides.

Fungal enzymes are very suitable as feed additives owing to their acidic pH optimum which facilitates their action in the upper intestine. Some enzyme action already takes place during the feed production, especially at and after the pelleting stage, but mostly it occurs in the animal's digestive track.

The optimal enzyme mixture varies depending on the animals the feed is made for. Different enzyme cocktails are used for pigs and chickens. In addition, the xylanase:cellulase ratio is carefully designed for each diet. Broilers and laying and breeding hens fed on diets based on barley, wheat, or wheat and barley mixtures each have their own optimal enzyme formulation. Postweaning young piglets can obviously benefit most from enzyme supplementation to their diet. Cellulases and xylanases are often used in combination with proteases and amylases, and the cereal diet composition will determine the optimal enzyme mixture to be used (85). Adult pigs are less susceptible to viscose polysaccharides because of the longer retention time in their digestive system and more effective dilution of the viscose polymer (97).

#### **F. Other Uses of Cellulases**

Clearly the largest industrial use of cellulases is outside the food and feed sector in textile processing of natural textile fibers composed of cellulose (85, 98). Cellulases have also found potential applications in the pulp and paper industry (99). The textile and pulp fibers must retain their strength after cellulase treatment. Thus, novel commercial products with altered cellulase profiles have been developed. The detergent industry is the other major user of enzymes. The main enzymes used are proteases, but cellulases are also added in some detergents. Enzymes are now entering dishwashing detergents, and cellulases could also find applications there.

The total enzymatic hydrolysis of agricultural and forest residues to monosaccharides is an actively studied field. For this purpose a complete mixture of all individual cellulolytic enzymes is desired. The cellulase mixtures are capable of hydrolyzing cellulose to glucose with good yields, but the hydrolysis requires a large enzyme dosage or a very long hydrolysis time and is therefore economically not yet competitive with the enzymatic production of glucose from starch (100). However, better enzymes are being intensively developed, as the use of renewable biomaterials for

raw materials in the chemical industry will increase in the future. Agricultural residues from farming and food processing, such as husks, straws, stems, brans, peels, etc., are normally fed to animals. These side fractions are rich in plant cell walls and could be upgraded with the aid of enzymes to several products including glucose. The hydrolyzed glucose can be further transformed by microorganisms to several valuable products, such as ethanol for fuel or lactic acid for bioplastics.

#### **G. Commercial Cellulase Products**

Several enzyme companies produce commercially available cellulases. The main producers are Nozymes (Denmark) and Genencor International (USA). Other companies manufacturing industrial enzymes are AB Enzymes (Germany/Finland/UK), DSM Bakery Ingredients (Netherlands), ICI-Quest (Netherlands/UK), Danisco (Denmark), Le Saffre (France), Beldem (Belgium), Frimond (Belgium), Biocatalysts (UK), Stern-Enzyme (Germany), Mühlenchemie (Germany), Enzyme Bio-Systems (USA), Valley Research (USA), Amano (Japan), Meiji (Japan), and Sankyo (Japan). However, several commercial cellulase products are not accepted for food use. Most cellulases that are now marketed for food applications are mixtures containing several EGs, CBHs, and  $\beta$ -glucosidases, as well as many other enzymes such as xylanases, proteases, amylases, etc., as minor components. This must be kept in mind when use of these enzymes in selective degradation of cellulose and/or 1,3-1,4- $\beta$ -glucan is desired. Some purified enzymes are also available in small quantities mainly for research purposes from Megazyme (Ireland) and Sigma (USA).

#### **XI. CONCLUSIONS**

Considering the significant variability of cellulolytic enzymes and the complexity of their substrates, it can be concluded that these enzymes still offer scientific challenges. Because of the better production techniques, complex enzyme mixtures will be in the future replaced by well-defined cellulases or tailor-made enzyme cocktails, which will enable better control the process and the quality of the end product. Modern genetic engineering techniques offer tools for improving cellulase properties to better suit different applications. As the structure-function relationships in food materials will be further understood, enzyme products

can be specifically designed to achieve targeted changes. Cellulases are very versatile enzymes and thus can offer practical solutions for several food applications.

## ACKNOWLEDGMENTS

We are thankful to Martin Schülein from Novozymes for providing information on *Humicola* cellulases and to our colleagues Silja Home, Marjatta Salmenkallio-Marttila, and Anu Koivula for valuable information and comments.

## **$\beta$ -Glucosidase**

**Asim Esen**

*Virginia Polytechnic Institute and State University, Blacksburg, Virginia, U.S.A.*

### **I. INTRODUCTION**

$\beta$ -Glucosidase ( $\beta$ -D-glucoside glucohydrolase, EC 3.2.1.21) catalyzes the hydrolysis of the  $\beta$ -glycosidic bond between two glycone residues (e.g., cellobiose and other  $\beta$ -linked oligosaccharides) or that between glucose and an aryl or alkyl aglycone (e.g., many naturally occurring substrates in plants). The enzyme constitutes a major group among glycoside hydrolases and occurs universally in all three domains (Eukarya, Archaea, and Eubacteria) of living organisms. A nomenclature system classifying glycosyl hydrolases into 82 families based on amino acid sequence similarities has been proposed (1–3) and is now widely used. A continuously updated server giving access to these families is available at URL: <http://afmb.cnrs-mrs.fr/~pedro/CAZY/db.html>. Under this classification scheme,  $\beta$ -glucosidases belong to families 1 and 3 of the clan GH-A. Unless otherwise stated, this chapter's emphasis will be family 1 enzymes.

$\beta$ -Glucosidases have been the focus of much research recently because of their key roles in a variety of fundamental biological (e.g., growth and development, chemical defense, host–parasite interactions, cellulolysis, lignification, glycosylceramide and vitamin B<sub>6</sub> metabolism, signaling, etc.) and biotechnological (biomass conversion, food detoxification, and beverage quality enhancement) processes. For example, plant  $\beta$ -glucosidases have been either implicated or shown to be involved in (a) defense against pests (4–6); (b) phytohormone activation (7); (c) lignification (8); (d) cell

wall degradation in the endosperm during germination (9); and (e) quality enhancement in wine, fruit juices (10; [Chapter 21](#)), and tea (12).  $\beta$ -Glucosidases hydrolyze either O-linked  $\beta$ -glycosidic bonds, as is done by  $\beta$ -glucosidases ( $\beta$ -D-glucoside glucohydrolase, EC 3.2.1.21), or S-linked  $\beta$ -glycosidic bonds, as is done by  $\beta$ -thioglucosidases (myrosinase, or  $\beta$ -D-thioglucoside glucohydrolase, EC 3.2.3.1). Thus, specific physiological functions and multiplicity of  $\beta$ -glycosidases in an organism depend on the nature and diversity of the aglycone (aryl or alkyl) or glycone (Glc, Gal, Fuc, Xyl) moiety of their substrates.

### **II. USE OF $\beta$ -GLUCOSIDASES IN FOOD PROCESSING AND QUALITY ENHANCEMENT**

The importance of  $\beta$ -glycosidases to food quality and processing is ably reviewed and discussed by Günata (see [Chapter 21](#)) with emphasis on flavor enhancement in fruit juices and various beverages derived from them. Therefore, the reader is referred to [Chapter 21](#) for more information on this aspect. There are several hundred different  $\beta$ -glycosidic flavor precursors identified from plants whose aglycones are products of mevalonate or shikimate pathways. Obviously, there are  $\beta$ -glucosidases in source plant tissues that hydrolyze these flavor precursors. Thus, in each case there is need for isolating and characterizing the specific enzyme that hydrolyzes a  $\beta$ -glucoside whose aglycone

moiety is of interest to food quality and processing. Such biochemical data are crucial to making practical decisions as to whether or not enzymes from host plants or other sources should be added to drinks and beverages before, during, or after processing to enhance flavor, aroma, and other quality factors. Likewise, such data are essential for targeting enzymes with desirable properties for overproduction in transgenic microbial or plant hosts and improvement of their catalytic properties and stability for specific uses by genetic engineering.

Another aspect of  $\beta$ -glucosidases that pertains to food processing and quality is that edible portions of some plants contain compartmentalized  $\beta$ -glucosidase– $\beta$ -glucoside systems that produce toxic aglycones and/or HCN when tissue is macerated during preparation or by chewing. This is exemplified by cassava roots and leaves, lima beans, and flax seeds. Of these, cassava is a food staple in tropical regions of Africa, Asia, and South America; consumption reaches about 1 kg/per capita per day in some parts of Africa (e.g., Congo). It contains the cyanogenic  $\beta$ -glucoside linamarin and the corresponding  $\beta$ -glucosidase linamarase. When consumed raw, cyanide poisoning can occur depending on the amount ingested, where symptoms are difficulty in breathing, paralysis, convulsion, coma, and even death. Similarly, certain processing methods (e.g., maceration of roots followed by washing) remove the components and products of cyanogenesis as well as many nutritional factors, thus reducing quality. Cooking inactivates the enzyme and eliminates the possibility of cyanogenesis. Similar symptoms can arise when bitter almonds are eaten and ingested without roasting.

The myrosinase–glucosinolate (or  $\beta$ -thioglucosidase– $\beta$ -thioglucoside) system, which occurs in cruciferous vegetables (e.g., mustard, cabbage, kale, broccoli, rapeseed, horseradish, etc.), also has importance for food quality and processing because the aglycone moiety and its breakdown products from enzymatic hydrolysis of glucosinolates are responsible for the bitter, pungent taste and aroma associated with these vegetables, as well as the processed foods and relishes that include them (13). The distinct flavor associated with glucosinolates comes primarily from isothiocyanates and is believed to have evolved to serve as a repellent against microorganisms and herbivores. Glucosinolates and their breakdown products may impart undesirable flavors to milk, meat, and eggs when farm animals graze on cruciferous plants or when their feed includes seed meals from such plants. Besides off-odors and off-flavors in foods of animal

origin associated with glucosinolates, direct ingestion of large amounts of cruciferous vegetables is thought to cause endemic goiter in man, as well as toxicity in laboratory animals. Similarly, claims have been made on anticarcinogenic effects of glucosinolates and their breakdown products in humans. Although the precise mechanism of action is not clear, studies on rodents showed that raw or cooked cruciferous vegetables (e.g., cabbage, broccoli, turnip, and cauliflower) increased aryl hydrocarbon hydroxylase activity (14).

### III. BIOCHEMISTRY

#### A. Structure

Family 1  $\beta$ -glucosidase monomers have molecular weights ranging from 55 to 65 kDa as estimated by SDS-PAGE, which is consistent with the determined polypeptide lengths ranging from 447 (e.g., *Bacillus polymyxa*) to 527 (e.g., white mustard myrosinase) amino acids long, depending on source organism of the enzyme. Not surprisingly, the longest polypeptide chains are found in eukaryotic enzymes while the shortest ones are in eubacteria and archaeabacteria (Fig. 1). All  $\beta$ -glucosidases isolated from animals and dicotyledonous plants (except indigo plant) so far are glycosylated and thus have estimated monomeric molecular weights 3–5 kDa larger than those calculated from sequences of mature polypeptide chains deduced from cDNA or genomic DNA sequences. The catalytically active form of  $\beta$ -glucosidases is a homodimer of ~120 kDa or its multimers. The amino acids and sites that contribute to the dimer interface are not well conserved based on crystallographic data from eight enzymes (see below). High-molecular-weight quaternary complexes of  $\beta$ -glucosidases are either homocomplexes differing from each other by a dimer or its multiples as is the case for example with avenacosidase from oats, or heterocomplexes formed between  $\beta$ -glucosidase dimers and certain specific proteins associated with them. For example, in maize  $\beta$ -glucosidase forms large, insoluble or poorly soluble aggregates resulting from a specific interaction between the enzyme and a 32-kDa small heat shock protein, which is expressed at elevated levels in certain maize inbred lines (15, 16). Similarly, high-molecular-weight aggregates of  $\beta$ -glucosidases have been described from oat (17), flax (18), and cabbage (19) where in the case of cabbage the aggregates were shown to be due to interaction with specific myrosinase-binding proteins.

**Figure 1** Sequence alignment of family 1  $\beta$ -glycosidases from representative species of three organismic domains (Eukarya, Archaea, and Eubacteria). TR-1CBG, white clover (*Trifolium repens* L.) linamarase; SA-1MYR, white mustard (*Sinapis alba*) myrosinase; ZMGl1, maize (*Zea mays* L.) Glu1; CP-Glu, guinea pig (*Cavia porcellus*) cytosolic  $\beta$ -glucosidase; BP-1BGA, *Bacillus polymyxa*  $\beta$ -glucosidase; BC-1QOX, *Bacillus circulans* sp. *alkalophilus*  $\beta$ -glucosidase; SS-1GOW, *Sulfolobus solfataricus*  $\beta$ -glucosidase; and TA-1QVB, *Thermosphaera aggregans*  $\beta$ -glucosidase. Regions with black background show the universally conserved sites, whereas regions with dark gray and light gray show highly conserved and moderately conserved sites, respectively. Regions with white background show variable sites, while dashes indicate the gaps (deletions) that the alignment software (ClustalW) introduced to optimize the alignment. The alignment was produced with ClustalW and formated with Boxshade, both of which are free downloads from the Web.

The primary structure of each family 1  $\beta$ -glucosidase monomer contains the highly conserved peptide motifs SAYQI, YRFSI, TFNEP, LGLNYY, YITENG, and DNFEW, which serve as fingerprints to identify an unknown protein as a family 1  $\beta$ -glucosidase (Fig. 1). Of these, TFNEP and YITENG are the most conserved; they make up a part of the active site and contain the two catalytic glutamates (20–23). Furthermore, the 3D structures of eight family I  $\beta$ -glycosidases [1CBG, white clover (*Trifolium repens*) linamarase; 1MYR, white mustard (*Sinapis alba*) myrosinase; ZMGl1, maize (*Zea mays* L., see Fig. 2); 1BGA, *Bacillus polymyxa*  $\beta$ -glucosidase; 1QOX, *Bacillus circulans* sp. *alkalophilus*  $\beta$ -glucosidase; 1PBG, *Lactococcus lactis* phospho- $\beta$ -galactosidase; 1GOW, *Sulfolobus solfataricus*  $\beta$ -glucosidase; and 1QVB, *Thermosphaera aggregans*  $\beta$ -glucosidase] have recently been solved (20–27). All eight enzymes have essentially the same basic  $(\beta/\alpha)_8$ -barrel fold structure (Fig. 2) although they share only 17–63% sequence identity (Fig. 1). It is remarkable that the basic catalytic machinery, reaction mechanism, and 3D structure have been rigidly retained in the three domains of living organisms in spite of large amounts of sequence divergence through eons of evolution.

## B. Multiple Molecular Forms (Isoforms)

$\beta$ -Glucosidase is ubiquitous, and thus a given organism is expected to have at least one molecular form of the enzyme. When the enzyme occurs in multiple molecular forms (isoforms) as detected by electrophoretic mobility or ion exchange chromatography, typically two or three forms are observed whose existence is also confirmed by molecular biological techniques (e.g., Southern blotting and Northern blotting) and DNA sequencing. However, electrophoretic and chromatographic detections are limited to those enzymes that hydrolyze the test substrate used for detection

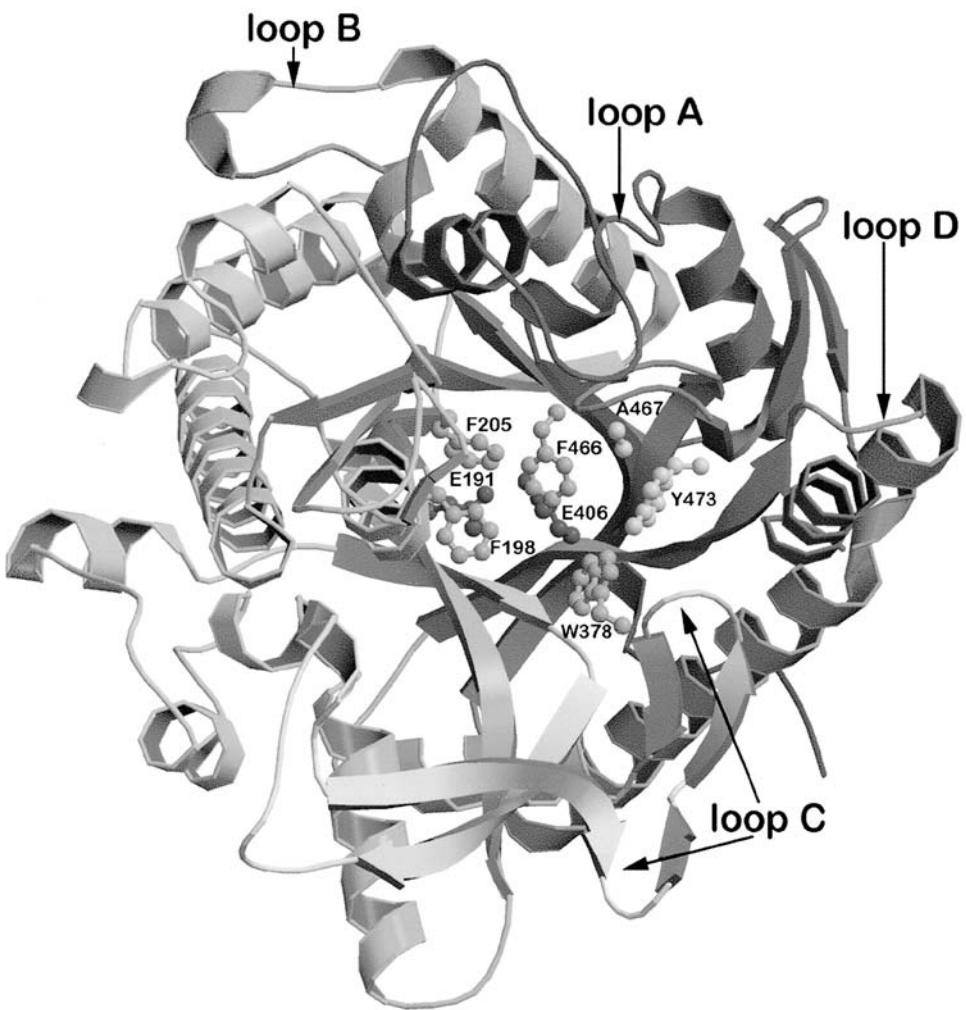

while blotting techniques are limited to those genes or mRNAs that have sufficient sequence similarity to the probe sequence. Therefore, the number of isoforms detected is very likely to be lower than the number of those that actually exist. Indeed, the data from genome sequencing projects appear to support this conclusion. For example, *Arabidopsis thaliana* genome sequence data so far indicate that there are at least 40 different genes encoding family 1  $\beta$ -glucosidase in this plant, which has the smallest and most streamlined genome among plants. Whether or not all of these putative genes are actually expressed and code for a functional enzyme remains to be shown by functional genomics studies. However, it would not be too surprising if there are more  $\beta$ -glucosidase isoforms than expected in view of the possibility that there may be tens of different physiological substrates ( $\beta$ -glucosides or glucoconjugates) produced during the life of, especially, a multicellular organism in specific tissues, organs, developmental stages, and environmental stresses. Some if not all of these substrates may have a corresponding specific  $\beta$ -glucosidase isoform hydrolyzing them under specific conditions and with specific kinetics.

In addition to genetically determined  $\beta$ -glucosidase multiplicity that can be demonstrated by DNA sequencing and blotting, there are many examples of  $\beta$ -glucosidase multiplicity generated by posttranslational modifications (e.g., glycosylation and proteolytic modification *in vitro*) during isolation and subsequent manipulations of enzyme preparations. For example, as many as six different forms of the maize  $\beta$ -glucosidase isozyme Glu1 can be detected on zymograms in a time- and pH-dependent manner. Five of these bands are artificial, and they result from the activity of an endogenous cysteine protease in buffers of pH 5–6 containing a reducing agent such as 2-ME (28). These data suggest that multiple forms of  $\beta$ -glucosidase detected on zymograms or after chromatography should not be interpreted as being distinct isozymes or allozymes without ruling out artificial heterogeneity due to proteolysis and differential posttranslational modification on the same polypeptide chain.

## C. Catalytic Site and Machinery

All family 1  $\beta$ -glycosidases are “retaining” enzymes in that the anomeric configuration of the glycone (e.g., glucose) is the same in the product ( $\beta$ -D-glucose) as it was in the substrate (a  $\beta$ -D-glucoside). Substrate hydrolysis involves two steps (enzyme glycosylation and deglycosylation) and requires participation of two specific glutamic acid residues in the active site.

\* Abbreviations: AH, amygdalin hydrolase; AS, ammonium sulfate; 6BNGlc, 6-bromo-2-naphthyl- $\beta$ -D-glucoside; DIMBOA, 2,4-dihydroxy-7methoxy-1,4-benzoxazin-3-one; DIMBOAGlc, 2-O- $\beta$ -D-glucopyranosyl-4-hydroxy-7-methoxy-1,4-benzoxazin-3-one; HIC, hydrophobic interaction chromatography; IEF, isoelectric focusing; 2-ME, 2-mercaptoethanol; 4MUGlc, 4-methylumbelliferyl- $\beta$ -D-glucoside; NP, nitrophenol; NPGlc, nitrophenyl glucoside; PAGE, polyacrylamide gel electrophoresis; PH, prunasin hydrolase; SB, *Sorghum bicolor*; SDS, sodium dodecyl sulfate; Xglc, 5-bromo-4-chloro-3-indolyl- $\beta$ -D-glucoside; ZM, *Zea mays*.

**Figure 2** Ribbon diagram representation of the tertiary structure of the maize  $\beta$ -glucosidase Glu1 monomer, showing the catalytic glutamates E191 and E406, four residues (F198, F205, W378, and F466) forming the aglycone-binding pocket, and two other residues (A467 and Y473) that are probably important for aglycone recognition. Note the  $(\beta/\alpha)_8$  fold barrel structure with alternating  $\beta$ -strands and  $\alpha$ -helices and the four loops surrounding and contributing to the structure of the active site. Different colors and the color transitions in  $\alpha$ -helices and  $\beta$ -strands in the original diagram trace the polypeptide backbone in the barrel-shaped 3-D structure from the N-terminal to C-terminal direction. The figure was produced with the softwares MOLSCRIPT and Raster3D.

In the glycosylation step, the nucleophilic glutamate residue in the motif YI/VTENG attacks at the anomeric carbon ( $C_1$ ) of the substrate and forms a covalent glycosyl-enzyme intermediate with concomitant release of the aglycone after protonation of the glycosidic oxygen by the acid catalyst glutamic acid residue in the motif (T/F/L/M)NEP (29, 30). In the deglycosylation step, the second catalytic glutamate residue, now an anion and a base catalyst, removes a proton from water, and the resulting OH<sup>-</sup> group performs a nucleophilic attack on the covalent bond between the glycone and the enzyme, releasing the glycone and regenerating

the nucleophilic glutamate residue. In all structures except myrosinase, a  $\beta$ -S-glucosidase, the residues of the TFNEP and I/VTENG motifs are involved in glycone binding and catalysis within a crater-shaped active site (31). The two catalytic glutamic acid residues (i.e., the nucleophile and the acid/base catalyst) are positioned within the active site at expected distances ( $\sim 5.5 \text{ \AA}$ ) (Fig. 2). In myrosinases, the motif that is homologous to TFNEP of  $\beta$ -O-glucosidases is TINQL, in which the acid/base catalyst glutamic acid residue is replaced by a glutamine residue. There is no need for protonic assistance for aglycone departure in

myrosinase, as the aglycone of  $\beta$ -glucosinolates is, by its chemical nature, an excellent leaving group.

#### D. Substrate Specificity

Substrate specificity in  $\beta$ -glycosidases literally means specificity for the chemical group attached to glycone through  $\beta$ -glycosidic linkage since the glycone moiety in a  $\beta$ -glycosidic substrate is an invariant monosaccharide (e.g., glucose in O- and S-linked  $\beta$ -glucosides). The group attached to glucose is either another glycone as in  $\beta$ -linked disaccharides (e.g., cellobiose) and oligosaccharides or an aglycone as in glucoconjugates. The aglycone moiety of the substrate is either an alkyl group (e.g., linamarin) or an aryl group (e.g., prunasin, dhurrin, and DIMBOAGlc). The subtle substrate specificity differences exhibited by  $\beta$ -glycosidases in general and plant  $\beta$ -glycosidases in particular, and the importance of the aglycone moiety in determining the specificity of  $\beta$ -glycosidases for their physiological substrates, have been well documented in the literature and reviewed (32, 33). The authors cited many cases of subtle substrate specificities and urged the use of physiological substrates during enzyme purification and characterization.

Conn (33) explained the historical reasons for the inaccurate perception that plant  $\beta$ -glycosidases have broad substrate specificity and cited as examples the popular plant  $\beta$ -glucosidase almond emulsin and crude plant extracts. Both of these sources contain mixtures of enzymes with  $\beta$ -glucosidase activity and exhibit broad specificity on artificial chromogenic (e.g., nitrophenyl- $\beta$ -D-glucosides) or fluorogenic (e.g., 4MUG1c) substrates. However, examples of narrow substrate specificity can be demonstrated if one uses purified enzyme in assays. Two such examples are  $\beta$ -glucosidases (also called dhurrinase) of sorghum and the Glu2 isozyme of maize whose primary structures have been determined in the author's laboratory (34, 35). In the first case, one isozyme (Dhr1) represents an extreme; it hydrolyzes only the natural substrate dhurrin and shows no activity toward other aryl or alkyl  $\beta$ -glucosides, including the popular artificial substrate pNPGlc. The second dhurrinase isozyme (Dhr2) also shows narrow specificity for dhurrin but it also hydrolyzes pNPGl1 and 4MUGlc, albeit at a very low rate (35, 36). Similarly, the maize Glu2 isozyme hydrolyzes the natural substrate DIMBOAGlc with the same efficiency as does the other maize isozyme (Glu1) but hydrolyzes poorly or not at all other substrates that are readily hydrolyzed by the Glu1 isozyme.

As for the so-called broad-specificity plant  $\beta$ -glucosidase, such as almond emulsin, Poulton and associates (37) showed that the black cherry homolog of the emulsin actually includes two distinct  $\beta$ -glucosidases, each with multiple forms and catalyzing different steps in amygdalin hydrolysis. One of these enzymes is amygdalin hydrolase (AH), and it has four isozymes and hydrolyzes amygdalin (mandelonitrile  $\beta$ -1,6-gentiotobioside) to prunasin (mandelonitrile  $\beta$ -Glc) and glucose. The second enzyme is prunasin hydrolase (PH), and it has three isozymes, each hydrolyzes prunasin to glucose and mandelonitrile. Both AH and PH hydrolyze only their own natural substrates in vivo, and each shows varying levels of activity on artificial substrates.

The above-cited examples support Conn's conclusion (33) that plant  $\beta$ -glycosidases exhibit narrow specificity when one uses purified enzyme in assays. Conn also points out that almost every research paper dealing with plant  $\beta$ -glucosidases used an NPGlc as substrate. In some studies, both artificial and natural substrates were used during enzyme purification while in others either a physiological substrate was not known or it was unavailable. In such cases two unfortunate outcomes are possible: (a) purifying and describing an enzyme that has no activity on an abundant natural substrate, and (b) failing completely to detect a physiologically relevant  $\beta$ -glucosidase that does not hydrolyze the artificial substrate used in the assay. Thus, the broad substrate specificity often attributed to  $\beta$ -glucosidases does not mean that the enzymes catalyze the hydrolysis of a large number of physiological substrates in vivo. Rather, it means that a large number of test substrates whose aglycone structure is similar to that of the physiological substrate can be hydrolyzed by an enzyme.

In fact, even some nonphysiological substrates may be hydrolyzed with a much higher catalytic efficiency than the physiological substrate. This is because the nonphysiological substrate may have better shape and functional group complementarity for binding with high affinity and its aglycone moiety may be a better leaving group in the glycosylation step of the reaction than that of the physiological substrate. For example, the maize  $\beta$ -glucosidase isozyme Glu1 hydrolyzes such natural and artificial substrates with aryl aglycone moieties as *p*- and *o*-NP, 4-methylumbelliferyl, 6-bromo-2-naphthyl, indoxyl, 5-bromo-4-chloro-3-indolyl, and cytokinin in addition to its abundant natural substrate DIMBOAGlc. Moreover, the maize enzyme hydrolyzes *p*NP-fucosides about 10 times more efficiently than *p*NP-glucosides. However, none of these substrates hydrolyzed by the enzyme

except DIMBOAGlc occur in maize. The only thing they have in common with the natural substrate is an aryl aglycone moiety that mimics DIMBOA. In fact, a research group (38) isolated Glu1 as an auxin-binding protein using an auxin analog as an affinity matrix because the enzyme was bound to the matrix owing to the similarity of the auxin analog to the aglycone (DIMBOA) of the natural substrate.

A simple and effective assay to search for natural substrates of  $\beta$ -glucosidases is to prepare an alcohol extract of the tissue of interest, concentrate, and fractionate it over a column (e.g., Sephadex LH-20) in 70% methanol. The resulting fractions are then dried and tested with a crude protein extract of the same tissue for glucose production, by a coupled PGO assay (see below) using appropriate controls. Once glucose production has been detected and confirmed in a fraction or crude organic extract, one can purify and identify the source glucoside by further analytical studies. Similarly, one can purify and identify the  $\beta$ -glucosidase that is hydrolyzing an isolated and identified physiological substrate by subjecting crude protein extracts of the same tissue or organ to purification by conventional biochemical procedures.

### E. Mechanism of Substrate Specificity

Much progress has been made in understanding the mechanism of catalysis and defining the roles of the two catalytic glutamates within the active site that are involved in catalysis (29, 30, 39, 40). However, until recently, there was little or no information as to how  $\beta$ -glucosidases recognize and interact with their substrates, specifically the aglycone moiety, which is the basis of tremendous diversity in natural substrates and is responsible for the subtle substrate specificity differences among  $\beta$ -glucosidases. None of the seven structures published on family 1 enzymes contained either an intact substrate or an aglycone product to address the issue of substrate specificity.

Studies with reciprocal ZMGlu1/SBDhr1 chimeric enzymes indicated that the aglycone (i.e., substrate) specificity determining sites are different in maize  $\beta$ -glucosidase isozyme ZMGlu1 and sorghum  $\beta$ -glucosidase isozyme SBDhr1 (41). These data show that specificity for dhurrin hydrolysis residues in a C-terminal region octapeptide ( $^{462}\text{SSGYTERF}^{469}$ ) of SBDhr1 where SBDhr1 and ZMGlu1 sequences differ from each other by four amino acid substitutions, while specificity for DIMBOAGlc hydrolysis is not within the ZMGlu1 homolog of the aforementioned octapeptide

nor within the extreme 47-amino-acid-long C-terminal domain of ZMGlu1.

Questions about the mechanism and the site of substrate (i.e., aglycone) specificity and affinity could be directly addressed if it were possible to crystallize the enzyme-aglycone, inactive enzyme-substrate, or enzyme-unhydrolyzed competitive inhibitor complexes and identify the residues that are interacting with the aglycone in the 3D structure. Recently, the author's laboratory in collaboration with that of Bernard Henrissat in Marseille (AFMB-CNRS) was able to directly investigate the mechanism and the site of substrate (i.e., aglycone) recognition and specificity in maize  $\beta$ -glucosidase by x-ray crystallography using co-crystals of a catalytically inactive mutant (Glu1E191D) in complex with the natural substrate DIMBOAGlc, the free aglycone DIMBOA, and unhydrolyzed competitive inhibitor para-hydroxy-S-mandelonitril  $\beta$ -glucoside (dhurrin). The structures of these complexes and uncomplexed mutant were solved at 2.0, 2.1, and 2.2 Å resolution, respectively. The structural data from the complexes for the first time allowed us to visualize an intact substrate, free aglycone, or an unhydrolyzed competitive inhibitor in the slotlike active site of a  $\beta$ -glucosidase (42). These data show that the aglycone moiety of the substrate is sandwiched between W378 on one side and F198, F205, and F466 on the other. Thus, specific conformations of these four hydrophobic amino acids and the shape of the aglycone binding site they form determine aglycone recognition and substrate specificity in maize ZMGlu1. In addition to these four residues, A467 interacts with the 7-methoxy group of DIMBOA. All but W378 of these sites are variable among  $\beta$ -glucosidases that differ in substrate specificity, supporting the conclusion that these sites are the basis of aglycone recognition and binding (i.e., aglycone substrate specificity) in  $\beta$ -glucosidases. The data also provide a plausible explanation for the competitive binding of dhurrin to maize  $\beta$ -glucosidases with high affinity without being hydrolyzed.

### F. Kinetic Constants

$\beta$ -Glucosidases show variable affinity toward  $\beta$ -glucosides. The  $K_m$  values for good substrates, including natural substrates, are typically 1 mM or less. Similarly,  $\beta$ -glucosidases have, relatively speaking, low  $k_{cat}$  values ( $\sim 300\text{ s}^{-1}$  or lower). It is believed that the physiological function of these enzymes for the cell dictates slow hydrolysis of the substrates rather than "bursts" and natural selection favored such slow

rate of hydrolysis. The best way to compare substrate specificities and affinities is to compare the  $k_{\text{cat}}/K_m$  (efficiency coefficient) values, as two substrates with similar  $K_m$  values may yield as much as an order of magnitude differences in catalytic efficiency owing to the aglycone moiety (better or worse as a leaving group) or the glyccone moiety. It is obvious that high  $k_{\text{cat}}$  and low  $K_m$  values would increase catalytic efficiency. When substrates differ with respect to leaving-group ability of their aglycones, the rate-limiting or enhancing step will be the glycosylation reaction. If they differ with respect to the glyccone moiety, either glycosylation or deglycosylation step, or both, would be rate limiting. For example, maize  $\beta$ -glucosidases (along with most other  $\beta$ -glucosidases) hydrolyze *p*-nitrophenyl  $\beta$ -fucoside 10 times more efficiently than *p*NPGlc although their  $K_m$  values are similar. The difference in this case is clearly apparent in  $V_{\text{max}}$  values, although how the fucopyranosyl moiety enhances the reaction rate is not known.

### G. Inhibitors and Cofactors

$\beta$ -Glucosidases are inhibited by transition state sugar analogs (e.g.,  $\delta$ -gluconolactone), substrate analogue glucosides, free aglycones of their substrates, and substrate analogs. Since the active site has distinct aglycone- and glyccone-binding pockets, sugars and sugar analogs with half-chair conformation can bind to the glyccone-binding site and inhibit the enzyme, as can free aglycones, and the aglycone moiety of substrate analogs bind to the aglycone-binding site.

Free glucose is a poor inhibitor ( $K_i = 100$ –200 mM) because glucose must be in a half-chair conformation for binding to the glyccone binding site, which it acquires after the aglycone moiety binds to the aglycone-binding site and distorts the conformation of the attached glucose to half-chair. In contrast, free aglycones are potent competitive inhibitors because their ground-state conformation is sufficient to recognize and bind to the glyccone binding site.

Metal ions, primarily  $\text{Ag}^+$  and  $\text{Hg}^{2+}$ , are also potent  $\beta$ -glucosidase inhibitors. The inhibition can be completely reversed by reducing agents such as 2-ME (43). The target of these cations on the enzyme is not known although the catalytic nucleophile glutamate is a potential target. There are also reports of inhibition by  $\text{Cu}^{2+}$  and  $\text{Fe}^{3+}$  (44). A complete listing of  $\beta$ -glucosidase inhibitors is given in Zollner (44). There is no well-documented case of a cofactor requirement for a  $\beta$ -O-glucosidase, whereas the requirement of ascorbate for activity of  $\beta$ -S-glucosidases (myrosinases) is well known

(45). Similarly, the presence of  $\text{Mn}^{2+}$  in the crystal structure of myrosinase suggests that this divalent cation might be required for activity by myrosinases.

### H. Heat and pH Stability and Resistance to Proteases

$\beta$ -Glucosidases are stable in the pH range 4–10 at 0–4°C, with highest stability at  $\sim$  pH 7. The sources of instability during storage are pH extremes, co-purifying proteases, and microbial contamination. Although most  $\beta$ -glucosidases are extremely resistant to proteases because of their tightly folded core structure, which exposes only the extreme N- and C-terminal regions to proteases, they are slowly degraded by contaminating or co-purifying proteases during prolonged storage without protease inhibitors in the medium. For example, maize Glu1 and almond emulsin lose only 10–15% of their activity after 18 h of exposure to one of the most potent proteases (proteinase K; Esen, unpublished) at room temperature. Under similar conditions, almost all of the other proteins in a crude extract are digested.  $\beta$ -Glucosidases are resistant to denaturation by ionic detergents such as SDS, which allows extraction with buffers containing up to 3% SDS and zymogram development after SDS-PAGE when samples are applied without heating.

As for thermostability, mesophilic  $\beta$ -glucosidases are irreversibly inactivated at and above 55–60°C, depending on the source, although they may show highest catalytic activity at 50–55°C (43). Increased catalytic activity at such high temperatures as 50–55°C is not physiologically and practically meaningful if the half-life of the activity is only 10 min or so due to thermal denaturation and inactivation, as is the case with maize  $\beta$ -glucosidase (43). However,  $\beta$ -glucosidases of thermophilic bacteria (e.g., *Thermosphaera* spp. and *Sulpholobus* spp.) have temperature optima  $\sim$  85°C (46). The basis of this thermostability is attributed to the increase in the number of proline residues, internal water molecules, internal and surface electrostatic bridges, and the decrease in the solvent-accessible surface area by a tetrameric quaternary structure as opposed to the dimeric structure of mesophilic enzymes (25).

### IV. ASSAYS FOR $\beta$ -GLUCOSIDASE ACTIVITY

There are well-established procedures for assay of  $\beta$ -glucosidase activity, and they can be used to determine not only whether or not a crude tissue extract or sam-

ple has enzyme activity, but also to quantify the amount of enzyme activity present in a preparation. To this end, solution assays utilizing a substrate whose aglycone moiety is either chromogenic or fluorogenic are desirable. Almost all published solution assays use the commercially available nitrophenyl glucosides as substrate and commercially available almond emulsin as enzyme source. The assay can be performed in cuvettes or in 96-well microtiter plates and the absorbance of the nitrophenolate ion ( $pK_a = 7.16$ ) can be read in a spectrophotometer or microtiter plate reader for quantification. A sample solution assay protocol for the microtiter plate format is given below. This procedure can be scaled up for test tube or cuvette format.

#### A. Spectrophotometric Assays

The following is a solution assay procedure that is applicable to any family 1  $\beta$ -glucosidase after changing the pH of the buffer to one that is optimum for the enzyme of interest. All reagent chemicals and substrates mentioned are available from Sigma Chemical Company. The solutions needed are:

1. 50 mM citrate 100 mM phosphate buffer, pH 5.8 (also known as McIlvaine Buffer). Titrate 100 mM citric acid solution with 200 mM  $Na_2HPO_4$ , until pH is 5.8 (Buffer 1).
2. 5 mM *p*-nitrophenyl- $\beta$ -D-glucopyranoside (*p*NPGlc) prepared in Buffer 1.
3. 0.4 M sodium carbonate ( $Na_2CO_3$ ) prepared in water (stored at room temperature).
4. Tissue extracts or purified  $\beta$ -glucosidase preparations, diluted with Buffer 1 to yield 0.1–1.0  $A_{410}$  units of activity in 5 min at 25°C. (Initially, tissue extracts may be diluted 10- to 100-fold in Buffer 1 and assayed to decide the appropriate dilution for quantitative assay.)

The procedure is as follows.

1. Add 70  $\mu$ L of enzyme solution (Solution 4) to the wells of a 96-well microtiter plate in quadruplicate. Add 70  $\mu$ L Buffer 1 to four blank wells (this is a minus enzyme control). Place the plate on rotary shaker-incubator set at 25°C for temperature equilibration (~5 min).
2. Pour sufficient volume of Solution 2 (substrate) in a 25-mL pipetting reservoir and leave it at 25°C for ~5 min to equilibrate to room temperature.
3. Draw 70  $\mu$ L of Solution 2 (substrate) with a multichannel pipette (if available, otherwise use a single-channel micropipette) from the trough, mark the

time, and add it to the wells that had received 70  $\mu$ L of enzyme solution (Solution 4) or Buffer 4 before.

4. Place in the incubator and shake at 50 rpm until exactly 5 min have elapsed from the time of substrate addition.

5. Remove the plate, add to each well 70  $\mu$ L of Solution 3, and mix gently.

6. Read the absorbance at 410 nm in the microplate reader.

7. Compute the mean and standard deviation of the four values for each sample (see step 8).

8. Express (calculate) the enzyme activity as below.

One unit of enzyme activity is defined as the amount of enzyme that hydrolyzes 1  $\mu$ mole of *p*NPG/h at 25°C. It has been determined that 1.69  $\mu$ g (or 0.0121  $\mu$ mole) *p*NP in 210  $\mu$ L of volume in a 96-well microplate reader well gives an absorbance of 1000 at 410 nm. Example: A tissue extract, after diluting 100×, yielded 0.711  $A_{410}$  units of  $\beta$ -glucosidase activity in 5 min at 25°C.

Enzyme activity =  $a \times b \times c \times d = 0.0121 \times 0.711 \times 100 \times 12 = 10.32$  U/h/70  $\mu$ L of original enzyme solution, or  $10.32 \times 1000/70 = 147.5$  U/mL.\*

Specific activity =  $147.5/1.5 = 98.3$  U/mg protein if the protein content of the original extract is 1.5 mg/mL.

To calculate the amount of *p*NP produced from *p*NPG by  $\beta$ -glucosidase activity, it is best to prepare serial dilutions of *p*NP, read their absorbance in the volume to be used in enzyme assays, and convert the reading to the amount of the *p*NP ( $\mu$ moles) from the extinction coefficient ( $\epsilon_{410} = 18,300 M^{-1} cm^{-1}$ ) (47) of the nitrophenolate ion.

The above spectrophotometric assay may be changed to a fluorometric assay, for even higher sensitivity, using the fluorogenic substrate 4MUGlc and a fluorometer. Although most  $\beta$ -glucosidases hydrolyze *p*NPGlc and 4MUGlc, albeit at varying rates, some such as dhurrinase-1 of sorghum may not have any detectable activity on these popular artificial substrates. Therefore, an assay measuring the amount of glucose rather than the aglycone is desirable to detect the activity of a known or unknown enzyme on known or unknown natural substrates that are not chromogenic or fluorogenic. Coupling  $\beta$ -glucosidase assay to glucose oxidase/peroxidase assay meets the requirement of measuring glucose produced by  $\beta$ -glucosidase activity by oxidizing glucose to  $\delta$ -gluconolactone by

\*  $a$ , Amount of nitrophenolate (0.0121  $\mu$ mole) yielding 1.0  $A_{410}$ ;  $b$ , measured  $A_{410}$  (0.711);  $c$ , enzyme dilution factor (100);  $d$ , time multiplication factor (12) to convert assay time (5 min) to 1 h.

glucose oxidase. The latter reaction produces hydrogen peroxide, which is used by peroxidase as a hydrogen acceptor to oxidize a chromogenic peroxidase substrate 2,2-azino-bis (3-ethylbenzthiazoline-6-sulfonic acid) (ABTS). The amount of oxidized peroxidase product is determined by measuring the absorbance and relating it to equivalent amount of glucose using a glucose calibration curve.

### B. Solid-Phase Assays (Dot Blots and Zymograms)

Solid-phase assays are performed in the dot-blot format using nitrocellulose, polyvinylidene difluoride (PVDF), or ordinary chromatography paper. The test protein solutions are directly spotted on the matrix (sheet or strips) and incubated with a substrate whose aglycone forms an insoluble colored or fluorogenic spot at the site of enzyme activity. The most suitable chromogenic substrates for spot assay are 6BNGlc and XGlc. The aglycone of 4MUGlc may be detected by viewing under a UV lamp or on a UV box within the first 5 min or so, but it is soluble and cannot be fixed and detected later.

### C. Detection of $\beta$ -Glucosidase Activity on Polyacrylamide Gels

Zymogram assays are also routinely used for detection of the presence and multiplicity of  $\beta$ -glucosidase activity after native polyacrylamide gel electrophoresis (PAGE), isoelectric focusing gel (IEF), or sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under nondenaturing conditions. A sample protocol for native PAGE is given. The same protocol can be used for IEF and SDS gels if samples are applied to SDS gels without boiling. The following is a gel assay procedure that is applicable to all family 1  $\beta$ -glucosidases after changing the pH of the buffer to the one that is optimum for the enzyme of interest (modified from 48). The solutions and reagents needed are:

1. 100 mM citrate–200 mM phosphate buffer, pH 5.8. Titrate 200 mM citric acid solution with 400 mM sodium phosphate (dibasic) until pH is 5.8.
2. 50 mM citrate–100 mM phosphate buffer. Dilute the above buffer with water at a ratio of 1:1.
3. 6-Bromo-2 naphthyl  $\beta$ -D-glucopyranoside (6BNGlc). Prepare just before using in dimethyl formamide at 100 mg/mL in a 1.5-mL micro-

fuge tube. Usually 1 mL of 1 mg/mL solution will be sufficient for two gels.

4. Fast Blue BB salt. Dissolve 150 mg in 200 mL of 50 mM citrate–100 mM phosphate buffer, pH 5.8, in a 250-mL flask by stirring.
5. Fixative. Acetic acid methanol water mixed in 1:1:5 ratio. Store at room temperature.

Alternative substrate: 1 mM 4-methylumbelliferyl- $\beta$ -D-glucoside (4 MUGlc) in 50 mM citrate–100 mM phosphate buffer, pH 5.8. This substrate is more sensitive and detects more  $\beta$ -glucosidases than 6BNGlc, but gels cannot be stored and dried. One needs to photograph the gel within 5–20 min under UV light.

The procedure is as follows.

1. Place the gel in a glass or clear plastic tray after electrophoresis or isoelectric focusing. Equilibrate in two changes of 50 mM citrate–100 mM phosphate buffer, pH 5.8 ~ 15 min each, at room temperature.
2. Pour off the last (second) change of the equilibration buffer and then add freshly mixed substrate-coupling dye solution onto the gel in the dish. For this, add the substrate solution to the Fast Blue RR salt solution, mix in flask, and then pour onto the gel. Make sure that there is enough solution to cover the gel and permit free movement of the gel in solution during incubation and shaking.
3. Cover the tray with Saran wrap and aluminium foil; incubate in a shaker-incubator (set at ~ 50 rpm) in the dark at 37°C for 2–16 h.
4. Stop the shaker-incubator at intervals, remove foil, and check for the appearance and intensity of enzyme bands. If no bands develop or they are too light after 2 h, it is best to continue incubation overnight.

5. When enzyme bands develop to a desired intensity and resolution, pour off the substrate-dye coupling solution, and rinse the gel several times with water in order to wash away the precipitated dye-substrate complex.

6. Add the fixative solution (#5) and store at room temperature for several hours before photographing, scanning, or imaging. Note that enzyme bands are completely stable in fixative solution up to several months, and the gel may be dried for long-term storage and record keeping.

When one's interest is surveying a food source for  $\beta$ -glucosidase activity, a simple, rapid, and inexpensive assay procedure is needed. Clearly, chromogenic solution assay in 96-well microtiter plates and dot-blot assay on nitrocellulose or ordinary chromatography paper are the best choices as long as the enzyme of

interest hydrolyzes the test substrate at detectable levels. In certain applications, one might be interested in detecting a  $\beta$ -glucoside present in a food sample using a specific enzyme that hydrolyzes and detects it. In this case, the PGO assay will be the choice since it measures glucose production.

#### D. Factors Interfering with Assays

The presence of  $\beta$ -glucosidase inhibitors in buffers or tissue extracts can interfere with solution assays, especially when extracts are not diluted much. In this case, endogenous substrates, substrate analog (aryl or alkyl glycosides), and glucose and its analog (e.g.,  $\delta$ -glucuronolactone) can competitively inhibit the hydrolysis of test substrate such that the enzyme activity is neither detected nor underestimated. This problem can be alleviated by diluting crude extracts 50- to 100-fold if they have high activity levels or removing interfering substances by precipitating the enzyme with ammonium sulfate (AS) and resolubilizing to the original volume and/or dialysis.

### V. PURIFICATION

When it comes to purification, every protein becomes a specific project and challenge to the skills and ingenuity of protein biochemists, although one can prescribe a general scheme for purification of related proteins. Having said that, it should be noted that  $\beta$ -glucosidases are relatively easier to purify than most proteins. The reader is referred to the primary literature for detailed procedures to design a protocol to purify a specific  $\beta$ -glucosidase of interest. In the author's

laboratory, a number of maize and sorghum  $\beta$ -glucosidases and their chimeras and mutants have been successfully purified to homogeneity using just a combination of differential solubility and hydrophobic interaction chromatography (41, 49). Needless to say, the first step in purification protocol should start with differential solubility fractionation. To that end, a survey of buffers with different pH and ionic strengths to solubilize the  $\beta$ -glucosidase of interest while keeping most of the contaminating proteins insoluble or partly soluble would be worthwhile. For example, Mkpung et al. (50) were able to isolate cassava  $\beta$ -glucosidase by extraction with a buffer (0.1 M Na phosphate) of pH 3.5 with very high specific activity because the enzyme was stable and soluble at such a low pH, whereas contaminating proteins were not. Once conditions to extract the enzyme with high specific activity have been defined, such conditions can be used in large-scale purification projects. The next step would be to make a 40–60% ammonium sulfate (AS) cut on the crude extract (prepared with a buffer of pH 5–7) at 0–4°C as all family  $\beta$ -glucosidases precipitate between 40% and 60% AS concentration and can be fully recovered from the pellet by suspension in a suitable buffered solution. This step can increase specific activity significantly and serves as a stepping stone to a chromatographic separation method such as ion exchange, chromatofocusing, and hydrophobic interaction chromatography (HIC). Of these, HIC is the most effective as the pellet can be solubilized with 1.5 M AS in a buffer of pH 6–8, which itself removes a substantial amount of contaminants and then is directly loaded onto the column. In the author's laboratory HIC is performed on a Toyo-Pearl butyl column, and the eluate from this column, if necessary,

**Table 1** Purification<sup>a</sup> of the Sorghum  $\beta$ -Glucosidase Isozyme Dhr2 after Expression in *E. coli*

Purification steps	Enzyme activity ( $\mu$ mole o-NP h <sup>-1</sup> )	Protein (mg/mL)	Specific activity ( $\mu$ mole o-NP h <sup>-1</sup> mg <sup>-1</sup> )	Purification (fold)
1. Crude extract (before sonication)	17.54	0.98	17.90	1.0
2. Crude extract (after sonication)	82.05	4.90	16.74	0.94
3. 30% AS supernatant	82.01	4.50	18.22	1.02
4. 65% AS, pellet suspended	417.36	10.50	39.75	2.22
5. Butyl-HIC	119.70	0.74	161.76	9.04
6. Ether-HIC	68.02	0.24	283.42	15.83

<sup>a</sup> *E. coli* cell pellet was lysed in the extraction buffer (100 mM Tris-HCl, pH 8, and 50 mM NaCl), sonicated, and centrifuged. Ammonium sulfate (AS) was added to the supernatant (30% final concentration) and centrifuged. The supernatant was transferred to a fresh tube and sufficient AS was added to obtain 65% final concentration. The slurry was centrifuged and the resulting pellet was suspended in buffer, cleared by centrifugation, and subjected to hydrophobic interaction chromatography (HIC) on Toyopearl Butyl 650M and Toyopearl Ether 650M columns, respectively. Enzyme activity and protein content were determined after each step during purification.

may be rechromatographed on Toyo-Pearl Ether-M650. This two-step procedure after optimization of elution conditions for HIC yields homogeneous or near homogeneous preparations for characterization and crystallization studies. A summary of purification steps and increase in specific activity using the described procedure for the sorghum  $\beta$ -glucosidase isozyme Dhr2 expressed in *E. coli* is given as an example in Table 1.

## **$\beta$ -D-Fructofuranoside Fructohydrolase**

**Laura Cantarella**

*University of Cassino, Cassino, Italy*

**Francesco Alfani<sup>†</sup> and Maria Cantarella**

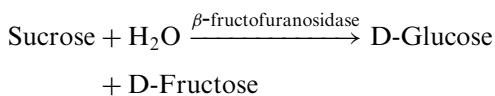

*University of L'Aquila, L'Aquila, Italy*

### **I. INTRODUCTION**

$\beta$ -D-Fructofuranoside fructohydrolases ( $\beta$ -Fs) are sucrose-hydrolyzing enzymes found in microbial, plant, and animal sources. Trivial names are  $\beta$ -fructofuranosidase, formerly called invertase or saccharase, and sucrase. The enzyme was first isolated by Berthelot in 1860 (1).  $\beta$ Fs occur in *Saccharomyces cerevisiae* and in strains used in brewing, distilling, wine making, and the baking of bread, as an extracellular glycoprotein, the predominant form, and an intracellular protein (2, 3). Several molecular forms exist differing in molecular weight and cell location even within the same yeast culture. Most  $\beta$ Fs in plants and tissues (5–9) are multimeric proteins discernible on their pH optima (acid, 4.5–5.0, and neutral (alkaline), 7.0–7.8) (10–13), glycosylation state, subcellular location, and pI values.  $\beta$ Fs from *S. cerevisiae* or *S. carlsbergensis* are commercially available.

#### **A. Chemical Reaction Catalyzed**

Sucrose hydrolysis is the main reaction catalyzed by  $\beta$ F. Raffinose and stachyose are hydrolyzed to a lesser extent.

Acid  $\beta$ Fs are able to catalyze transfructosylation reactions. At high sucrose concentration (1 M), the  $\beta$ -D-fructofuranosyl residue is transferred to a primary alcohol (methanol, ethanol, n-propanol) and to only isopropanol as a secondary alcohol (3).

#### **B. Chemical Structure of Substrates**

1. Sucrose,  $\alpha$ -D-glucopyranosyl [1 → 2]- $\beta$ -D-fructofuranoside, also indicated as [Glc  $\beta$  1,2 Fru]
2. Raffinose, O- $\alpha$ -D-galactopyranosyl [1 → 6]- $\alpha$ -D-glucopyranosyl [1 → 2]- $\beta$ -D-fructofuranoside, also indicated as [Gal  $\alpha$  1,6 Glc  $\beta$  1,2 Fru]
3. Stachyose,  $\alpha$ -D-galactopyranosyl [1 → 6]- $\alpha$ -D-galactopyranosyl [1 → 2]- $\beta$ -D-fructofuranoside, also indicated as [Gal  $\alpha$  1,6 Gal  $\alpha$  1,6 Glc  $\beta$  1,2 Fru]
4. Substituted  $\beta$ -D-fructofuranosides, such as methyl- $\beta$ -D-fructofuranoside, and *p*-nitrophenyl- $\beta$ -D-fructofuranoside

#### **C. Classification According to Enzyme Commission Nomenclature**

All  $\beta$ Fs are classified as EC 3.2.1.26. True  $\beta$ Fs have to show no activity with nonsubstrates such as cellobiose [Glc  $\beta$ 1,4 Glc], gentobiose [Glc  $\beta$ 1,6 Glc], lactose [Gal

<sup>†</sup>Deceased.

$\beta$ 1,4 Glc], maltose [Glc  $\alpha$ 1,4 Glc], melezitose [Glc  $\alpha$ 1,3 Fru  $\alpha$  2,1 Glc],  $\alpha$ -methyl-D-glucopyranoside,  $\beta$ -methyl-D-glucopyranoside,  $\alpha$ , $\alpha$ -trehalose [Glc  $\alpha$ 1,1 Glc] or turanose [Glc  $\alpha$ 1,3 Fru], and *p*-nitrophenyl- $\beta$ -glucoside ( $\alpha$ -fructofuranosides, fructopyranosides,  $\beta$ -L-sorbofuranosides,  $\beta$ -D-xyloketofuranosides, and sugars with substituent on the  $\beta$ -fructofuranosyl residue).

## II. IMPORTANCE TO QUALITY OF FOOD DURING GROWTH, MATURATION, STORAGE, AND PROCESSING

In plants, the different  $\beta$ F isoforms independently control import sucrose metabolism, sugar composition in storage organs, translocation from source tissues to sink tissues, osmoregulation, and gravitropism (6, 14–16). Compositional changes observed in several developing fruits are associated with the changes in enzyme activities related to sucrose metabolism. Acid and neutral  $\beta$ F activities are very high in immature fruits of *Cucumelis melo* L. and decline rapidly and concomitantly with the accumulation of sucrose, as the fruit matures (7). The activation of preexisting invertase in dormant *Helianthus tuberosus* (Jerusalem artichoke) tubers takes place at the beginning of the germination process.

The absence of  $\beta$ F contributes to the accumulation of sucrose rather than hexoses as a source of carbon and energy. Vacuolar  $\beta$ F controls the sugar composition in tomato species (15). *Lycopersicon esculentum* has high  $\beta$ F activity, accumulates high levels of glucose and fructose, and stores little sucrose. In contrast, *L. peruvianum* and *L. chmielewskii* (15) have low  $\beta$ F activity, accumulate high levels of sucrose and store little glucose and fructose. Vacuolar  $\beta$ Fs are also involved in glucose and fructose accumulation in grape berries that is one of the main features of the ripening process and is a major commercial consideration for grape growers, wine makers, and dried-fruit producers (17). Alkaline  $\beta$ F activities increase during the development and maturation of tissues in sugar cane stalks, carrot, and sugar beet roots and young *versus* mature leaves of *Citrus sinensis*.

During cold storage (1–3°C), potato tuber  $\beta$ F isoforms cause the accumulation of reducing sugars that are responsible for the development of unpalatable flavor and texture in cooked potatoes (18). Darkening of the potatoes due to a nonenzymatic Maillard reaction also occurs. Sugarbeet roots contain an endophytic population of sucrose-hydrolyzing bacteria (*Pseudomonas fluorescens*) that possibly utilize the sucrose in

stored roots awaiting processing (19). During the pre-storage phase of *Vicia faba*, high levels of hexoses in the cotyledons are correlated with the activity of seed coat-associated invertases. The degradation of the thin-walled parenchyma expressing the invertase (developmentally regulated) apparently initiates the storage phase and is characterized by a switch to a low sucrose/hexose ratio (8). During the storage of raw juice extracts from healthy tubers of *Cyperus esculentus* Linn. (earth almond), yeasts possibly play a greater role than bacteria in the hydrolysis of sucrose. *Saccharomyces rouxii*, an osmophilic yeast strain, was isolated from dried prunes where the natural environment typically has a high concentration of sucrose. The species survives by initially metabolizing other components in the medium. After death of a fraction of the population, cryptic  $\beta$ F hydrolyzes sucrose, and the osmotic pressure is gradually lowered. Competition with other microorganisms in the ecological niche is thus delayed.

In plant intact tissue nearly all the  $\beta$ F activity can be attributed to alkaline  $\beta$ F, while in the case of injury, acid  $\beta$ Fs are rapidly formed in response to wounding and bacterial infection, suggesting their possible role in pathogen defense mechanisms (20). The active defense response can be induced by chemical stimuli (elicitors) derived from fungi (21).  $\alpha$ -Chymotrypsin cleavage of yeast  $\beta$ F generates small glycopeptides, acting as elicitors in tomato cells, inducing the biosynthesis of ethylene (plant stress hormone) and of phenylalanine ammonia-lyase. By contrast, the isolated glycan side chains act as suppressors.

Freezing-tolerant wheat cultivars may respond to subzero temperatures and increase hardiness by the conversion of fructan to cryoprotective sugars, such as fructose and sucrose, whereas snow mold-resistant cultivars continue to accumulate fructan. This difference in response to subzero temperature may depend on differences in gene expression of enzymes in fructan metabolism, which involves several enzymes (22).

## III. RAW-FOODS ENZYMES FOUND

In *Saccharomyces cerevisiae*, internal  $\beta$ F is found in the cytoplasm whereas external  $\beta$ F resides on the cell wall (cw- $\beta$ F), and functions to cleave extracellular sucrose to fructose and glucose, sugars that yeast can import (2, 3).

In plants, the subcellular location of soluble  $\beta$ F is controversial: the enzyme is described either as cytoplasmic, despite its glycoprotein nature, or as vacuolar. Spatially,  $\beta$ Fs occur as intra- and extracellular forms.

Both soluble and cw- $\beta$ Fs are found (23–27). Two types of acid  $\beta$ F (N-linked glycoproteins) are located either as soluble proteins in the vacuole or ionically bound to the cell wall. Acid and neutral  $\beta$ Fs may coexist even in the same tissue (11). However, acid  $\beta$ F is mainly found in immature tissues while neutral  $\beta$ F is confined to mature storage tissues of sucrose-accumulating plants. In contrast, neutral  $\beta$ F in the mesocarp of developing muskmelon declined with the accumulation of sucrose (7). Soluble acid  $\beta$ F also occurs in the apoplast of plant tissues (papaya, sugar cane, oat, radish, wheat, maize, artichoke, barley, potato, carrot, cherry, tomato, peach, strawberry). Acid  $\beta$ F is extremely low in the reserve cotyledon tissue throughout development, and activity appears to be correlated with the growth and differentiation of certain plant tissues, particularly involved in organ elongation and cell enlargement (6). It declines rapidly when roots begin to enlarge, and is hardly detectable in mature roots and organs. Acid cw- $\beta$ F plays a key role in the generation of sink strength of storage sinks (photosynthetically less active or inactive tissues such as stems, flowers, and roots) during development of *Vicia faba* L. seeds (28). Less information is available on neutral or alkaline  $\beta$ Fs (10) present in the cytoplasm of most living cells of higher plants.

#### IV. UTILITY/UTILIZATION OF ENZYMES IN FOODS

In the food industry, the main use of  $\beta$ F is for producing chocolate-coated candies with a soft and creamy center. A hard and firm center is prepared with sucrose and molded into the desired shape. After coating with chocolate the  $\beta$ F is inoculated into the center to change its consistency to a permanent and noncrystallizable cream. Purified  $\beta$ F is preferred to yeast since variations in both the added amount and in the strains of yeast utilized does not assure uniform quality of softer centers. Other  $\beta$ F uses are related to the production of artificial honey and to the enzymatic determination of glucose and sucrose in dietetic foods (29). The productivity value, the operational stability and mechanical stability of  $\beta$ F, the low cost of the immobilization on a variety of carrier, and the absence of undesirable reaction byproducts make the scale production of inverted syrups from sucrose and nonrefined sugars economically very attractive. In the confectionery industry fructose is preferred over sucrose because it is sweeter and does not crystallize as easily. Health and taste reasons require highly purified  $\beta$ F. Invertase from *S. cerevisiae* is utilized for the commercial production

of invert sugars from sucrose at concentrations up to 3 M (30).

Brewing, distilling, wine making, and the baking of bread all require freshly grown, specially developed yeast strains (*S. cerevisiae*) to inoculate each fermentation. The activity of  $\beta$ F and of  $\beta$ -glucosidase determines the physical and organoleptic properties of bread. The capacity of a given strain for sugar uptake and the further conversion of the sugars present in bread dough are of primary importance for its bread-making suitability (31).

Fructo-oligosaccharides (1-kestose, nystose, and 1<sup>F</sup>- $\beta$ -fructofuranosyl nystose), produced by transferring one, two, or three molecules of fructose to the fructose residue in sucrose by the action of fungal  $\beta$ F (32), have been shown to decrease the levels of cholesterol and lipid in the serum and to stimulate the growth of intestinal bifidobacteria.

Transgenic tomato plants that expressed a yeast  $\beta$ F show a decrease in the growth rate. Accumulation of hexoses and amino acids (proline) is up to 40-fold higher than in the wild type. The fruits were ~30% smaller than controls. Soluble acid  $\beta$ F controls this differential growth which correlates with high rates of sugar accumulation during the last stage of development (33). Potato tubers expressing yeast  $\beta$ F in the cytosol result in a reduction in tuber size and an increase in tuber number per plant, whereas apoplastic targeting leads to an increase in tuber size and a decrease in tuber number per plant (18).

#### V. PROPERTIES AS PROTEIN

##### A. Molecular Weight

The molecular mass of  $\beta$ Fs varies considerably: in plants from 42 kDa to 504 kDa, in microorganisms from 37–560 kDa. The glycosylated nature may lead to a lack of precision in estimating the molecular weight. Values are reported in Tables 1 and 2.

##### B. Primary, Secondary, Tertiary, Quaternary, and Macromolecular Structures

Internal and external yeast  $\beta$ Fs appear with identical protein moieties. The same (SUC2) gene is translated from different start codons resulting in one or two additional amino acids (a.a.) at the N-terminus of external  $\beta$ Fs (44). The subunit has an MW of ~58 kDa. Internal  $\beta$ F exists in its native state as a nonglycosylated active monomer. A signal sequence directs external  $\beta$ F into the endoplasmic reticulum, where it

is glycosylated (45). The enzyme consists of 140-kDa subunits, which are in excess of 50% by weight mannose glycan and 3% glucosamine. The carbohydrate is attached as short oligosaccharides ( $\text{Man}_{8-14}\text{GlcNAc}_2$ ) to hydroxyamino acids or as polysaccharide chains ( $\text{Man}_{>50}\text{GlcNAc}_2$ ) to asparagine through N-acetylglucosamine. The protein consists of 13 or 14 potential glycosylation sites with an Asn-X-Ser (or Thr) although only 9–10 appear to be glycosylated (45). Yeast  $\beta\text{F}$  presents a continuous spectrum of molecular forms that might represent different degrees of glycosylation during the secretion process, which culminates in the formation of the heavy extracellular enzyme (4). The oligosaccharide moiety maintains external  $\beta\text{Fs}$  in an oligomeric equilibrium of dimer, tetramer, hexamer, and octamer, equally active, and facilitates, without affecting the active sites of  $\beta\text{F}$ , subunit interactions to form active oligomers. The very stable dimers present a spherical nature presumably with the two monomers tightly bound (46), occluding some oligosaccharides at the interacting subunit surfaces. Dissociation to a monomer results in the generation of a form devoid of enzyme activity (43).

In contrast to *Saccharomyces*, SUC2  $\beta\text{F}$  secreted by *Pichia pastoris* is a homogeneous product of ~85-kDa subunits associated with 8–10 oligosaccharides of the size  $\text{Man}_{8-14}\text{GlcNAc}_2$ . However, the majority of component of  $\text{Man}_{8-10}\text{GlcNAc}$  family has structures identical to those found associated with *Saccharomyces*  $\beta\text{F}$ . The protein produced by *A. niger*  $\beta\text{F}$  gene (SUC1) contains 14 potential glycosylation sites with equal numbers of the two sequences Asn-X-Thr and Asn-X-Ser, for N-linked glycosylation. The  $\beta\text{F}$  a.a. sequences from *S. cerevisiae* and *Schwanniomyces occidentalis* contain large conserved domains but do not exhibit extensive homology in any region of the protein with the predicted sequence of the *A. niger* enzyme. Six domains of *S. cerevisiae*  $\beta\text{F}$  and *Schw. occidentalis* are conserved in  $\beta\text{Fs}$  from prokaryotes, *Zymomonas mobilis*, *Bacillus subtilis*, *Streptococcus mutans*, and *Vibrio alginolyticus*. By contrast, only one could be partially identified in the *A. niger*  $\beta\text{F}$  since only six a.a. were identical of the nine a.a. which comprised the domain.

Homologous sequences in 14 *S. cerevisiae* strains and in 10 closely related *Saccharomyces* spp. are detected by using cloned SUC2 DNA probes. The SUC DNA sequence is highly conserved within the genus *Saccharomyces*; only the DNA from *Saccharomyces kluyveri* UCD51-242 fails to hybridize with the SUC2 DNA probe. During evolution its SUC gene has diverged sufficiently to leave no detectable homology (44).

Significant sequence homologies around the catalytic residues (Asp23 and Glu204) has been shown with other fructosylhydrolases from different sources. Inulinase from *Kluyveromyces marxianus* and  $\beta\text{F}$  from *Pichia anomala* share 53% and 44% homology, respectively, and the inulinase contains a single cysteine residue that corresponds to Cys205 in the  $\beta\text{F}$ . Yeast  $\beta\text{F}$  is closer to levanases and fructosyltransferase from bacteria (34–35% homology) than bacterial sucrases (30–31% homology) and plant  $\beta\text{Fs}$  (27–29% homology) (47).

In plants, alkaline  $\beta\text{Fs}$  are thought to be nonglycosylated proteins (6). The glycosylation of cytoplasmically synthesized acid  $\beta\text{F}$  is necessary for its transport across either the tonoplast or the plasma membrane. Nucleotide and predicted amino acid sequences of acid invertase cDNA are known for tomato fruit, carrot, potato tuber, and grape berries (17, 48–50) with the following homologies in the amino acid sequences: tomato acid  $\beta\text{F}$  and carrot extracellular acid  $\beta\text{F}$  are 40.5% identical; isoenzyme I of carrot soluble acid  $\beta\text{F}$  and acid  $\beta\text{F}$  from tomato are closely related; isoenzyme II and acid  $\beta\text{F}$  from bean show the highest homology; carrot extracellular cw- $\beta\text{F}$  and acid  $\beta\text{F}$  potato share high homology. A phylogenetic tree was generated (49). Table 3 reports some identified genes producing  $\beta\text{F}$  in plants and microorganisms together with molecular characteristics.

### C. Isoforms

Some of the identified  $\beta\text{F}$  isoforms in plants and microorganisms are reported in Tables 1 and 2. Growth conditions and glucose concentration determine the cellular content of internal and external forms and their distribution in yeasts. In repressed *S. cerevisiae* cells, most of the enzyme is intracellular; in derepressed cells, 95% of the total enzyme is mainly located outside the cytoplasmic membrane. In *Saccharomyces* wild type six different genes encode six isoforms of  $\beta\text{F}$ . The existence of multiple forms of  $\beta\text{F}$  is common also in fungi (40).  $\beta\text{F}$  isoforms are not uncommon in plants with their location in tissues well distinct, and concentration levels within cells appeared to be regulated during development.

#### 1. From Different Genes

Six  $\beta\text{F}$  structural genes in unlinked loci, similar in structure and expression but not identical, are known in the yeast *S. cerevisiae*—SUC1–SUC5 and SUC7. Each SUC gene encodes both the constitutive

nonglycosylated  $\beta$ F and the glycosylated one (4, 44). The different yeast strains contain zero, one, or several of these genes, and the possession of one active SUC gene enables a yeast strain to ferment sucrose and raffinose. Strains expressing different SUC genes reveal different specific  $\beta$ F activities under both repressing and derepressing conditions. SUC4 determines the highest  $\beta$ F activity on raffinose as carbon source. Strains expressing SUC7 are unable to grow on raffinose as the sole carbon source. SUC4 and SUC5 differ in their  $\beta$ F activity about fivefold. SUC2, the most extensively studied, encodes the enzyme  $\beta$ F, required for growth of yeast cells on sucrose. SUC2 is transcriptionally repressed in high glucose whereas it is derepressed in low glucose, and transcription is increased > 100-fold (44).

In many plants  $\beta$ F is encoded by a multigene family (9). The different isoforms of tomato fruit  $\beta$ F may originate from a single gene or from closely related genes (16). In *Daucus carota* L. different genes encode acid  $\beta$ F while the neutral  $\beta$ F is encoded either by different genes or by the same gene and is generated by differential splicing or proteolytic cleavage of alkaline  $\beta$ F (12, 24). Only one gene appears to encode  $\beta$ F in *Helianthus tuberosus*, although it is possible that several genes produce transcripts of a similar size. The transcript size (2.5 kb) is close to those shown in tomato fruit (2.4 kb), carrot (2.0 kb), and yeast (1.8 and 1.9 kb). Multiple  $\beta$ F cDNAs were isolated from carrot tissue and exhibited between 44% and 99.1% identity of amino acid sequence. Two cDNAs (GIN1 and GIN2) were cloned from berries; the translation products are 62% identical to each other, and both appear to be vacuolar forms of  $\beta$ F (17).

## 2. From Posttranslational Modification

The most posttranslational modification of  $\beta$ Fs is the extensive glycosylation that could affect the efficiency of biosynthesis and secretion of both the heterologous and homologous proteins. During secretion and transport to the periplasm the signal peptide is cleaved and the external yeast  $\beta$ F becomes glycosylated. The polymannose chains aid the self-association of homodimer into tetramer, hexamer, and octamer (46, 47).

## 3. Artifacts

Freezing or addition of PEG promotes the self-association of only external yeast  $\beta$ F subunits. Low NaCl concentration favors the presence of internal  $\beta$ F dimers while concentration as high as 0.8 M yields the maximum octamer-hexamer mixture. In external

$\beta$ F oligosaccharides shield the subunit from large interactions with NaCl. The formation of higher oligomers is also facilitated by KCl. Concentrations up to 0.4 M of CH<sub>3</sub>COONa, (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, K<sub>3</sub>PO<sub>4</sub>, and NaF have no effect, indicating that chloride ions are primarily responsible for promoting self-association. External  $\beta$ F exists mostly as tetramers in 0.8 M GuHCl, reflecting the opposing effects of dissociation by guanidium and association by chloride ions (46).

Soluble  $\beta$ F of carrot isoenzyme I (68 kDa) and tomato are cleaved into an N-terminal and a shorter C-terminal fragment, neither of which separates during protein purification (16, 24, 49). Whether this proteolytic cleavage occurs in vivo or during protein purification is not known. The monomeric nature of the carrot enzyme suggests a labile bond such as a disulfide bridge between the two polypeptide fragments. Maturation of tomato acid  $\beta$ F may involve additional proteolytic processing at the C-terminus (48) since the MW of predicted mature polypeptide (60 kDa) exceeds that determined by SDS (52 kDa).

## VI. PROPERTIES AS ENZYME

### A. $K_m$ , $V_{max}$ , Substrates, Nonsubstrates, and Activation Energy

Tables 4 and 5 report the Michaelis constant for sucrose,  $K_m^{\text{Suc}}$ , and raffinose,  $K_m^{\text{Raf}}$ , of  $\beta$ Fs from several plants and microorganisms, other identified substrates and nonsubstrates, the optimal pH, and maximal velocity. In plants,  $K_m^{\text{Suc}}$  for alkaline  $\beta$ F is higher than that of the acid form. The activation energy,  $E_a$  of plant  $\beta$ F has been reported to be 57.3 kJ/mol for *Ricinus communis* (25) and 147 kJ/mol for nodules of *Cicer arietinum* L. (51). The  $E_a$  value is 37.63 kJ/mol in whole yeast cell for acid  $\beta$ F (56) and 29.30 kJ/mol for a soluble preparation of acid  $\beta$ F from yeast (57).

### B. Effect of Environmental Factors

The optimal pH depends on the form and the source of  $\beta$ F as presented in Tables 4 and 5. *Saccharomyces cerevisiae*  $\beta$ F exhibits relatively high activity over a broad range of pH (3.5–5.5), with the optimum near pH 4.5. The enzyme activity reaches a maximum at ~55°C. Certain ions affect the pH optimum of  $\beta$ F. The symbol (—) in Table 6 indicates a weak inhibition, with at the most 20% loss of  $\beta$ F activity. Inhibition constants and inhibition mechanism, when identified, are reported in Table 7. Plant  $\beta$ Fs are characteristically inhibited by heavy metals and reagents that react with sulphydryl

groups.  $Hg^{2+}$ , *p*-chloromercuribenzoate (100  $\mu M$ ), and *p*-chloromercuriphenyl sulfonic acid (100  $\mu M$ ) completely inhibit the  $\beta F$ .  $Co^{2+}$  and  $Zn^{2+}$  are inhibitors to a weaker extent.  $Ag^+$  ions attach to the histidine side chains of the  $\beta F$  molecule and render it inactive. Dithiobis 2-nitrobenzoic acid and iodoacetamide, reagents known to inactive enzymes that require free sulphydryl groups for activity, have no effect because such groups are perhaps inaccessible under the assay conditions (10). Inhibitors of plant  $\beta F$ s are pyridoxal, pyridoxine, and pyridoxamine (5–7, 26, 27). Yeast external  $\beta F$  is weakly inhibited by *p*-hydroxymercuribenzoate, N-ethylmaleimide, iodoacetic acid, and iodoacetamide. Alkaline metal ions and related cations affect alkaline  $\beta F$  activity from *Ipomoea batatas* in the order of  $Li^+ > Na^+ > K^+ > Rb^+ > NH_4^+ > Tris^+$ , while anions affect the activity in order of  $F^- > NO_3^- > Br^- > I^- > Cl^-$ . The interrelated effect of cations and anions on  $\beta F$  activity prevents distinction between activator (suggested  $Na^+$  and  $K^+$ ) and inhibitor (suggested  $Cl^-$ ) (20). Some alkaloids found in vacuoles (caffeine, berberine, strychnine, morphine, ethyl-narceine, and nornicotine) produce an inhibiting effect on  $\beta F$  activity of *Ricinus communis*, *Solanum tuberosum*, *Oryza sativa*, and *Carica papaya* (60). Acid  $\beta F$ s activity is curtailed by endogenous proteinaceous inhibitors (36) as it occurs in red beet, sugar beet, and sweet potato and in maize endosperm. Plant  $\beta F$ s are activated by exogenous proteins (*R. communis*  $\beta F$  activity is increased 30%), PVP, and dextran sulfate (25), which suppress the inhibitory action of glucose, fructose, and organic acids. Since the vacuoles contain ~19% of the total protein of the protoplast, it appears unlikely that fructose or the other vacuolar metabolites could exert control on  $\beta F$  activity.

### C. Specific Mechanism of Action

The mechanism of yeast  $\beta F$  action involves a nucleophile and a proton donor in a two-step reaction. The Glu204 residue acts as a proton donor to the glycosidic oxygen of sucrose. The C-2 of the fructose moiety is attacked by the nucleophile Asp23. A covalent fructosyl-enzyme complex is formed and glucose is released. In the second step a proton from the water molecule is abstracted by Glu204. The hydroxyl group displaces fructose, and the original active center residues are restored. Glu204 is essential for sucrose hydrolysis while Cys205 possibly plays a supportive role in catalysis by maintaining a suitable microenvironment in the active site, or perhaps in aiding substrate binding. A carboxylate group, along with histidine, methionine,

and tryptophan residues, is essential for  $\beta F$  activity. An ester linkage of the carboxylate group with conduritol B epoxide causes an irreversible inactivation of  $\beta F$ . The participation of carboxyl imidazole groups in catalysis is suggested for *Neurospora*  $\beta F$ s and in some higher plants (47).

### D. Unique Properties

Yeast  $\beta F$ s have a transferring activity for  $\beta$ -fructofuranosyl residues that is negligible under the usual assay conditions (2).  $\beta F$ s from barley leaves exhibit a fructosyltransferase activity, at high concentrations of sucrose, forming mainly 1-kestose (34). The action of transglycosylation or transfructosylation of different microorganisms'  $\beta F$  (61, 62) leads to fructosyl and oligofructosyl trehaloses. Methyl fructosides are prepared from sucrose and methanol by  $\beta F$ s from *S. cerevisiae* (63). Mold  $\beta F$ s also (*A. niger*, *A. sydowi*, *A. japonicus*, *A. oryzae*, *Penicillium oxalicum*, *Aureobasidium* sp.) show high transfructosylating activity (38).

The hydrolysis of inulin is also catalyzed, albeit very slowly, by  $\beta F$ s. Unlike that in higher plants, the majority of microbial inulinases also possess sucrose hydrolytic activity and are thus classified as nonspecific  $\beta F$ s. The reverse situation, that all microbial  $\beta F$ s possess inulinase activity, has not been verified (40). The question in debate is whether inulinase should be regarded as a special type of  $\beta F$  or as a different enzyme with an analogous mode of action. Inulinases are characterized by the ratio of the activities with sucrose versus inulin as substrates < 50. The physiological role of  $\beta F$  mainly concerns the hydrolysis of sucrose within the cell wall. The main physiological role of inulinase is the breakdown of fructans outside the cell wall. Difructose dianhydride is hydrolyzed to D-fructose in two reaction steps by the enzyme from *Arthrobacter aureafaciens* presumed to be a  $\beta$ -fructofuranosidase, which is markedly different from yeast enzyme. It is not clear whether *Arthrobacter* enzyme is some other fructan hydrolase.

## VII. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

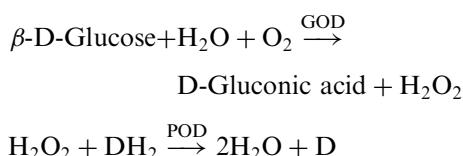

### A. Assay Conditions

Approximately 0.03–0.05 units of acid  $\beta F$  are incubated in 0.05 M acetate buffer, pH 4.6, with 100–200 mM sucrose for 10–60 min at 30 or 37°C. Phosphate

buffer, pH 7.5, is used for alkaline  $\beta$ F. Crude extracts require 0.1 M buffer.

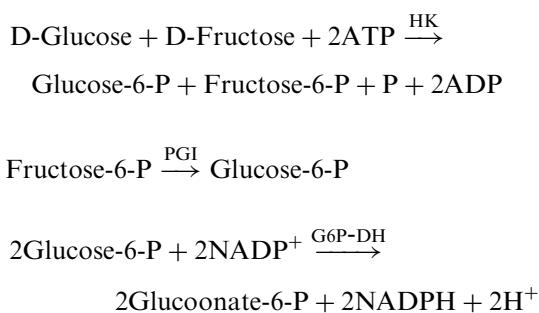

The amount of glucose or fructose released can be estimated by enzymatic quantitative assay or by any of the procedures commonly used for determining reducing sugars such as the dinitrosalicylic acid (DNS) method (64) or the Nelson-Somögyi method (65). Glucose always serves as standard in the calibration curve.

1.  $\beta$ -D-Glucose is determined by coupled reactions involving glucose oxidase (GOD), peroxidase (POD), and *o*-dianisidine dihydrochloride (DH<sub>2</sub>) as chromogen.

The  $\beta$ F activity is stopped by changing the pH with the 0.5 M addition of Na<sub>2</sub>HPO<sub>4</sub>, pH 8.83 (which also accelerates the mutarotation of  $\alpha$ -D-glucose), and heating in a boiling bath for 10 min. A 0.4-mL volume of GOD-POD mixture (0.4 unit of each enzyme and 400  $\mu$ g of DH<sub>2</sub>) is mixed with 0.8 mL incubation mixture and kept for 30 min at 37°C. Then 0.3 mL of 6N HCl is added. The color developed is measured at 460 nm against blanks.

2. The D-glucose and D-fructose released are determined using a commercial kit (Boehringer Mannheim) based on hexokinase (HK), phosphoglucomutase (PGI), and glucose-6-phosphate dehydrogenase (G6P-DH).

A 0.01-mL volume of the sample for  $\beta$ F activity assay is added with 2.5 mL triethanolamine buffer (0.1 M, pH 7.6), 0.1 mL MgCl<sub>2</sub> (0.2 M), 0.1 mL ATP Na salt, 0.1 mL NADP Na salt, 0.01 mL HK, 0.01 mL PGI (all 10 mg/mL), and 0.01 mL G6P-DH (5 mg/mL). The reaction is kept at 25°C for 15 min and the absorbance is read at 340 nm. Deproteinization of biological samples (e.g., food) and addition of 0.5 mM EDTA to

inhibit the nonspecific reoxidation of NADPH are recommended.

3. *Dinitrosalicylic reagent* (DNS): Dissolve 40 g dinitrosalicylic acid, 8 g phenol, 2 g Na<sub>2</sub>SO<sub>3</sub>, 800 g Rochelle salt (NaKC<sub>4</sub>H<sub>4</sub>O<sub>6</sub> · 4H<sub>2</sub>O) in 2 L of 2% (w/v) NaOH solution and then dilute it to 4 L with distilled water. *Procedure:* Add 1 mL DNS reagent to 0.5 mL assay mixture, and it stops the action of  $\beta$ F by shifting the pH of the medium into the alkaline range. Heat 5 min in a boiling water bath, then dilute with 2–10 mL water, and measure the absorbance at 540 nm. The molar extinctions of glucose and fructose are identical.

4. *Nelson-Somögyi reagents.* *Reagent A:* Dissolve 25 g Na<sub>2</sub>CO<sub>3</sub>, 25 g NaKC<sub>4</sub>H<sub>4</sub>O<sub>6</sub> · 4H<sub>2</sub>O (Rochelle salt), 20 g NaHCO<sub>3</sub>, and 200 g anhydrous Na<sub>2</sub>SO<sub>4</sub> into distilled water (1 L final volume). Store at room temperature. *Reagent B:* Dissolve 15% (w/v) of CuSO<sub>4</sub> · 5H<sub>2</sub>O in water with few drops of concentrated H<sub>2</sub>SO<sub>4</sub>. *Reagent C:* Dissolve 50 g (NH<sub>4</sub>)<sub>2</sub>MoO<sub>4</sub> in 900 mL water. Add slowly under stirring 42 mL concentrated H<sub>2</sub>SO<sub>4</sub>, then add 6 g Na<sub>2</sub>HAsO<sub>4</sub> · 7H<sub>2</sub>O in 50 mL water. Mix, incubate at 37°C for 24–48 h, and store in a dark bottle.

**Procedure:** The enzyme reaction (1.0 mL) is stopped with 1 mL of a freshly prepared solution (25 mL reagent A + 1 mL reagent B) and heated for 20 min in a boiling bath. Cool on ice bath, add 1 mL reagent C with immediate mixing to develop a blue color and CO<sub>2</sub>. Dilute with water to 25 mL and mix. Read absorbance at 520 nm against reagent blank.

## B. Specific Activity

One unit of activity is defined as the amount of enzyme that hydrolyzes 1  $\mu$ mol substrate (expressed as glucose equivalent) per min under the assay conditions. Alternately, units can be expressed in microkatal—i.e., the amount of enzyme catalyzing the hydrolysis of 1  $\mu$ mol substrate per sec under the assay conditions. The specific activity of  $\beta$ F is expressed as units of katal/mg protein as measured by the method of Lowry et al. (66) with bovine serum albumin as a standard protein.

## VIII. PURIFICATION

Most purification schemes of  $\beta$ F from different sources are adapted from the procedure of Goldstein and Lampen (3) with extensive modifications. Purification-fold,  $\times$ P, and percentage of activity recov-

ery, R, are listed in Table 8 for  $\beta$ F from some microorganisms and plants.

The procedure of Chu et al. (43) for internal  $\beta$ F from *S. cerevisiae*, leading to a 19,390-fold purification and 19% activity recovery, is hereafter outlined. All operations are carried out at 0–5°C.

1. Yeast paste is suspended in equal weight of 50 mM Tris-HCl pH 7.5, with 5 mM MgCl<sub>2</sub>, 40 mM  $\beta$ MSH, 1 mM phenylmethylsulfonylfluoride (PMSF, a protease inhibitor), and broken in a Bead-Beater. Cell lysate is centrifuged 20 min at 30,000g (R = 100;  $\times P$  = 1).

2. 1% streptomycin sulfate is added to the supernatant and after 1 h in an ice bath; nucleic acids and ribosomes are removed by centrifugation (R = 98;  $\times P$  = 1.04).

3. A precipitate is obtained from streptomycin supernatant at 40–85% (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> saturation and is then dissolved in 10 mM Tris-HCl buffer, pH 7.3 (buffer 1) containing 1 mM  $\beta$ MSH and 0.5 mM PMSF, and dialyzed thoroughly against this buffer.

4. 2 M acetic acid solution is added to the dialysate to bring the pH to 4.9. A proteic precipitate is

formed and is discarded. The supernatant, containing  $\beta$ F, is adjusted to pH 7.3 with a Trizma base solution.

5. The supernatant is loaded onto a Whatman microgranular DE 52 column (2 × 18 cm). This is developed with 1 L linear gradient of 50–350 mM NaCl in buffer 1. External  $\beta$ F is eluted at ~0.1 M NaCl, while the internal form is eluted at 0.2 M NaCl (R = 54;  $\times P$  = 1.5).

6. Fractions exhibiting internal  $\beta$ F activity are pooled and concentrated by precipitation with solid (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> up to 80% saturation (R = 35;  $\times P$  = 5024).

7. The precipitate is dissolved in 1–2 mL buffer 1 with 0.1 M NaCl and loaded onto a Ultrogel AcA 44 column (1.5 × 98 cm) equilibrated with the same buffer. The  $\beta$ F fractions are pooled and added with (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> to a final concentration of 20%, then chromatographed on a 1 × 4 cm column of phenyl-Sepharose CL-4B equilibrated with buffer 1, plus 20% (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>. A linear gradient, 20–0% (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> in buffer 1, is applied for eluting internal  $\beta$ F in a pure form at 5% (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> (R = 22;  $\times P$  = 19,610).

8. Concentration by ultrafiltration and dialysis against 10 mM NaH<sub>2</sub>PO<sub>4</sub>/Na<sub>2</sub>HPO<sub>4</sub>, pH 7.2 (R = 19; ×P = 19,390).

The procedure suggested by Bracho and Whitaker (36) for a plant glyco- $\beta$ F and outlined hereafter allows good purification-fold (1560) and enzyme recovery (29%). All steps are performed at 0–5°C.

1. Potato slices (1 kg) are homogenized with 100 mL NaHSO<sub>3</sub> (0.1 M) in a Waring blender. The filtrate through eight-layer cheesecloth is centrifuged and the supernatant is dialyzed against water. The formed precipitate is removed by centrifugation. The supernatant is lyophilized and suspended in buffer A (20 mM Tris-HCl/500 mM NaCl, pH 7.4) containing CaCl<sub>2</sub>, MgCl<sub>2</sub>, and MnCl<sub>2</sub> (1 mM of each) (R = 100; ×P = 1).

2. The sample is loaded onto an affinity column (2.5 × 10 cm) Con A-Sepharose 4B equilibrated and eluted with buffer A. 30 mM of methyl α-D-mannopyranoside in buffer A allows enzyme elution.  $\beta$ F is concentrated by ultrafiltration and then dialyzed against buffer B (20 mM NaH<sub>2</sub>PO<sub>4</sub>/Na<sub>2</sub>HPO<sub>4</sub>, pH 6.0) (R = 110; ×P = 11).

3. The solution is chromatographed on a DEAE-Sephadex A-50-120 column (2.5 × 18 cm) equilibrated in buffer B and eluted with a linear gradient of 0–250 mM NaCl. The active fractions are pooled and concentrated by ultrafiltration. The concentrate is dialyzed three times against buffer B (R = 69; ×P = 193).

4. The sample is loaded on a Sephadex G-150 column (1.5 × 90 cm), equilibrated, and eluted with 50 mM NaH<sub>2</sub>PO<sub>4</sub>/Na<sub>2</sub>HPO<sub>4</sub>/100 mM NaCl buffer (pH 7.2).  $\beta$ F fractions are pooled and concentrated (R = 51; ×P = 210).

5. The purified enzyme is obtained upon a second run on a DEAE-Sephadex A-50-120 column (1.5 × 18 cm), equilibrated in buffer B, and eluted with buffer B/100 mM NaCl (R = 29; ×P = 1560).

To the memory of Prof. Francesco Alfani, our intellectual guide, who prematurely died.

## $\beta$ -Galactosidase

Raymond R. Mahoney

University of Massachusetts, Amherst, Massachusetts, U.S.A.

### I. INTRODUCTION

$\beta$ -Galactosidase ( $\beta$ -D-galactoside galactohydrolase, EC 3.2.1.23) is often known as lactase because it catalyzes the hydrolysis of lactose into its constituent sugars—viz., lactose +  $H_2O \rightarrow$  galactose + glucose. All lactases are  $\beta$ -galactosidases but some  $\beta$ -galactosidases, including those from plant cells and mammalian organs other than the intestine, have little or no activity on lactose because their function is to hydrolyze other galactosyl moieties, including glycolipids, glycoproteins, and mucopolysaccharides (1).

$\beta$ -Galactosidase hydrolyzes O-glycosyl bonds and exhibits strict specificity for the glycone part of the substrate (Fig. 1). The only changes that allow activity (albeit reduced) are replacement of the hydroxymethyl group on carbon 6 with a methyl group or a hydrogen atom. Consequently, the enzyme shows some activity on  $\alpha$ -L-arabinosides and  $\beta$ -D-fucosides. Other changes such as methylation of the hydroxyl on carbons 2, 3, 4, or 6; loss of the pyranose ring structure; or conversion to the  $\alpha$ -anomeric form, lead to loss of activity (1). Replacement of the glycosidic oxygen with sulfur causes loss of activity but not loss of binding affinity (1). The enzyme shows wide tolerance for the structure of the aglycone which may be another sugar, an alkyl group or an aryl group. The nature of the aglycone, however, strongly influences the kinetic parameters (1).

Activity of intestinal lactase in mammals decreases after weaning, and this leads to some degree of lactose intolerance in many population groups. Consequently,

the enzyme is used in clinical settings to aid lactose digestion and in commercial operations to produce low-lactose dairy products.

### II. IMPORTANCE TO FOOD QUALITY

Enzymatic hydrolysis of lactose is of interest in both food science and nutrition, as well as in waste management and byproduct utilization. The product sugars are sweeter, more soluble, more easily fermented, and more readily absorbed from the intestine. Consequently, hydrolysis of lactose in milk and whey provides new functional properties for these ingredients which can be exploited in a variety of products (see Sec. IV below).

The principal reason for hydrolyzing lactose in fluid milk, however, is to overcome the problem of lactose

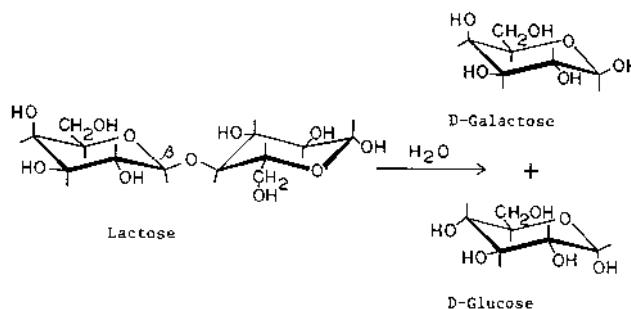

Figure 1 Hydrolysis of lactose by  $\beta$ -galactosidase.

intolerance, which is widespread among non-Caucasian adults and leads to reduced milk consumption. This is of concern since milk is a good source of high-quality protein and an especially good source of calcium.

Whey is the principal byproduct of cheese manufacture and contains > 70% lactose on a dry-weight basis. Hydrolysis of the lactose improves whey utilization in a variety of products and processes (see Sec. IV).

### III. SOURCES

$\beta$ -Galactosidases are widely distributed in nature according to their various functions, which include digestion, lysosomal degradation, and catabolism. However, lactases are found essentially only in the mammalian intestinal tract and in various microorganisms, including many fungi, yeasts, and bacteria (2).

In the intestine, the enzyme is located in the microvilli of the mucosal cells of the brush border membrane. In microorganisms, the enzyme is usually intracellular in bacteria and yeasts but may be intra- or extracellular in fungi.

For commercial use lactase is extracted from a few microbial sources, primarily yeasts and fungi, which are considered safe as hosts for food grade enzymes (see Table 1). It may be possible to use  $\beta$ -galactosidases from other sources by cloning them into one of these hosts. The commercial enzymes are usually classified as acid pH (pH optimum < 5) for use in acid whey, or neutral pH (pH optimum 5.5–7.0) for use in milk or sweet whey. The enzyme is also produced from *Escherichia coli* for biochemical and analytical uses.

**Table 1** Commercial Sources of  $\beta$ -Galactosidase for Hydrolysis of Lactose in Foods

Organism	pH Optimum <sup>a</sup>	Molecular weight (kDa)
<b>Bacteria</b>		
<i>Bacillus</i> spp. related to <i>B. stearothermophilus</i>	5.5–6.5	116
<b>Yeasts</b>		
<i>Kluyveromyces fragilis</i>	6.5–7.5	201
<i>K. lactis</i>	6.5–7.0	117

<b>Fungi</b>		
<i>Aspergillus niger</i>	2.5–4.0	109–112
<i>A. oryzae</i>	4.5–5.0	90

<sup>a</sup> Dependent on strain.

<sup>b</sup> Not known.

### IV. USE IN FOODS

Reduction of the lactose content of milk or whey by hydrolysis with  $\beta$ -galactosidase leads to several products/applications, as shown in Table 2. These applications have been reviewed extensively elsewhere (2).

### V. PROPERTIES AS A PROTEIN

The best-understood  $\beta$ -galactosidase in terms of protein structure is the enzyme from *Escherichia coli* encoded by the lac Z gene. This enzyme has a molecular weight of 464 kDa and is composed of four identical subunits (each 116 kDa), each containing 1023 residues (3). X-ray crystallography confirms that the protein is a tetramer with 222 point symmetry (4). Each subunit contains a binding site for Mg<sup>2+</sup> and has five essentially independent domains. The key active site residues are located in a depression formed from loops connecting the C-terminal ends of  $\beta$ -strands to surrounding  $\alpha$ -helices in an  $\alpha/\beta$  barrel. Subunits and dimers of subunits are inactive whereas activity in the tetramer state is due to completion of each active site by a loop donated from a neighboring monomer (4).

At the primary sequence level, each subunit contains 16 half-cystine residues per 116-kDa monomer; virtually none of these residues appear to be involved in disulfide linkages (5).

**Table 2** Applications of Lactose Hydrolysis

Product/process	Advantages
Low-lactose milk	Overcomes the problem of lactose intolerance
Sweetened condensed milk, ice cream, dulce de leche	Reduce lactose crystallization in concentrated or frozen milk products
Yogurt and cheese	Accelerates ripening by production of more easily fermented sugars
Sugars syrups from deproteinized whey	Increased sweetness of glucose and galactose allows multiple uses in ice cream, baked goods, confectionery, and soft drinks
Fermentation to ethanol	Fermentation yeasts grow more easily on the glucose produced

In contrast to the above, very little is known about the protein structure of  $\beta$ -galactosidase from eukaryotes. However, amino acid sequences have been established for  $\beta$ -galactosidase from several other bacteria and from the yeast *Kluyveromyces lactis* (6). Comparison of the yeast  $\beta$ -galactosidase with the subunits of  $\beta$ -galactosidase from prokaryotes show similarity in molecular weight (117 kDa) and extended sequence homology, suggesting close structural and evolutionary relationships (6).

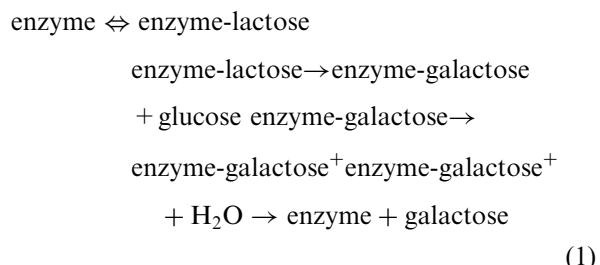

Extracts of *E. coli* subjected to electrophoresis and stained histochemically for  $\beta$ -galactosidase show multiple bands (7), and a similar phenomenon has been seen with both crude and purified enzyme from *Kluyveromyces fragilis* (8). Purification and characterization of the isoforms from *E. coli* have shown them to be polymers and have not revealed compositional differences (9). In the case of fungal enzymes, however, isoforms have been observed which do differ in the extent of glycosylation (10).

## VI. PROPERTIES AS AN ENZYME

The enzymatic properties of  $\beta$ -galactosidase vary with the source. These properties are summarized in Table 3 for three different  $\beta$ -galactosidases (one each from bacteria, yeasts, and molds).

Comparison of  $k_{cat}/K_m$  shows that the synthetic substrate ONPG (*o*-nitrophenyl  $\beta$ -D-galactopyranoside) is a better substrate than lactose in all cases. The fungal enzyme from *Aspergillus niger* is the most thermostable and is unaffected by cations or sulphydryl modifiers such as *p*-chloromercuribenzoate. However, it is the most susceptible to product inhibition by galactose.

The mechanism of action is not completely understood, but the *E. coli* enzyme appears to work in a fashion analogous to that of lysozyme. Thus, one group acts as a general acid, donating a proton to the glycosidic oxygen, and another, negatively charged group stabilizes a positively charged carbonium galactosyl-enzyme intermediate for reaction with water (11). Site-directed substitutions in the *E. coli* enzyme indicate that Tyr503 functions as the general acid and that Glu461 functions as the stabilizer for the intermediate which alternates between a carbocation and a covalently bound form (12). The hydrolytic reaction [Eq. (1)] can then be described as:

Reaction of the enzyme-galactose<sup>+</sup> complex with another sugar (such as lactose, galactose, or glucose) instead of water allows for the synthesis of oligosaccharides by the transferase reaction, which can become significant at high substrate concentrations and/or when the degree of substrate conversion is high (13).

There are several substrate/product analogs which inhibit  $\beta$ -galactosidase. Galactose is a competitive inhibitor, but glucose is often ineffective except at very high concentrations, where it is noncompetitive (14). Thiogalactosides such as *p*-aminophenyl  $\beta$ -D-thiogalactoside are weak competitive inhibitors (15, 16). The most powerful inhibitors are the 1-4 and 1-5 galactonolactones, especially the latter, which, it has been suggested, may resemble the transition state form of the substrate (17).

## VII. DETERMINATION OF ACTIVITY

$\beta$ -Galactosidase activity can be followed quite readily by following the disappearance of substrate or the appearance of product, but it is usually easier to follow product formation.

Determination of lactose hydrolysis is complicated by transferase activity, although the latter is minimal (and can often be ignored) when the lactose concentration is 5% or less, or only initial rates are being measured. Under these conditions, it is easy to assay activity on lactose by measuring the production of glucose or galactose, preferably enzymatically. The most commonly used method is determination of glucose with glucose oxidase coupled to peroxidase (see Sec. VII.A below).

Where a large percentage of the original lactose is hydrolyzed, determination of total monosaccharides is a good practical indicator of the extent of hydrolysis, but it may underestimate the number of glycosyl bonds broken in lactose, owing to the formation of oligosaccharides by the transferase reaction.

Hydrolysis of lactose can also be followed by polarimetry due to a small change in specific rotation (from +52.5° to +67.0°). However, this method is not

**Table 3** Enzymatic Properties of  $\beta$ -Galactosidase

	<i>Escherichia coli</i> (14)	<i>Kluyveromyces fragilis</i> (8, 15)	<i>Aspergillus niger</i> (10, 27)

used much compared to chemical estimation of the products.

Synthetic substrates such as *o*-nitrophenyl  $\beta$ -D-galactopyranoside (ONPG) and *p*-nitrophenyl  $\beta$ -D-galactopyranoside (PNPG) are usually hydrolyzed faster than lactose and provide an easy, convenient, colorimetric assay since the nitrophenol released absorbs in the range 400–420 nm when in alkaline solution.

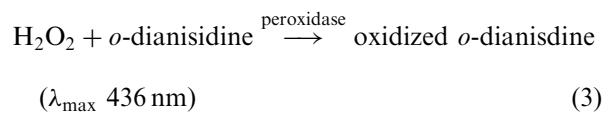

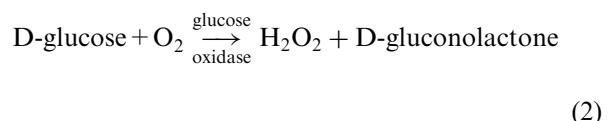

For detection of very low levels of activity, fluorimetric methods of assay can be used with substrates such as 4-methylumbelliferyl  $\beta$ -D-galactoside (8).

The conditions for assay vary with the source of the enzyme and the substrate; representative examples are given below.

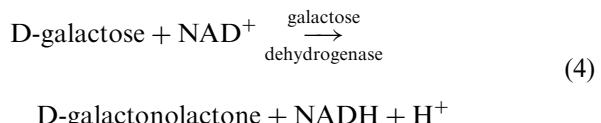

#### A. Assay of $\beta$ -Galactosidase Activity on Lactose with Neutral-pH Enzyme

Enzyme 100  $\mu$ L ( $\leq 30$  U/mL) is added to 4 mL of 5% lactose in 0.1 M potassium phosphate buffer, pH 6.6, containing 3.2 mM MgCl<sub>2</sub>, at 30 $^{\circ}$ C, or to 4 mL milk at the same temperature. The reaction is stopped after 10 min by adding 0.1 mL of 4 N HCl and then neutralized by adding 0.1 mL of 6.4 N NaOH. The solution is then

analyzed for glucose, preferably by the use of glucose oxidase and peroxidase in conjunction with a dye such as *o*-dianisidine [Eqs. (2) and (3)].

Alternatively, the galactose produced can be estimated indirectly by use of galactose dehydrogenase [Eq. (4)].

The increase in absorbance at 340 nm is a measure of the NADH produced and of the lactose hydrolyzed.

## B. Assay of $\beta$ -Galactosidase Activity on *o*-Nitrophenylgalactoside (ONPG) Using Neutral-pH Enzyme

Enzyme ( $100\ \mu\text{L}$  ( $\leq 1\ \text{U/mL}$ ) is added to  $4\ \text{mL}$  of  $2\ \text{mM}$  ONPG in  $0.1\ M$  potassium phosphate buffer, pH 6.6, containing  $0.1\ \text{mM}$   $\text{MnCl}_2$  and  $0.5\ \text{mM}$  dithioerthritol. The reaction is stopped after 5 min by adding  $1\ \text{mL}$  of  $0.5\ M$   $\text{Na}_2\text{CO}_3$  containing  $15\ \text{mM}$  EDTA, and the absorbance is determined at  $420\ \text{nm}$ . Activity is calculated using a molar extinction coefficient of  $4500\ \text{M}^{-1}\ \text{cm}^{-1}$  for *o*-nitrophenol at pH 10 (15). For acid-pH enzymes, the substrate buffer is changed to  $100\ \text{mM}$  sodium acetate buffer, pH 4.0, and the reaction is stopped as described above.

## C. Other Aspects

$\beta$ -Galactosidase activity in tissues can be detected by histochemical staining with 6-bromo-2-naphthyl- $\beta$ -galactosidase. The product 6-bromo-2-naphthol, reacts with tetrazotized *o*-dianisidine (Diazo Fast Blue B) in alkaline solution to give a blue-purple color at the site of enzyme activity (19). The same method can be used to detect activity of  $\beta$ -galactosidase in electrophoresis gels (7).

Neutral-pH enzymes require  $\text{Mg}^{2+}$  or  $\text{Mn}^{2+}$  for maximum activity, but acid-pH enzymes (from fungi) do not require metal ions. Incorporation of a sulphydryl reagent (2-mercaptoethanol or dithiothreitol) often increases activity with neutral-pH enzymes.

Activity and stability of  $\beta$ -galactosidase in milk and whey can be very different from that in lactose solutions. Activity is often lower in milk or whey (20, 21) owing to the high level of calcium, which exerts a strong inhibitory effect (21, 22). Stability against thermal denaturation is markedly increased—up to 100-fold in milk (23). This appears to be due to several milk constituents: salts, lactose, and proteins, acting in concert. Casein is the prin-

cipal stabilizer, but its effect is markedly lactose dependent.

The  $\beta$ -galactosidase from *Streptococcus thermophilus* can be stabilized by a number of proteins, such as bovine serum albumin and casein, via hydrophobic interactions (24). The  $\beta$ -galactosidase from *K. lactis* is stabilized by several amino acids, notably histidine, which decreases the rate of unfolding of the enzyme during heat denaturation (25).

## VIII. PURIFICATION

$\beta$ -Galactosidase can be purified by the conventional methods of protein separation such as gel filtration and ion exchange chromatography and also, very effectively, by affinity chromatography. Examples are shown below.

### A. Purification of $\beta$ -Galactosidase from *Kluyveromyces lactis* (26)

The yeast cells were disrupted in a steel press, and the ruptured cells were extracted with  $50\ \text{mM}$  phosphate buffer, pH 7.0, containing  $10\ \text{mM}$   $\text{MgCl}_2$  (Buffer 1). After centrifugation to remove cell debris, the supernatant was brought to 55% saturation with  $(\text{NH}_4)_2\text{SO}_4$  to precipitate the enzyme. The precipitate was dialyzed against Buffer 1 containing  $1\ \text{mM}$  2-mercaptoethanol to stabilize the enzyme against activity loss. The enzyme was then purified by gel filtration chromatography on Sephadex G-100 using Buffer 1 followed by ion exchange chromatography on DEAE-Sephadex A50. The enzyme was applied in Buffer 1 and was eluted with a gradient of  $0\text{--}0.5\ M$   $\text{NaCl}$  in Buffer 1. A summary of the purification is shown in Table 4. Overall, this enzyme was purified 79-fold with a yield of 19% and was judged homogeneous by polyacrylamide gel electrophoresis.

**Table 4** Purification of  $\beta$ -Galactosidase from *Kluyveromyces lactis*

Fraction	Volume (mL)	Protein (mg/mL)	Activity ( $\text{U} \times 10^{-3}$ )	Specific activity ( $\text{U}/\text{mg}$ )
Centrifuged cell extract	46	77	14.9	4.22
Ammonium sulfate fractionation	30	48	12.7	8.25
Sephadex G-100	123	2.7	14.5	43.7
DEAE Sephadex-A50	26	0.55	2.04	143

Source: Ref. 26

## B. Purification of $\beta$ -Galactosidase from *Escherichia coli* by Affinity Chromatography (16)

Cells of *E. coli* were suspended in 50 mM Tris-HCl, pH 7.5, containing 100 mM NaCl and 10 mM MgCl<sub>2</sub> (Buffer 2) and disrupted by sonication. After centrifugation to remove cell debris, the supernatant was brought to 50% saturation with (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and centrifuged, and the pellet was dissolved in Buffer 2 and dialyzed against the same buffer. The enzyme solution was then applied to a column of an affinity matrix consisting of the inhibitor *p*-aminophenyl- $\beta$ -D-galactopyranoside ( $K_i \sim 5$  mM) attached to Sepharose 4B via a long spacer arm (3-aminosuccinyl-3-aminodipropylamine). The column was washed with Buffer 2, and the enzyme was eluted by 0.1 M borate buffer, pH 10; it was homogeneous as judged by gel electrophoresis. The yield was 95% compared with a yield of ~ 50% using conventional procedures (5).

## Pectic Polysaccharides

H. A. Schols and Alphons G. J. Voragen

*Wageningen University, Wageningen, The Netherlands*

### I. INTRODUCTION

In the vast amount of literature on pectic enzymes an unambiguous interpretation of presented results is often hampered by the fact that ill-defined substrates and inadequate methodology have been used. The importance of the use of well-defined substrates and adequate methods is demonstrated by the facts that in the last decade more than five new enzymes active on specific structural elements of pectin have been identified and that within classes of specific enzymes a further differentiation became possible based on differences in substrate specificity. So can polygalacturonases be differentiated with respect to their tolerance of methyl esterified galacturonic acid residues in their active sites ([Chapter 69](#)). Also, to understand the technological role of a specific enzyme in an application, its action at a molecular level should be known. We therefore felt the need to devote a chapter to the description of the structural elements present in pectins, which variations are found in nature in these structural elements, and the methodology to measure the activity and mode of action of the enzyme families active on pectins.

Pectins or pectic substances are collective names for a group of closely associated polysaccharides present in plant cell walls, where they contribute to complex physiological processes like cell growth and cell differentiation and so determine the integrity and rigidity of plant tissue. They also play an important role in the defence mechanisms against plant pathogens and

wounding. As constituents of plant cell walls and due to their anionic nature, pectic polysaccharides are considered to be involved in the regulation of ion transport; they determine the porosity of the walls, and they may thus control the permeability of the walls for enzymes. They also determine the water-holding capacity of the wall (1, 2).

The following groups of polysaccharides are comprised in the term pectic substances:

1. Linear homogalacturonan consisting of  $\alpha$ - $(1 \rightarrow 4)$ -linked D-galacturonic acid units in which varying proportions of the carboxyl groups are esterified with methanol, and secondary hydroxyl groups at O-2 and O-3 with acetyl groups.
2. Linearly branched xylogalacturonan carrying single-unit xylopyranosyl residues and the rarely occurring apiogalacturonan carrying mono- and diapiosyl side chains (2).
3. Highly branched galacturonan, in the literature in retrospect wrongly termed rhamnogalacturonan II (RG-II).
4. Rhamnogalacturonan having a backbone of alternating  $\alpha$ - $(1 \rightarrow 2)$ -linked L-rhamnosyl residues and  $\alpha$ - $(1 \rightarrow 4)$ -linked D-galacturonosyluronic acid residues ramified at O-4 of the rhamnosyl residue with neutral sugar side chains of varying composition and size (1 to  $\sim$  50 sugar moieties).

5. Polymeric side chains of pectin usually distinctly referred to as arabinans, galactans, and arabinogalactans.

Next to the xyloglucan-cellulose network, these pectic polysaccharides are suggested to form an independent network determining, e.g., the porosity of the cell wall (3).

The texture of fruits and vegetables during growth, ripening, and storage is strongly influenced by the amount and composition of the pectic molecules present. Consequently, the structure of pectins present in fruit and vegetables depends on enzymatic and chemical modifications occurring during these processes. Endogenous as well as exogenous enzymes (processing aids) play an important role in determining the pectic structures present in plant tissues or food products at a given time.

Pectin used in the food industry as natural ingredients for their gelling, thickening, and stabilizing properties are extracted from suitable agrobyproducts like citrus peel and apple pomace (2, 4). Commercially produced pectins usually contain > 65% of galacturonic acid by weight, since the extraction conditions used remove the greatest part of the neutral side chains present in native pectin rather specifically (2, 4, 5).

The chemistry and technology of pectin are discussed extensively by Walter (6). A general representation of native pectins is given in [Figure 1](#). This figure shows that the major part of the galacturonosyl residues is present in homogalacturonan segments (smooth regions of pectin), whereas only a relatively small part of the uronic acids is present in so-called hairy regions (7, 8).

The proportion of the various structural elements of pectin may differ strongly from one pectin to another ([Table 1](#)). The proportion of homogalacturonan can be > 65% for commercially extracted pectins but can also be zero in the case of soybean pectin. Large variations are also found for xylogalacturonan, arabinan, or galactan segments ([Table 1](#)) (8, 26).

The various different structural elements present in pectic substances will be discussed in more detail below. Enzyme systems which are able to (specifically) degrade or modify homogalacturonans, xylogalacturonans, rhamnogalacturonans, arabinans, and (arabino) galactans are covered in [Chapters 67–70, 73, and 80](#) of this book.

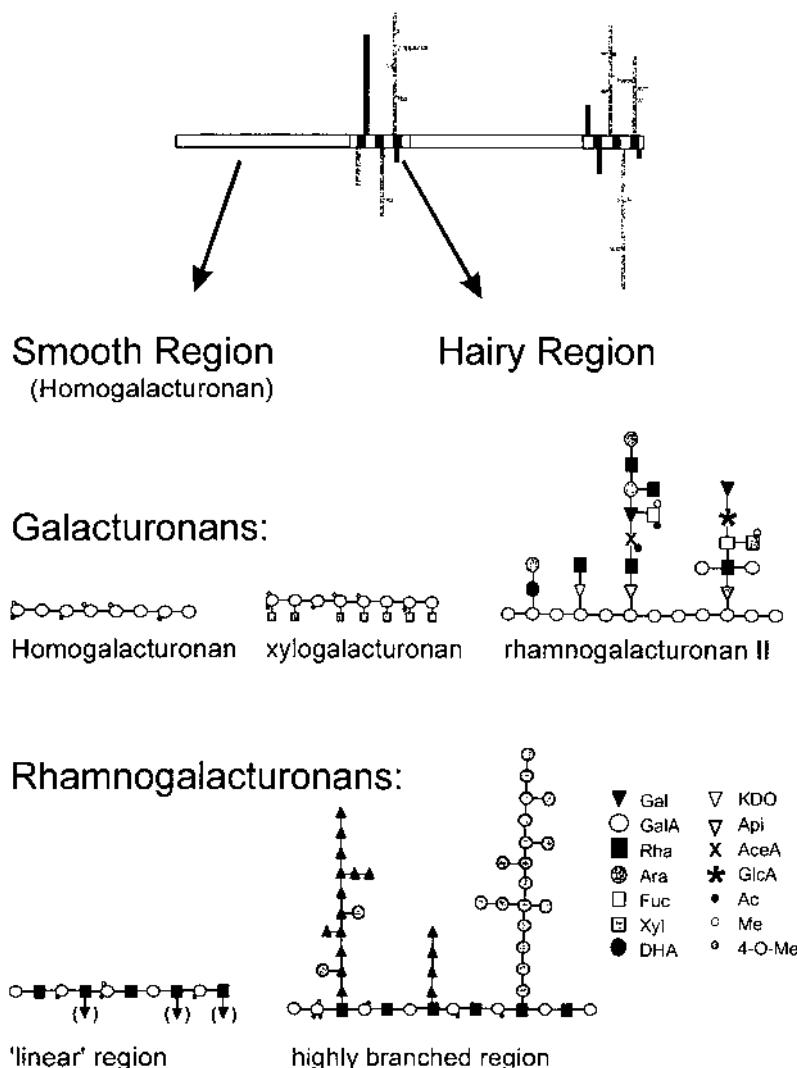

## II. HOMOGALACTURONAN

As described above, the linear homogalacturonan dominates in commercial pectins and plays a prominent role in plant physiology (e.g., ripening). Therefore, both the chemical fine structure of homogalacturonans ([Fig. 2](#)) and enzymes specific to (methyl esterified) galacturonans are studied in great detail. In addition to the type and amount of neutral sugars present, the major structural differences among various commercial pectins (in essence homogalacturonans) are explained by the level of methyl esters present at C6 of the galacturonic acid residues and the distribution of these esters and neutral sugar side chains over the galacturonan backbone. Usually, the degree of methyl esterification (DM) is expressed as moles of methanol present per 100 moles of galacturonic acid. When the DM is 50 or higher, pectins are called high-methoxyl (HM) pectins, whereas the term low-methoxyl (LM) pectins indicates a DM < 50.

Methyl esters may be distributed over the homogalacturonan quite differently where the two extremes are formed by a random distribution where all esters are “spread out” over the polymer in a rather statistical way or by a blockwise distribution where blocks of nonesterified galacturonic acid residues are interspersed with segments having a rather high degree of methyl esterification (2, 10). Such distributions are strongly influenced by the presence of endogenous enzymes like plant pectin methylesterase, whose activity may cause a blockwise distribution or by the conditions under which the raw material is processed or the pectin extracted (2). Pectin lyase can therefore be active on an LM pectin with a blockwise distribution and polygalacturonase on an HM pectin with blockwise distribution. In addition to methyl esterification, depending on the origin of the pectin, galacturonic acid moieties may be substituted with acetyl groups at O-2 or O-3 (e.g., sugar beet pectin, potato pectin) (2).

## III. XYLOGALACTURONANS

In xylogalacturonans, the amount of  $\beta$ -xylose substitution to the O-3 position of galacturonic acid residues in the backbone may vary significantly ([Fig. 3](#)), depending on their origin (e.g., apple, pea hulls, watermelon,

**Figure 1** Structural elements of pectin. Occurrence, amount, and chemical fine structure of the individual segments may vary significantly depending on the origin of the pectin. Gal, galactose; GalA, galacturonic acid; Rha, rhamnose; Fuc, fucose, Xyl, xylose; DHA, 3-deoxy-D-lyxo-2-heptulosaric acid; KDO, 2-keto-3-deoxy-D-manno-octulosonic acid; Api, apiose; AceA, aceric acid, GlcA, glucuronic acid, Ac, acetyl group; Me, methyl ester; 4-O-Me, 4-O-methyl ether. (From Refs. 7, 8.)

soybeans). This is also the case for the amount and distribution of methyl esters present, since for apples various populations of xylogalacturonans with a rather distinctive methyl ester level have been reported (7).

#### IV. HIGHLY BRANCHED GALACTURONAN (HBG) OR RHAMNOGALACTURONAN II

HBG or RG-II consists of a backbone of about nine  $\alpha$ -(1  $\rightarrow$  4)-linked galacturonosyl residues carrying four side chains containing a number of rare sugars (e.g.,

apiose, aceric acid, KDO, and DHA) in a defined and rather conserved structure (Fig. 1). This structural element is involved in the crosslinking of two pectin molecules within the cell wall through a borate diester (11, 12). No enzymes able to degrade the complex HBG structure have been described in detail.

#### V. RHAMNOGALACTURONAN

Rhamnogalacturonan has a backbone of up to 300 repeating units of alternating  $\alpha$ -(1  $\rightarrow$  2)-linked rhamnosyl and  $\alpha$ -(1  $\rightarrow$  4)-linked galacturonosyluronic acid

**Table 1** Occurrence and Proportion of the Various Structural Elements of Native Pectin in Apple, Sugar Beet, and Soybean

	Soybean meal	Sugar beat pulp	Apple

Source: Ref. 8.

residues, which may be methyl esterified and/or acetylated (Fig. 4) (7, 13, 14). Depending on the origin of the cell walls examined (type of cell wall, tissue, plant segment, etc.), the length of the side chains attached to 20–80% of the rhamnose residues can vary from one single galactose residue up to chains of 50 residues or more being composed of arabinose (e.g., sugar beet), galactose (e.g., flax, garlic, onion) or both (e.g., soy, potato) (7, 13). Taking all possible variations into account, it can be stated that rhamnogalacturonans are a family of quite complex structures with “only” the rhamnogalacturonan backbone in common.

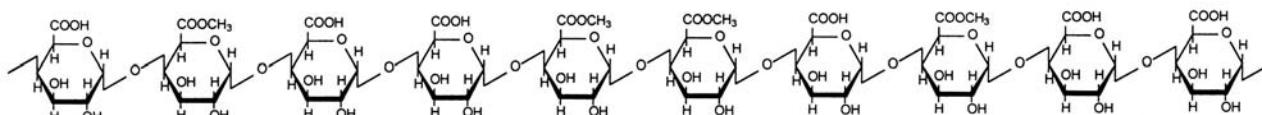

Recently, a whole family of rhamnogalacturonan-specific carbohydrases has been recognized which is discussed in Chapter 73. Using a specific rhamnogalacturonan hydrolase, it was shown that rhamnogalacturonan contains blocks highly ramified with long neutral sugar side chains, and in addition segments of alternating rhamnose and galacturonic acid sequences with or without single-unit galactose substitution on O-4 of the rhamnosyl residues up to ~30 residues in length. Some rhamnogalacturonan preparations (e.g., from sycamore cells) were resistant to degradation by RG hydrolases (7), demonstrating the absence of low-substituted

RG segments. A common feature of these RG structures is that they are also (highly) substituted with acetyl groups, either attached to O-2 or to O-3 or to both O-2 and O-3 of the galacturonic acid moieties (7, 14) which inhibits RG-hydrolase and -lyase (see Chap. 73).

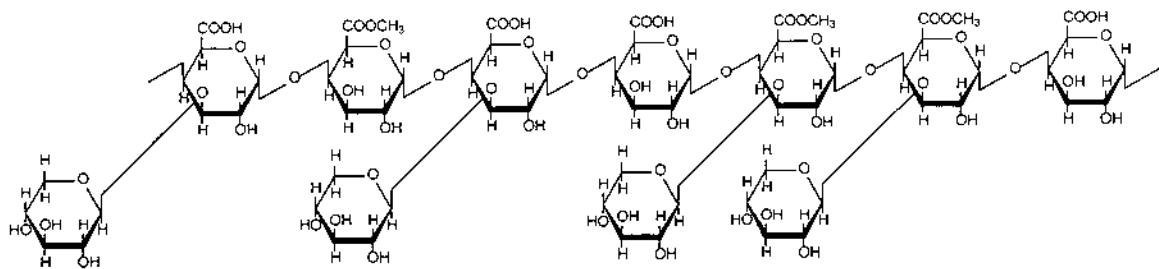

## VI. ARABINANS

Arabinans are branched homoglycans mainly composed of a backbone of  $\alpha$ -L-(1 → 5)-linked arabinosyl residues and in native form substituted with  $\alpha$ -arabinofuranosyl residues at O-2 and/or O-3 position. Such a substitution can be a single arabinosyl residue, but longer (branched) chains can also be present mostly one to three arabinosyl residues (see Fig. 5), resulting in complex structures (see the reviews 15–17 and references herein).

Arabinans have been described to be present in cell walls from apples, sugar beet, rapeseed, carrot, cowpea, azuki- and soybean, rape, mustard, lemon, grape, cabbage, onion, potato, and others (17). Arabinans can have molecular weights up to 10 kDa and are

**Figure 2** Homogalacturonan fragment of pectin. Acetyl groups may be present at O-2, O-3 or both at O-2 and O-3 for some pectins from some sources. (From Ref. 2.)

**Figure 3** Schematic structure of a xylogalacturonan. The position of methyl esters is chosen arbitrarily.

often covalently linked to galacturonic acid-rich polymers. Although arabinans have been isolated in a pure form, the extraction conditions used may have resulted in chemical ( $\beta$ -elimination, chain peeling) or enzymatic degradation of any attached pectin structures (17 and references herein).

## VII. GALACTANS

Galactans and arabinogalactans in which the galactan backbone is substituted with various amounts of arabinose or galactose have been found in a broad range of higher plants (18–20). Aspinall (21) classified the arabinogalactans as type I and type II arabinogalactans, where both types may be present as side chains of pectin or as a single polymer. Type II arabinogalactans may also be present as side chains of a protein segment and as such be referred to as arabinogalactan proteins (AGPs).

### A. Arabinogalactan Type I

Arabinogalactans of type I are quite common for various types of plant tissues (20) and consist of a (1  $\rightarrow$  4)-linked linear chain of  $\beta$ -D-galactopyranosyl residues. Pure galactans have been isolated from lupine, potato, and tobacco, although type I galactans usually are substituted with short chains of  $\alpha$ -(1  $\rightarrow$  5)-

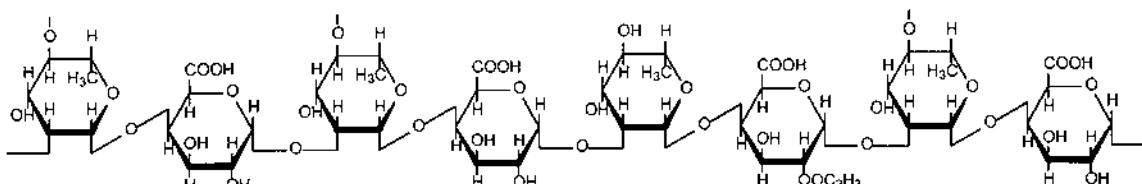

arabinofuranosyl residues attached through the O-3 position (20). O-6 substitution of the galactan backbone with  $\beta$ -galactose is also found. Figure 6 shows the schematic structure of type I arabinogalactans.

Depending on the way of extraction, remnants of the pectic backbone may still be present.

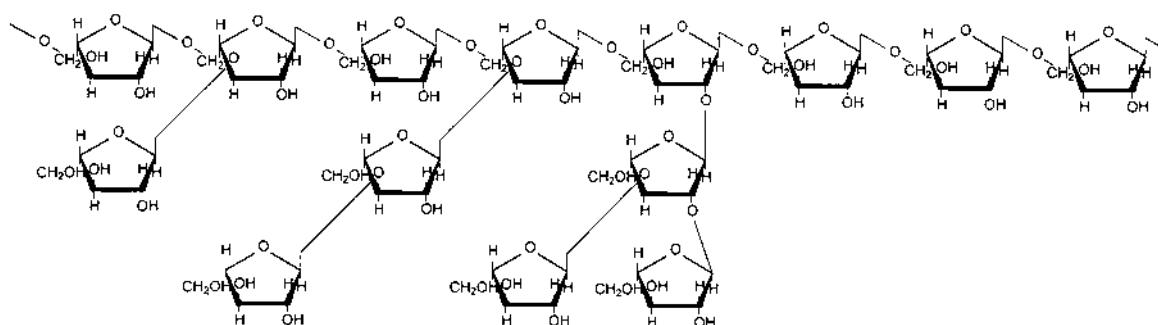

### B. Arabinogalactan Type II

Arabinogalactans of type II are highly branched polysaccharides with ramified chains of  $\beta$ -D-galactopyranose residues joined by 1,3 and 1,6 linkages. They are more common in plants than type I and have been reported in leaves, stems, roots, floral parts, seeds, and media of suspension cultured cells (20).

In general, the interior backbone of a type II galactan consists mainly of  $\beta$ -(1  $\rightarrow$  3)-linked galactose moieties;  $\beta$ -(1  $\rightarrow$  6)-linked galactopyranosyl residues occur mainly in the exterior chains which may be terminated with an L-arabinopyranosyl residue. The (1  $\rightarrow$  3)-galactan may be branched through O-6 with arabinofuranose residues or (to a lesser extent) with arabinopyranose units, while also longer  $\alpha$ -(1  $\rightarrow$  3)-linked arabinose chains may be present. In general, galactose is more abundantly present than arabinose, although the ratio of arabinose to galactose may differ significantly. Arabinogalactans of type II may be present within the ramified regions of pectins but are also

**Figure 4** The alternating structure of rhamnogalacturonan segments of pectin. The number, length, and structure of the side chains may vary significantly depending on the origin of the pectin. The acetyl groups may be substituted to O-2, O-3 or both O-2 and O-3 of the galacturonic acid residues. (From Refs. 7, 13, 14.)

**Figure 5** Schematic structure of a highly branched  $\alpha$ -L-(1  $\rightarrow$  5)-arabinan.

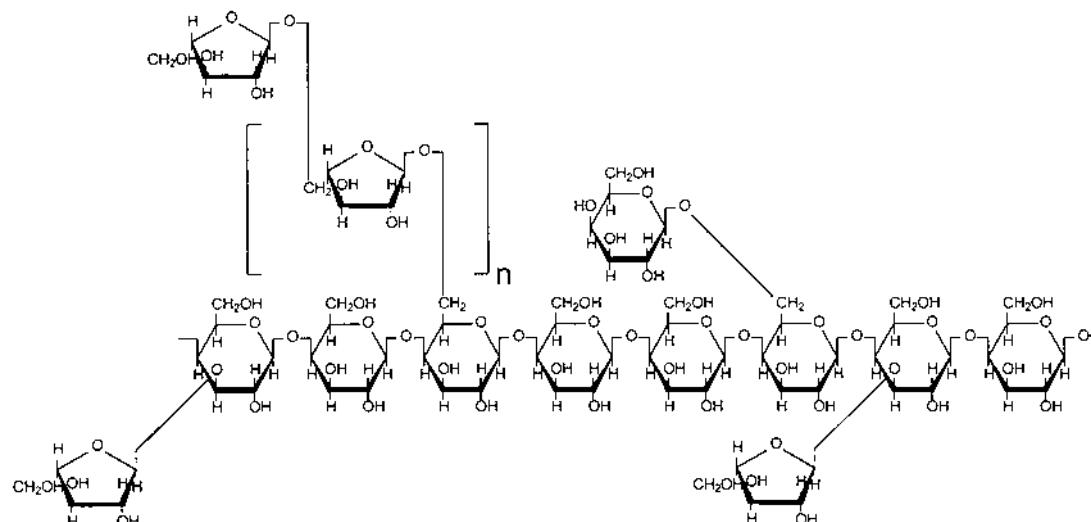

often reported to be linked to a hydroxyproline-rich protein (AGP), of which gum arabic from *Acacia senegal* is a well-known example. The hypothetical structure of a type II arabinogalactan is shown in Figure 7. It should be emphasized that many variations with respect to the model shown have been reported including substitution with glucuronic acid (22, 23).

### VIII. ISOLATION OF POLYSACCHARIDE STRUCTURES

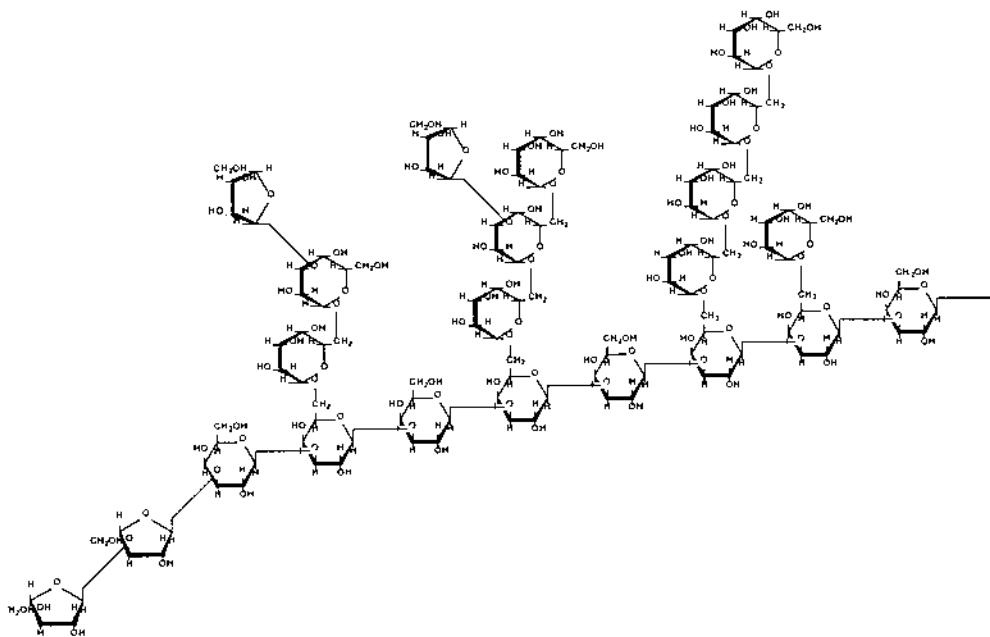

It should be realized that all commercially available polymeric substrates to be used in enzyme screening and characterization have been isolated from the complex plant material. As mentioned above, pectins with a high galacturonic acid content (> 70%) are extracted under acidic conditions from suitable raw materials,

followed by precipitation with alcohol and possibly treatment with acidic alcohol to remove salts like potassium, sodium, and calcium. The precise conditions (pH, time, temperature) will determine the molecular weight, the amount of neutral sugars still present, and the degree of methyl esterification (2, 5).

Arabinans and (arabino)galactans are not yet being used routinely by the food industry. However, for research purposes, these polysaccharides are commercially available and are usually obtained by alkaline treatment at increased temperatures to enhance degradation of the pectic backbone and lowering the strength of hydrogen bridges between the neutral polysaccharides and the cellulose matrix. Further purification of neutral polysaccharides includes preparative anion exchange chromatography to remove charged "impurities."

**Figure 6** Schematic structure of a type I  $\beta$ -(1  $\rightarrow$  4)-linked arabinogalactan.

**Figure 7** Hypothetical structure of type II  $\beta$ -(1,3,6)-arabinogalactan. (From Refs. 22, 23.)

Defined polysaccharides with various degrees of methyl esterification or branching are usually not commercially available and should be prepared in the laboratory. Purification of polysaccharides is often a compromise: extensive handling in order to obtain pure polysaccharides often changes the chemical composition (as compared to the polysaccharide in its native form), whereas mild procedures may result in the presence of "contaminating" polysaccharides, originally linked to the polysaccharide of interest. This latter phenomenon may result in the presence of galacturonic acids in an arabinan or galactan preparation. More universal assays to monitor enzyme action as based on the release of reducing end groups may so produce unreliable results because they do not give information as to which glycosidic bond in the substrate is split. Analysis of the degradation product by high-performance liquid chromatography (HPLC) or mass spectrometry (MS) will avoid such a confusion in most cases.

## IX. METHODS TO MONITOR "PECTIC" ENZYMES

It should be realized that the summary of frequently used methods given below is only a short list selected from the literature and from our own laboratory and is not complete. In most cases, adequate references are

given rather than extensive descriptions of the method mentioned.

### A. Substrates

Pectic substrates can be purchased from several (specialized) suppliers (e.g., Megazyme, Ireland; Sigma-Aldrich Fine Chemicals, USA), but the origin, purity, and specifications are not always clear and straightforward. When monitoring crude enzyme mixtures, relatively small amounts of other polysaccharides accompanying the polysaccharide indicated on the label may give erroneous results.

A broad range of synthetic substrates like p-nitrophenyl- and p-methylumbelliferylglycosides can be obtained (e.g., Sigma-Aldrich) to assay glycosidase activity. Specific oligosaccharides may also be purchased from the same companies, although the choice and purity are limited. Alternatively, oligosaccharides can be produced and purified in the laboratory (24).

Branched polysaccharides like arabinan or arabinogalactans can be rather easily de-branched by mild acid treatment (17, 20, 25, 26) to obtain a more suitable substrate for endoacting enzymes. A wide variety of both soluble azopolysaccharides and insoluble azurine-crosslinked polysaccharides which can be used to screen for specific classes of carbohydrases are commercially available from Megazyme.

When a series of pectins is needed with various degrees of methyl esterification, it is better to prepare such a series in-house than to buy pectins with a different DM. In the former situation, relatively homogeneous substrates are obtained; in the latter situation these preparations may be very heterogeneous owing to their different history (origin, MW, neutral sugars), and these different characteristics may influence the outcome of the experiments. Lowering the DM in a random way is possible by controlled alkali treatment (27) or by using fungal pectin methylesterase (see [Chapter 68](#)). A more blockwise-distributed methyl esterification can be obtained using pectin methylesterase from plant origin ([Chapter 68](#)). Degrees of esterification up to 85–90% can be obtained by methyl esterification using a MeOH–H<sub>2</sub>SO<sub>4</sub> treatment as described previously (28). Polygalacturonic acid can be obtained from chemical supply stores and is a rather well-defined substrate for endopolygalacturonase owing to the absence of methyl esters and neutral sugars (as a result of a bleaching step).

## B. Substrate Solubility and Stability

Not all polysaccharides, when added to cold water, will readily dissolve but they may cause lump formation. This phenomenon can be avoided by premoistening the sample with a drop of ethanol prior to adding the water/buffer. Heat treatment (80–100°C) may also be helpful. However, for esterified pectins, care should be taken to avoid circumstances which allow  $\beta$ -eliminative degradation ( $\Delta T$ ; pH > 5). Especially when the solubilization of insoluble cell wall polysaccharides as consequence of enzyme action is monitored, it is important not to have inaccurate results caused by cleaving a few pectin bonds chemically. Depending on the structure of the substrate, the “history” of the sample (cold storage, freezing, etc.) may influence aggregation/association behavior of the polymeric molecules, which may result either in a rather poor solubility or in a high apparent molecular weight. When only part of the substrate is soluble and only this part is used further for enzyme assays, it is relevant to examine whether this part is representative for the desired substrate.

## X. ANALYSIS OF DIGESTS OF PECTIC POLYSACCHARIDES

Enzymic digests of pectic substances can be analyzed from different points of view, each requiring its own

approach and method. Some of the methods and approaches used in the characterization of enzymes are described below.

### A. Reducing End Groups

Carbohydrases increase the number of reducing ends when degrading their substrates. Many methods have been described to determine the amount of reducing sugars released including the Somogyi-Nelson procedure, neocuproine assay, ferricyanide, and the 2,4-dinitrosalicylic acid test (29; [Chapter 71](#)). One has to be aware that the outcome of the different assays may depend on the type of sugar moieties present in the oligomers formed and the length of the oligomers (29, Chap. 71). Recently, the use of the very sensitive bicinchoninic acid (BCA) reducing value assay has been described to detect any carbohydrase activity degrading any polysaccharide by which both endo- and exoenzymes can be measured (30). The reaction can be carried out in wells of microtiter plates so that large numbers of samples can be analyzed simultaneously. Because of the sensitivity, several precautions should be taken to prevent too high background levels as a result of the enzyme protein itself. Furthermore, depending on the polysaccharide used, the background caused by the reducing end group of the polymer can also be too high. This can be avoided by choosing a rather low substrate concentration or, alternatively, by reducing the reducing end of the polymer by treatment with NaBH<sub>4</sub> prior to use (31).

### B. Assays Using Synthetic or Dyed Substrates

The most commonly used assays to determine glycosidases and exocarbohydrases make use of synthetic substrates like *p*-nitrophenyl- and *p*-methylumbelliferylglycosides where the release of the glycosyl group results in a colored solution, which can be quantified using a spectrophotometer set at the appropriate wavelength.

Endoacting enzymes can be measured using polysaccharides to which usually an azocompound has been attached. Degradation with endoenzymes results in the release of dyed fragments which remain soluble after the addition of ethanol to precipitate the remaining polymer. The color of the supernatant (and thus the enzyme activity) is measured spectrophotometrically (Megazyme).

### C. Solubilizing Activity of Carbohydrases

When enzymes are tested on insoluble substrate (e.g., cell wall polysaccharides), a relatively simple assay to monitor the solubilization of pectic material is by using (automated) colorimetric assays like the *m*-hydroxybiphenyl assay (32, 33) for uronic acids and the phenol-sulfuric acid or orcinol-sulfuric acid assay for neutral sugars (34, 35). Obviously, the latter two methods are not very discriminative for the various neutral sugars, but can be used quite satisfactorily to monitor enzyme activity. More information on the enzyme is obtained when the determination of concentration of the solubilized carbohydrates is combined with information on their size (e.g., reducing sugar assay or size exclusion chromatography).

### D. Molecular-Weight Measurement

To establish whether the (purified) carbohydrase is an exo- or an endoacting enzyme, a relatively simple assay is based on the measurement of viscosity reduction during the enzymatic degradation, since endoacting enzyme activity results almost immediately in a loss of viscosity. However, using this method, quantification of the enzyme activity is rather difficult and the method is not very specific in case of mixtures of pectic enzymes (36). Using high-performance size exclusion chromatography, a more accurate impression of the mode of action of the enzyme is obtained. Although many different types of columns can be used for such HPSEC measurements (37), fairly good results to determine the enzymic degradation of pectic polysaccharides includes elution on three Bio-Gel TSK columns in series (40 XL, 30 XL, 20 XL; identical to TSK-Gel G4000, 3000, 2000 PWXL, respectively), eluted with 0.4 M acetic acid, pH 3, or 0.2 M NaNO<sub>3</sub> and monitored using a refractive index detector (38). In a time course experiment, HPSEC allows quantification of the enzyme activity fairly well, whereas also endo- and exoactivity can be distinguished rather easily (even in enzyme mixtures having both activities).

### E. Assays for Specific Pectic Enzymes

#### 1. Lyases

Enzymes acting by  $\beta$ -eliminative cleavage like pectin and pectate lyase or rhamnogalacturonan lyase may be monitored quite easily by measuring the absorbance at 235 nm due to the formation of  $\Delta$ 4,5-unsaturated

products from their specific substrate ( $\epsilon_{235} = 4600 \text{ M}^{-1} \text{ cm}^{-1}$  for pectate and  $5200 \text{ M}^{-1} \text{ cm}^{-1}$  for pectin (39–41).

#### 2. Pectin Methyl Esterase

The action of pectin methyl esterase results in the release of methanol and consequently in the formation of carboxylic acid groups, and allows two ways of monitoring the action of the enzyme. The release of the H<sup>+</sup> can simply be monitored in a nonbuffered system using a pH indicator which corresponds to the optimal pH range of the pectin methyl esterase assayed (42, 43). Furthermore, a more quantitative assay to measure the action of the enzyme includes an automated titration at the optimal pH (nonbuffered) where the amount of NaOH necessary to compensate the pH changes caused by the enzyme is measured (43, 44).

The release of methanol can be measured using gas-liquid chromatography (GLC) directly (45) or after conversion of the methanol to methyl nitrite (46). Although this latter method is quite sensitive and reliable, it is also quite laborious (42). Alternatively, methanol can also be determined by HPLC on an Aminex column 87H column (47) although this method may not be sensitive enough for all purposes. Colorimetric methods have been developed in which methanol is oxidized to formaldehyde (43, 48–50), but they are not easy to perform (51).

#### 3. Acetyl Esterases

The release of acetyl groups by enzymatic action is usually followed by HPLC using the so-called organic acid column (Aminex HPX 87H) and refractive index detection (47; Chap. 71). An alternative procedure is an enzymic assay for acetic acid including a NADH/NAD<sup>+</sup> conversion step using a commercial test kit (Boehringer-Mannheim, Germany). Obviously, care should be taken when using the frequently applied acetate buffers when using these methods. This is less important (although product inhibition may occur) when using colorimetric assays based on *p*-nitrophenyl acetate, *p*-naphthyl acetate, or *p*-methylumbelliferylacetate (Chap. 71). Another synthetic substrate used for the determination of acylesterases is triacetine, where the acetic acid released has to be measured by one of the methods mentioned. However, these latter substrates are usually also deesterified by nonpectin esterases.

## XI. CHROMATOGRAPHY AND MASS SPECTROMETRY OF COMPLEX ENZYME DIGESTS

Chromatography in its wide variety is a powerful technique to detect activities of specific enzymes and to obtain important information on their substrate specificity and mode of action. Especially for heterogeneous carbohydrate substrates, chromatography (with or without MS detection) is almost indispensable to determine enzyme's substrate requirements. High-performance anion exchange chromatography (HPAEC) as introduced by Dionex in the late 1980s is able to separate oligosaccharides having the same size and sugar composition but differing in branching and/or linkage composition. A similar breakthrough in oligosaccharide characterization and identification as achieved by the introduction of HPAEC was obtained by the introduction of matrix-assisted laser desorption/ionization time of flight mass spectrometry (Maldi Tof MS) during the last 5 years enabling molecular-mass measurements of oligosaccharide mixtures rather accurately and easily. Nowadays, HPAEC, Maldi Tof MS, and LC-MS techniques have been developed into quick, reliable, and easy-to-operate techniques allowing a more detailed examination of the mode of action of enzymes on complex substrates by characterizing the enzymic degradation products.

### A. High-Performance Anion Exchange Chromatography of Oligosaccharides

Although many different types of chromatography have been used to separate oligosaccharides (52, 53), HPAEC using alkaline elution conditions in combination with pulsed amperometric detection (PAD) is preferred for specifically monitoring oligosaccharides (55–57). The principles for both separation and detection are nicely described by Hensall (56). In principle, separation is based on interaction with a strong anion exchange resin, and usually salt (sodium acetate) gradients in 100 mM NaOH are used to elute the oligosaccharides. Since elution is usually performed in alkali, even neutral carbohydrates bind to the column and can be eluted later on. HPAEC allows separation of oligosaccharides with a DP up to 50. PAD detection is direct (no derivatization required), highly sensitive, and compatible with the gradients commonly used in HPAEC. When neutral eluents are used to separate charged oligosaccharides, alkali should be added post column prior to detection since PAD detection of (part of the) sugar residues requires a high pH (56, 57). A

“disadvantage” of the method is that the separation is influenced by the size, sugar (linkage) composition, and degree of branching of the oligomer (55).

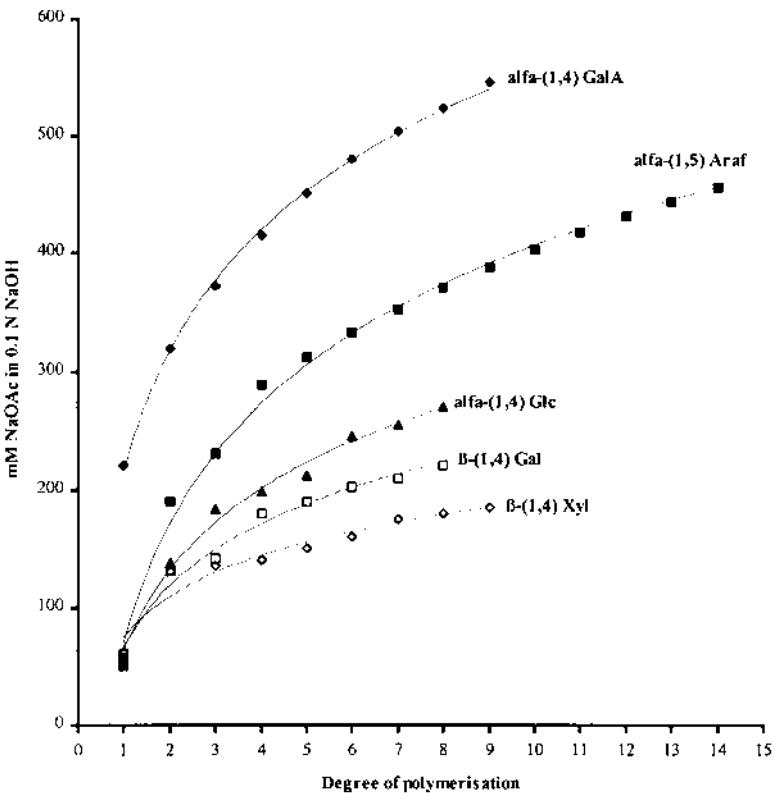

Figure 8 shows the dependency of the elution behaviour of various homologous series of oligosaccharides on the “elution power” of the gradient expressed as NaOAc. This can result in a rather unpredictable elution behavior when not much is known about the complexity of the oligosaccharide mixtures under investigation (55), and other methods of identification like mass spectrometry might be necessary. However, when the polymeric substrate is well defined and the (class of) enzyme is known, even complex elution patterns might be interpreted reasonably. This is illustrated in Figure 9, where a complex HPAEC elution pattern of a pectic arabinogalactan type I from soybean after digestion with arabinan- and galactan-degrading enzymes is shown (26). The more intensive peaks eluting between 10 and 25 min represent linear galactose oligomers, whereas the smaller peaks eluting in this time frame represent “mixed” oligomers consisting of both arabinose and galactose. Oligomers of arabinose are eluted after 25 min.

The broad applicability of HPAEC/PAD is demonstrated by the fact that also the release of the various monomeric sugar residues can easily be monitored using weaker elution conditions (58). In case of UV-absorbing oligosaccharides (e.g., after lyase action), degradation products can be monitored using an UV detector set to 235 nm (59). HPAEC-PAD may give some problems when quantifying “unknown” compounds where response factors are not available, since such response factors may also depend on size and structure of the analyte (55).

When the oligomeric degradation products released by the enzyme under investigation are expected to be negatively charged, HPAEC can be performed under neutral elution conditions (56, 60). Such conditions are relevant when the oligomers are substituted with alkali-labile groups (e.g., methyl-esterified galacturonic acid oligomers). Identification of these partially esterified oligomers may give information about the precise mode of action of the enzyme (10, 61–63).

### B. Matrix-Assisted Laser Desorption/Ionization Time of Flight MS

Maldi Tof MS is a rather new mass-spectrometric technique, enabling collection of valuable data concerning the molecular masses of compounds present in a complex mixture of biomolecules in the range of 400–300,000 daltons (64, 65). Maldi Tof MS gives a good

**Figure 8** Total sodium concentration at which series of linear oligosaccharides elute in HPAEC as a function of the degree of polymerization (DP). Gradient: 0–600 mM NaAc in 100 mM NaOH in 40 min. CarboPac PA100 column. (From Ref. 54.)

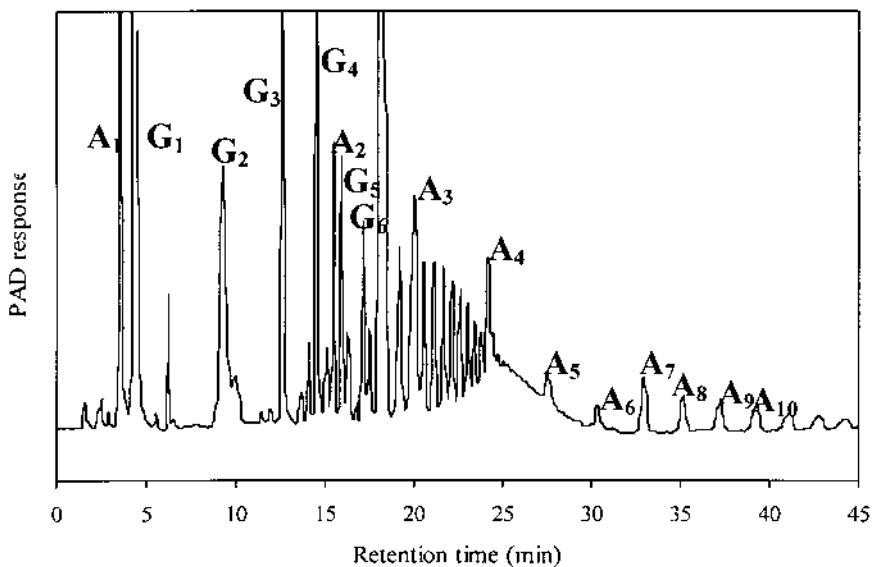

mass accuracy, is easy to operate, and requires relatively little sample preparation. For oligosaccharides, mass determinations in the range of 400–4000 are rather easy to perform.

Figure 10 shows a Maldi Tof mass spectrum for the pentamer/hexamer fraction of enzymatically degraded soybean arabinogalactan, obtained after size exclusion chromatography of the whole digest, as shown in Figure 9. It can be seen that the different oligomers consisting of arabinose and galactose can be easily recognized. Obviously, isomers having the same molecular mass cannot be distinguished from each other. If necessary, electrospray tandem MS analysis following HPAEC analysis may be used to verify the precise structure of different isomers present (26). Kabel et al. (66) described the off-line coupling of HPAEC and Maldi Tof MS where on-line desalting by membrane suppressors, microtiterplate fraction collection, and automated sample handling followed by Maldi Tof MS analysis allow determination of the molecular mass of individual peaks within a complex HPAEC elution pattern rather routinely. The precise structure

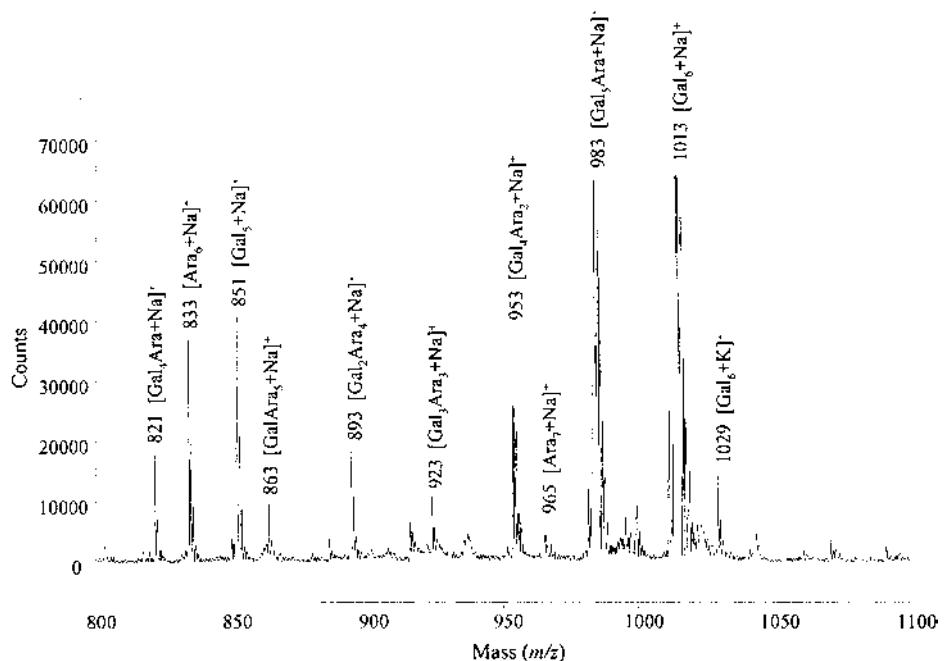

of galacturonic acid oligomers having methyl or ethyl esterification, glycosidation, or amidation, and oligomers as present in an enzyme digest have been studied by Maldi Tof MS and nanoelectrospray MS in detail (61, 63, 67–70).

### C. Screening Using Plate Assays and Chromogenic Substrates

When huge amounts of enzyme samples have to be screened for specific activities (e.g., cDNA libraries), commonly used assays are based on the property of the substrate to specifically bind to a coloring agent like Congo Red (71–73) or Ruthenium Red (74), or by using polysaccharides where a chromogen is covalently attached (Megazyme catalog). In specific cases, enzyme action may result in a modified substrate which can specifically be precipitated by metal complexation in a plate assay (75). Also the use of synthetic substrates in plates like *p*-methylumbelliferylglycosides and *p*-nitrophenylglycosides to screen for glycosidases

**Figure 9** HPAEC elution pattern for the oligosaccharide-containing pool from digest obtained after incubation of soybean-chelating agent extractable pectin with endogalactanase, exogalactanase, endoarabinanase, and arabinofuranosidase B.  $G_n$ , linear  $\beta$ -1,4-linked galactose oligomers;  $A_m$ , linear  $\alpha$ -1,5-linked arabinose oligomers. (From Ref. 26.)

**Figure 10** MALDI-ToF MS of a size exclusion chromatography fraction containing mainly pentamers and hexamers released from soybean pectic arabinogalactan type I by arabinogalactan-degrading enzymes. (From Ref. 26.)

is quite common. The same holds for the inclusion of a pH indicator to the medium to detect esterase activity.

### I. INTRODUCTION

The pectic enzymes comprise a diverse group of enzymes. In view of the complexity of the substrate, the multitude of different enzymes active toward pectin can easily be envisaged. Formally, the enzymes acting on the side chains, galactanases and arabinases, do not belong to the pectic enzymes although these substrates are in general strongly associated with pectin as side chains.

The pectic enzymes consist of main-chain depolymerases and esterases active on methyl- and acetylestes of galacturonosyl uronic acid residues in the galacturonan and rhamnogalacturonan structures. The depolymerizing enzymes comprise hydrolases as well as lyases. Both classes of enzymes contain enzymes that act on the homogalacturonan backbone or "smooth" part, and enzymes that degrade the rhamnogalacturonan part, also known as "hairy regions". The methylesterases hydrolyze the methylester at O6 of a galacturonic acid residue whereas acetylestes hydrolyze the acetylestes at O2 and/or O3 of a galacturonic acid. Acetylestes specific for the smooth regions as well as for the hairy regions have been identified (1). It is not known whether a hairy region-specific methylesterase exists. A list of pectic enzymes is provided in Table 1.

In the literature a class of enzymes named protopectinases is described (2, 3). Protopectinases are those enzymes active on protopectin, the insoluble pectin

that cannot be extracted from the plant tissue by chemical or enzymatic treatment without degradation. The action of a protopectinase results in the release of soluble pectin or pectin constituents. Several protopectinases have been studied in detail, and it turned out that most of them belong to either the polygalacturonases, rhamnogalacturonases, pectate lyases, or the pectin lyases (3). One of the protopectinases was in fact an arabinase whereas another was a galactanase. The nondiscriminative term protopectinase will therefore not be used.

In recent years knowledge about pectic enzymes has increased significantly. Numerous genes encoding pectic enzymes of all classes have been cloned from bacterial, fungal, and plant origin. Several of these genes have been overexpressed, and the corresponding enzymes have been purified and extensively characterized. Three dimensional structures have now been solved for representatives from many classes of pectic enzymes—viz., pectate and pectin lyases (4–7), polygalacturonases (8, 9), a rhamnogalacturonase (10), a pectin methylesterase (11), and a rhamnogalacturonan acetyl esterase (12). Surprisingly, except for the rhamnogalacturonan acetyl esterase, all the enzymes show the same basic  $\beta$ -helical architecture. This new architecture was first described for a pectate lyase by Jurnak and coworkers (4). Despite the rather low degree of sequence similarity between different classes of pectic enzymes, ranging from 10% to 25%, the common  $\beta$ -

**Table 1** Enzymes Involved in Pectin Degradation

Hydrolases	Lyases	Esterases	Auxiliary enzymes
endopolygalacturonase	endopectate lyase	pectin methyl esterase	galactanase
exopolygalacturonase	exopeptate lyase	pectin acetyl esterase	arabinanase
exo-poly- $\alpha$ -D-galacturonosidase	pectin lyase (endo)	rhamnogalacturonan acetyl esterase	$\beta$ -galactosidase
rhamnogalacturonan hydrolase	rhamnogalacturonan lyase		$\alpha$ -L-arabinofuranosidase
rhamnogalacturonan rhamnohydrolase			feruloyl esterase
xylogalacturonanhydrolase			coumaryl esterase

helical structure suggests that these pectinases have evolved from one ancestral gene (13). The unique structural features of each class will be described in the corresponding chapters.

Coutinho and Henrissat (14) have classified the pectic enzymes based on amino acid sequence similarities with the intention that such similarities reflect structural features of these enzymes. The classification can be found at the following URL: <http://afmb.cnrs-mrs.fr/CAZY/CAZY/db.html>

## II. ENDOGENOUS AND EXOGENOUS PECTIC ENZYMES IN FRUIT AND VEGETABLE PROCESSING

Pectic enzymes occur naturally in many fruits and vegetables (endogenous enzymes), but they are also added as processing aids (exogenous enzymes). The latter are mostly derived from food-grade fungi, e.g., *Aspergillus niger*, *A. aculeatus*. In higher plants, particularly pectin methyl esterase and polygalacturonase, both endo- and exoacting, are present. Pectin acetyl esterase has been found in citrus fruit and more recently also pectate lyase and rhamnogalacturonan hydrolase have been found in plants. The endogenous enzymes are assumed to play important roles in plant development and during ripening. The modern genomic approach will enable us to better understand their presence in plants in numerous isoforms and their roles in plant developments. Pectic enzymes are also produced by many microorganisms, and here also numerous isoforms have been described. The impact of endogenous enzymes on fruit and vegetable processing will be discussed in the chapters devoted to the various pectic enzymes (15–17).

As processing aids, pectic enzymes have predominantly found applications in the fruit juice industry. Traditional processes to manufacture fruit juices in essence consist of mechanical destruction of cells by

grinding of intact tissues into a semifluid system in which cells and cell wall fragments are suspended in cell liquid. From this pulp a crude juice can be obtained by mechanical separation methods—e.g., pressing, sieving, or centrifugation. Clear juices can be obtained from the crude juice by additional clarification treatments: cloudy or pulpy juices by adjustment of the amount of fineness of the pulp particles through mechanical treatments in which large and insoluble particles are removed. Clarification is obtained through reduction of the viscosity of the cloudy and pectin-rich crude juice by treatment with enzymes, which causes coagulation and precipitation of the cloud particles. The viscosity reduction also allows the production of fruit juice concentrates which, for economic and technological reasons, can be stored and transported.

From the pulp of apples, grapes, and pears, juice can be obtained quite easily by pressing. In the manufacture of juices from berries or bananas, grinding results in a highly viscous juice which sticks as a gel to the pulp particles. A mechanical separation of juice and pulp particles is here impossible. To facilitate this separation the pulps are treated with enzymes, which are able to degrade the polysaccharides forming the gel. This enzyme treatment results in higher juice yields and improves the color of the juice. This treatment is also successfully used for grapes and for stored overripe apples.

Industrial enzymes used in these applications contain pectin methyl esterases, polygalacturonases, pectin lyases, rhamnogalacturonan hydrolases, rhamnogalacturonan lyases, and rhamnogalacturonan acetyl esterases in varying amounts, as well as arabinanases, galactanases, xylanases,  $\beta$ -1,4-glucanases, amylases, many glycosidases, and proteases.

The enzymes of technological relevance in the various steps of fruit juice manufacture have been identified and we are now more and more able to formulate enzyme cocktails tailored to specific applications. It

was established that enzyme mixtures able to readily degrade high esterified pectins (pectin methyl esterase, endopolygalacturonase, and/or pectin lyase) are also very suitable for improving the pressability of fruit pulps and for clarification of fruit juices. The presence of rhamnogalacturonan hydrolase or rhamnogalacturonan lyase and rhamnogalacturonan acetyl esterase in these formulations further enhances juice extraction but also the solubilization of cell wall polysaccharides (18, 19).

Food-grade fungal enzyme preparations which predominantly contain endopolygalacturonase activity and no pectin methyl esterase and pectin lyase are successfully used as macerating enzymes for the production of pulpy nectars. These nectars are characterized by a creamy consistency and have higher contents of fruit solids, more pigments, and more nutrients than nectars prepared by thermomechanical treatments. Cloudy or pulpy products can be obtained by further grinding, finishing, and homogenization. Maceration can also be achieved by endopectin lyase and endopectate lyase.

By combining pectin-degrading enzymes like endopolygalacturonase, pectin methyl esterase, and/or pectin lyase with cellulose-degrading enzymes like endoglucanases, endoxyloglucanase, cellobiohydrolase, and cellobiase plant cell walls can be almost completely degraded. As a result, the cells cannot withstand the osmotic pressure, and they collapse. The phenomenon of complete liquefaction of the fruit tissues can be observed. This process enables a new, rather simple, flexible, and economical technology for the manufacture of clear or cloudy juices with high yields (18). The liquefaction process can be further enhanced by including rhamnogalacturonan hydrolase or rhamnogalacturonan lyase and rhamnogalacturonan acetyl esterase in the formulation and by also including xylogalacturonan-, arabinan-, and galactan-degrading enzymes. The clarification of the juices by ultrafiltration is substantially improved by avoiding fouling of the membranes (19). The liquefaction technology is particularly suitable for fruits from which no juice can be obtained by pressing or for which no presses have yet been developed, e.g., tropical fruits such as mango, guava, and banana (19–21). The liquefaction process limits losses of nutrients and makes them even more bioavailable (22). The liquefaction process can also be used for extraction of oils from oleaginous fruits and seeds or for the extraction of other valuable cell constituents. In the conversion of agricultural biomass to sugars or alcohol, enzymatic liquefaction is the first step to further saccharification. For each of these applications optimal

formulations have to be established depending on the starting raw material. In the following chapters the different classes of enzymes active toward pectin are covered. In these chapters also specific application aspects as processing aids are mentioned. A separate chapter is devoted to the description of the characteristics of the structural units making up pectins and of methods to monitor activity of pectic enzymes.

### I. INTRODUCTION

Pectic esterases comprise enzymes that hydrolyze the esters present in the pectin backbone (EC 3.1.1.-). Currently three classes of esterases have been identified: (a) the pectin methylesterases (EC 3.1.1.11) that hydrolyze methylesters from O6 of galacturonic acid in the homogalacturonan part; (b) the pectin acetylesteraes (EC 3.1.1.6); and (c) the rhamnogalacturonan acetylesteraes (3.1.1.-). The acetylesteraes remove acetyl groups from O2 and/or O3 of galacturonic acid residues either in the homogalacturonan part or in the rhamnogalacturonan part. Until now, no pectin methylesterase active toward methylesters in the rhamnogalacturonan part has been identified. The pectin methylesterases belong to family 8 of the carbohydrate esterase classification (1). The microbial rhamnogalacturonan and homogalacturonan acetylesteraes have been grouped into family 12 whereas the plant pectin acetylesteraes make up family 13 (1). Other esterases, like feruloylesterase, which are not active on the backbone but rather on side chains, will be covered elsewhere in this volume.

### II. ENDOGENOUS PECTIC ESTERASES IN PLANTS

A major part of the pectic esterase nucleotide sequences present in the databases originate from

plants and represent pectin methylesterases and pectin acetylesteraes. As for the endopolygalacturonases, by far the largest portion is taken by open reading frames (putative genes) from *Arabidopsis thaliana*.

#### A. Pectin Methylesterase

Apart from the presence of many genes encoding putative pectin methylesterases (PMEs), these enzymes have also been detected in various plants by their activity, which confirms their wide distribution. They have been identified in higher plants, particularly in apple, banana, berries, citrus (lime, orange, grapefruit, and mandarin), cherry, grape, mango, papaya, passion fruit, pear, plum, beans, carrot, cauliflower, cucumber, leek, onion, pea, potato, radish, and tomato. Within each species multiple forms of PME can be present as was shown for example for citrus fruits (2, 3), mung bean hypocotyl (4–6), and flax seedlings (7). In general, basic, neutral, and acidic isoforms are found, which differ in various biochemical properties, such as relative molecular mass and pH optimum. PMEs are found in various tissues and are mainly associated by ionic interactions with cell wall proteins, although some soluble forms have been detected as well. Their exact role is not known, but since they are able to deesterify pectin and are often present in the cell wall, it is obvious that they are involved in pectin modification. The degree of methylesterification is very important for the gelling properties of pectin. Highly methylated pec-

tins form gels via hydrogen bonds and are generally associated with young, differentiating and elongating cells, whereas  $\text{Ca}^{2+}$ -pectate gels are formed by low-methoxyl pectins in older, elongated, and differentiated cells (8). Thus, it can be inferred that pectin methylesterases serve important developmental processes in plants by modulating the degree of methylesterification.

During growth, ripening, and storage, the texture of the fruit changes, and fruit softening occurs. These alterations are believed to be due to changes in the turgor of the cell and cell wall metabolism. In tomato these are caused by the degradation of both pectins and hemicelluloses (9, 10). Pectin degradation is caused by the combined action of PME and PG in the fruit. But since PG activity appears to be limited by some chemical or physical restrictions despite being present in high abundance, pectin degradation is limited. As a consequence, antisense suppression of PG activity or PME activity in tomato results in only a small decrease in pectin degradation and a very small increase in fruit firmness later, during ripening (11). Despite the low effect of the antisense downregulation of PG or PME, in normal tomato fruits, during processing, these enzymes are liberated and, without precautions, will degrade the pectin. This may result in either desirable or undesirable changes (11).

In the processing of tomatoes a heat shock treatment called "hot break" is used to inactivate PME and PG and keep a high consistency and viscosity of the juice. When this high consistency is not desired, a "cold break" is used during which PME and PG degrade pectin, thereby lowering the viscosity (11).

During fruit fermentation PME action is responsible for methanol release (12). To keep methanol levels below legal limits, fruit pulps have to be pasteurized before fermentation. PMEs play important roles in fruit and vegetable processing. In citrus processing they cause cloud loss due to precipitation of pectin demethylated by endogenous PME with calcium ions and negatively charged proteins. This is desirable in the production of lemon juice but causes a serious quality defect of orange juice. In orange juice concentrates strong calcium pectate gels may form which prevent reconstitution of single-strength juice. The problem can be overcome either by heat inactivation of PME, which will harm the flavor, or by keeping the concentrate at  $-20^{\circ}\text{C}$ . Another possibility is the addition of endopolagalacturonase, which breaks down the low-ester pectin formed before it can coagulate with calcium (13). Versteeg et al. (2) identified a high-MW isoform of PME, which was much more heat stable than

the other isoforms. It was found to occur in all the component parts of the orange fruit. In the traditional French cider industry, the endogenous PME of apple was used for the self-clarification of apple juice. Today fungal PME preparations free of depolymerizing activity are available for industrial application in cider and lemon juice clarification (13).

The calcium pectate coagulation phenomenon as a result of PME action improves the pressing characteristics of citrus peel and lowers costs when the peel has to be dried for use as cattle feed. Before drying the peel is ground up together with calcium hydroxide. This limiting operation activates the enzyme, pectin coagulates as calcium pectate, and peel juice is released easily before and during pressing (13). Endogenous PME can also be used for protecting and improving the texture and firmness of several processed fruits and vegetables such as apple slices, cauliflower, carrots, potatoes, beans, and peas. Through adjustment of the blanching temperature and time, PME is activated. By the demethylation of cell wall pectin, the cation uptake is increased. Firming effects by the addition of  $\text{Ca}^{2+}$  ions are well established and have long been used to prevent excess vegetable softness. Fungal PME preparations have also been developed for these applications, for improving the consistency of tomato pastes, and also for the manufacture of low-ester pectins with reduced  $\text{Ca}^{2+}$  sensitivity (13).

## B. Pectin Homogalacturonan Acetylesterase

Pectin homogalacturonan acetylesterases (PAE) have so far been purified from orange (3) and mung bean hypocotyl (14, 15). In orange the enzyme was distributed over the whole fruit, with higher levels in the outer parts of the peel (albedo and flavedo) and in the segments. In mung bean the PAE expression was shown to be tissue specific. The highest expression was found in the hypocotyl, whereas expression was significantly lower in the leaves and roots and almost absent in the cotyledons (15). PAE activity has been detected in carrots as well (16), and it is likely that this activity is more widespread among plants.

## C. Rhamnogalacturonan Acetylesterase

Thus far, rhamnogalacturonan acetylesterase (RGAE) activity has been demonstrated only for the fungus *Aspergillus* (17, 18). Despite the absence of any reports describing this activity in plants, it is reasonable to assume plants have this activity, as it has recently been shown that rhamnogalacturonan degrading

enzymes, which require RGAE activity for optimal activity, are present in carrot (16).

### III. APPLICATION OF ESTERASES

#### A. Pectin Methylesterases

Pectin enzymes find a wide application in fruit and vegetable juice manufacturing, like fruit juice clarification, enzymic pulp treatment for juice extraction, liquefaction, and maceration (19). In most of these applications pectic enzymes are used for the complex degradation of pectin. Since these juices are generally acidic, the depolymerization of the pectin is accomplished by polygalacturonases which are generally specific for low-methylated polygalacturonic acid. To convert the pectin into a PG-accessible substrate, the action of PME is required. For maceration of fruits and vegetables, complete pectin degradation is not desired. Only pectin in the middle lamella should be degraded, which can be accomplished by either PG or PL action alone. Therefore, endogenous pectin methylesterase has to be inactivated.

Pectin is widely used in industry because of its gelling properties. High-methoxyl (HM) pectins are able to form sugar acid gels (jams) in which cosolutes like sugar and acid are present to lower water activity or diminish electrostatic repulsion, respectively. LM pectins (degree of methylation [DM] < 50%) can gel in the presence of divalent ions. In food gels this ion is usually  $\text{Ca}^{2+}$ . The  $\text{Ca}^{2+}$  gel-forming ability increases with decreasing DM, although the distribution of the methylesters along the homogalacturonan backbone strongly influences the gelling properties of the pectin. LM pectins with a blockwise distribution of the carboxyl groups (long stretches of de-esterified homogalacturonan) are extremely sensitive to low calcium levels, whereas randomly de-esterified pectins are far less sensitive. This distribution of methylesters can be controlled by the manner of de-esterification of HM pectin. De-esterification of HM pectin by plant PME results in blocks of unmethylesterified galacturonic acid residues, whereas NaOH or fungal PME yields a random distribution of free carboxyl groups. Thus, pectin methyl esterases are of major importance for the preparation of pectins for specific applications. Recently, techniques like MALDI-TOF MS and HPAEC (pH 5) have been developed to discriminate among the various types of pectins and thus allow correlation of functional properties of the pectin to the degree and distribution of methylesterification (20, 21).

#### B. Pectin Homogalacturonan Acetylesterase

Sugar beet pectin is rich in methylated and acetylated galacturonic acid residues and hence has poor gelling properties with either acid/sugar or  $\text{Ca}^{2+}$  ions (22). PME treatment of sugar beet pectin results in partial hydrolysis of the methylesters, resulting in better gelling properties using  $\text{Ca}^{2+}$  ions. Upon addition of PAE isolated from *A. niger* (23), part of the acetyl groups are removed as well. This action in turn allows PME to further remove methylesters. This synergistic effect results in an increase of the stiffness of the  $\text{Ca}^{2+}$ -formed gel (24).

#### C. Rhamnogalacturonan Acetylesterase

Rhamnogalacturonan acetylesterase is essential for the breakdown of rhamnogalacturonan. After deacetylation of the galacturonic acid residues in rhamnogalacturonan, the hairy regions can be further degraded by rhamnogalacturonan hydrolase (25) and rhamnogalacturonan lyase (26), which is of technological importance for the extraction of fruit and fruit juice ultrafiltration (18).

### IV. BIOPHYSICAL PROPERTIES OF PECTIC ESTERASES

Pectin methylesterases have been known and characterized for several decades, which has yielded a wealth of information compared to the recently discovered pectin and rhamnogalacturonan acetylesterases. As with many enzyme families, the more enzymes one studies, the more the variety in biochemical and biophysical properties one observes within the family. The pectic esterases are medium-size enzymes as their MWs are 25–54 kDa. These enzymes are active as monomers. Many PMEs from eukaryotic origin are glycoproteins, and there is even a report of a bacterial PME from *E. chrysanthemi* that is in fact a lipoprotein (27). The isoelectric point of the pectic esterases varies from as low as 3.1 for fungal PME to 11 for a tomato PME. The pH stability depends on the source of the enzyme, and the range for all PMEs stretches from pH 1.1 to pH 10.0. The temperature stability is moderate (40–70°C) with a slightly higher stability for the plant enzymes compared to the microbial enzymes.

## A. Three-Dimensional Structures of Pectic Esterases

Currently, 3D structures are only available for the *Erwinia chrysanthemi* PME (PDB code: 1QJV) (28) and the *Aspergillus aculeatus* rhamnogalacturonan acetyl esterase (RGAE) (PDB codes: 1DEO and 1DEX) (29). The structure of the PME reveals a similar topology as found for the pectate and pectin lyases, and polygalacturonases/rhamnogalacturonases (30–33). This topology is characterized by a right-handed parallel beta-helix structure with loops protruding from the helix core that form the substrate-binding cleft. The conservation of the unique topology among these enzymes strongly indicates that a complete set of different pectinases have evolved from the same ancestral gene.

The structure adopted by RGAE is completely different. This enzyme folds into an  $\alpha/\beta/\alpha$  structure (29), which is different from the normally observed  $\alpha/\beta$  structure common to esterases and lipases. As for the  $\alpha/\beta$  enzymes in the RGAE, the active-site residues are Ser, Asp, and His, in the same sequential order, but the Asp and His residues are only three residues apart instead of being located on different loops (29). Based on the strict sequence conservation in the esterase family 12 of Ser and His and two additional residues, Gly and Asn, which both act as hydrogen bond donors to the oxyanion hole, it has been proposed that this group of esterases be named the SGNH hydrolase family (29).

## B. Isoforms of Pectic Esterases

The *Arabidopsis* genome sequencing project has resulted in > 50 putative pectin methylesterases and numerous pectin acetyl esterases. The databases also contain multiple (putative) PME sequences from other plants. The presence of isoforms at the genetic level therefore seems a common theme among plants. Such a large variety of pectic esterases is not present in microorganisms. At the genetic level, two PME isoforms have been identified in *E. chrysanthemi* (27, 34) whereas all other microorganisms studied so far have only one *pme*, *pae*, or *rgae* gene.

Eukaryotic enzymes and proteins are prone to N- and O-linked glycosylation. Heterogeneous glycosylation can often lead to multiple isoforms of the same enzyme. There are no reports describing the analysis of (heterogeneous) glycosylation patterns of pectic esterase isoforms.

## V. BIOCHEMICAL PROPERTIES OF PECTIC ESTERASES

In the pre-molecular biology era, numerous pectin methylesterases, primarily of plant origin, were characterized. In the past few years the pectin acetyl esterase and rhamnogalacturonan acetyl esterase activities were discovered and studied, but the number of reports on these enzymes is limited (3, 14–18).

Pectin methylesterases hydrolyze the ester bond between methanol and the carboxylic function of galacturonic acid. The action of the enzyme thus results in the formation of a free carboxylic function, methanol, and  $\text{H}_3\text{O}^+$ . In general, the plant and bacterial PMEs have pH optima between pH 6 and 8 whereas some fungal PMEs have pH optima between pH 4 and 6. The plant enzymes often require the addition of 0.1–0.2 mM NaCl for the optimal catalysis. Action of any PME on (highly) methylated pectins does not result in full demethylation. Generally, the residual DM is between 20% and 30%. In part this is due to the presence of acetyl groups in certain pectins (24). Pretreatment or simultaneous treatment with PAE increases the amount of methyl groups removed, but still not all groups will be hydrolyzed (2).

Plant and microbial PMEs differ in their mode of action. Whereas plant enzymes generally remove blocks of methyl groups on a single chain, fungal PMEs attack the methyl groups on the pectin randomly, resulting in a random distribution of the unmethylated galacturonic acid groups. Recently, three different isoforms from mung bean hypocotyls—PME $\alpha$ , PME $\beta$ , and PME $\gamma$ —were subjected to a detailed analysis of their mode of action (35). This elaborate study in which PME activities were measured at pH 5.6 and 7.6 revealed that the three isoforms have different substrate specificities and rates. Strikingly, for PME $\alpha$  at pH 5.6, a sharp drop in activity was observed when the DM decreased below 70% whereas at pH 7.6 the reaction rate remained constant down to 40% DM. For PME $\beta$  and PME $\gamma$  this effect was less pronounced. However, PME $\beta$  showed at both pH values the strongest preference for highly methylesterified pectin. Not only in this respect did the enzymes differ; in their mode of action a clear difference was also observed. The mode of action of the enzymes was simulated and fitted to the actual distribution of methylesters after partial hydrolysis of various DM pectins as recorded by NMR (35).

For PME $\beta$  at both pH values the reaction was best described by a single-chain mechanism. The enzyme remains attached to one substrate molecule and con-

tinues to demethylate the pectin molecule toward the reducing end until the end of the molecule is reached. Similar behavior was concluded for PME $\alpha$  and PME $\gamma$  at pH 5.6, but at pH 7.6 the single-chain mechanism changed into a multiple-attack mechanism. According to this mechanism, only a limited number of methyl groups is removed during each encounter. Furthermore, the studies revealed that for catalysis the presence of an unesterified galacturonic acid residue is required for all three enzymes. For PME $\alpha$  and PME $\gamma$ , this unesterified residue should be present two residues toward the nonreducing end from the methylated residue to be attacked. For PME $\beta$ , this distance was three residues in the same direction (35).

From a practical point of view, pectins treated with either plant or microbial PME result in pectins with different gelling properties and thus are suitable for different applications. Recently, a PAE encoding gene (*paeY*) was cloned from the phytopathogenic bacterium *Erwinia chrysanthemi*, sequenced, and overexpressed in *Escherichia coli* (36). An *E. chrysanthemi* strain with a disrupted *pae* gene showed a reduced invasion of the host plant tested, demonstrating the important role of PAEY in the soft-rot disease (36).

#### A. Effect of Environmental Factors

To date no pectic esterase-specific low MW inhibitory compounds have been reported. However, there are numerous compounds ( $Hg^{2+}$ ,  $Al^{3+}$ ,  $NH_4^+$ , sugar, gallic acid) that inhibit some PMEs, whereas other PMEs are not inhibited (reviewed in Ref. 2). Many PMEs are also inhibited by polygalacturonic acid, the product of its action. NaCl and KCl have been reported to stimulate activity of PME and it has been argued that this stimulation is a result of reduced inhibition by polygalacturonic acid in the presence of NaCl or KCl (2).

Recently, a glycoprotein inhibitor of PME has been identified in kiwi fruit (37, 38). This 16.7-kDa protein was purified by affinity chromatography using partially purified tomato PME coupled to Sepharose. The interaction between the PME and the inhibitor appeared to be a 1-to-1 complex formation. This interaction is very strong and the complex was only dissociable at high pH and high ionic strength (pH 9.5, 1.5 M NaCl). The physiological function of the protein may be in the defense mechanism of plants against phytopathogens, similar to the polygalacturonase-inhibiting proteins (PGIPs) or, alternatively, in the regulation of endogenous PME activity in relation to cell wall development. The primary sequence of the PME inhibitor

was established by peptide sequencing (38), which now allows in vitro gene synthesis. Primary sequence homology searches have revealed significant sequence homology with some plant invertase inhibitors (38). Thus, the presence of a family of inhibitor proteins may be common in plants.

#### B. Specific Mechanism of Action

Based on the 3D structure of PME and primary sequence alignments, Pickersgill and Jenkins hypothesized a possible mechanism (28). Two aspartates and one arginine are strictly conserved among PMEs. One of the Asp residues makes a hydrogen bond to the Arg and is therefore most likely unprotonated. The other Asp is likely to be protonated. A water molecule adjacent to the unprotonated Asp may be activated by transferring its proton to the Asp. The hydroxyl generated can then attack the carbonyl carbon. Simultaneous protonation of one of the oxygens results in the formation of a tetrahedral intermediate, which collapses with the release of methanol and thus results in demethylation (28).

For RGAE it can be postulated that catalysis will proceed via the general mechanism observed for lipases where the catalytic triad Asp-His-Ser, which forms a charge-relay system, will attack the ester bond via the activated serine (29).

For PAE no mechanism has been proposed yet.

#### C. Subsites in Binding to the Substrate

For PAE and RGAE no studies have been reported with respect to the number of subsites involved in substrate binding. For PME such studies have not been carried out either, but some reports allow inferring the number of subsites. Kester and coworkers (39) reported that the rate of de-esterification by fungal *A. niger* PME of individual fully esterified oligomers increased by a factor of 100 when the chain length increased from  $n = 3$  to  $n = 6$ . The increase in reaction rate for  $n = 5$  to  $n = 6$  still amounted to a factor of 2. These results indicate that the number of subsites for *A. niger* PME is at least five and may even be six. Catoire et al. (35) simulated the mode of action of PME isoforms from mung bean hypocotyls using NMR data of (partially) de-esterified pectins. For one of the PME forms, PME $\beta$ , successful simulation of the data was only possible by allowing an unesterified residue to interact with the enzyme at a subsite three subsites in the direction of the nonreducing end away from the active site (35). Thus, for this particular

enzyme, at least four subsites are involved in binding the substrate.

#### D. Synthetic Substrates

Using monomethylesterified trigalacturonides carrying the monomethyl group at a defined position (40) and fully methylesterified oligogalacturonides of chain length  $n = 3\text{--}6$ , Kester et al. (39) studied the mode of action of *Aspergillus niger* PME. These studies revealed that this fungal enzyme cannot remove a methyl group from a galacturonic acid residue at the nonreducing end. It was further shown that an unesterified residue somewhere along the chain is not necessary for this enzyme. *A. niger* PME preferentially attacked a methyl group in the middle of the methylesterified oligomers. The distribution of the products observed after partial saponification demonstrates that this enzyme acts according to a multiple-chain mechanism: each encounter results in the removal of only one methyl group (39).

Triacetin is often used as a substrate for esterases. For *A. niger* esterase, the substrate was specifically used by pectin acetyl esterase, whereas it was not hydrolyzed by RGAE (23). Alternative substrates for acetyl esterases are paranitrophenyl acetate and 4-methylumbelliferyl acetate.

### VI. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

In order to determine the different enzymes qualitatively and/or quantitatively, specific substrates and assays are needed. This preparation of substrates, together with the assays, is described by Schols and Voragen in Section IX. in [Chapter 66](#).

### I. INTRODUCTION

Polygalacturonases cleave the  $\alpha$ -1,4-D-galacturonosidic linkage by hydrolysis. Whereas endopolygalacturonases (EC 3.2.1.15) hydrolyze the polymer substrate randomly, the exopolygalacturonases are confined to cleave off galacturonic acid monomers (EC 3.2.1.67) or digalacturonides (EC 3.2.1.82) from the nonreducing end. The names of these enzymes suggest that polygalacturonic acid is their sole substrate. However, as found for the pectate lyases, endopolygalacturonases are also active on pectins with a lower or moderate degree of esterification. Recently it was shown that endopolygalacturonases A and B from *Aspergillus niger* even prefer a low degree of esterification (1).

The polygalacturonases have all been grouped into family 28 of the general glycosyl hydrolase classification (2). In addition to the endopolygalacturonases, this family also comprises the rhamnogalacturonases and the recently cloned xylogalacturonase (3). Three-dimensional structures of two endopolygalacturonases (4, 5) and a rhamnogalacturonase have been solved (6), and their close resemblance indeed justifies the grouping in one family. By far the largest group of potential polygalacturonase genes (52 open reading frames) is formed by those from *Arabidopsis thaliana*. This large amount originates from the recent *Arabidopsis* genome-sequencing project. Such an abundance

of genes indicates a profound developmental role of the corresponding enzymes. Contrary to plant polygalacturonases, microbial polygalacturonases serve to mobilize nutrients from pectin to support growth. For several yeasts such as *Kluyveromyces marxianus* (7) and *Saccharomyces cerevisiae* (8), polygalacturonase production has been documented and respective genes have been cloned, whereas no obvious physiological function is served since those yeasts can not utilize galacturonic acid.

### II. ENDOGENOUS POLYGALACTURONASES IN PLANTS

In view of the important role of pectin in the primary cell wall of plants, it is obvious that endogenous polygalacturonases play important roles in the development of plants. Polygalacturonase activity has been demonstrated in almost any plant tissue. Based on mRNA expression studies in *Arabidopsis thaliana* (9), tomato [*Lycopersicon esculentum* (10)], and lemon [*Citrus melon* (11)] among others, it was shown that there are at least three types of polygalacturonases: the pollen-specific polygalacturonases, the fruit-specific enzymes, and the abscission-specific polygalacturonases. For tomato it was established that the specific expression, i.e., auxin repression and ethylene and abscisic acid induction, resides in the regulatory

elements within the individual promoters of the polygalacturonase-encoding genes (10).

A phylogenetic analysis by Hadfield and coworkers (11) revealed that the plant polygalacturonases belong to three clades. Clade A comprises fruit- and abscision-specific polygalacturonases without pro-sequence, clade B consists of fruit- and abscision-specific polygalacturonases with a pro-sequence, and clade C contains all the pollen-specific polygalacturonases. It has been hypothesized that all clade C enzymes are exopolygalacturonases, as those enzymes characterized were of the exolytic type. In an excellent review Hadfield and Bennet (12) have compiled the major findings on endogenous plant polygalacturonases of the past two decades. In a more recent review Lang and Dörnenburg (13) further elaborate on this and also pay attention to the role of polygalacturonases in wounding of plants, the interaction of phytopathogenic fungi and plants, and the plant response to this.

To the food enzymologist the most interesting endogenous polygalacturonases are those present in the part of the plant that is used as or in food. One of the best-characterized subjects in this respect is the tomato. As a major food, either as the complete fruit or as puree, catsup, or juice, the influence of endogenous polygalacturonases on fruit ripening and processing has been studied extensively. To this end gene-silencing techniques have been employed that have revealed that endopolygalacturonases are not necessary for fruit ripening (reviewed in 12–14). However, owing to the gene silencing it turned out that the shelf life of the tomato increased profoundly as a result of reduced cracking of the tomato. Upon homogenization of nongenetically modified tomatoes, the deleterious effect of endogenous polygalacturonases becomes evident—i.e., a decrease in viscosity of the homogenate upon aging. To prevent the action of these enzymes, tomatoes are homogenized after heat pretreatment to inactive the enzymes and yield the so-called hot break pastes.

### III. BIOPHYSICAL PROPERTIES OF POLYGALACTURONASES

Although all polygalacturonases belong to family 28 of glycosyl hydrolases, considerable variation in molecular mass (30–75 kDa) and isoelectric point (pI 3.8–8.8) can still be obtained from the databases going from enzyme to enzyme. Currently no relation has been established between molecular mass and/or isoelectric point and/or specificity.

#### A. Three-Dimensional Structures of Polygalacturonases

Currently, 3-D structures are only available for the *Erwinia carotovora* endopolygalacturonase [PDB code: 1 BHE (4)] and the *Aspergillus niger* endopolygalacturonase II [PDB code: 1CZF (5)]. Despite limited sequence identity between the two enzymes (19%), a striking similarity of the two  $\beta$ -helical structures is observed at the C-alpha trace level although certain differences can be observed as well, notably in the loop regions. Details are discussed by Van Santen et al. (5). Unfortunately, no structure is available for any enzyme-substrate complex. However, Van Santen et al. (5) and Armand et al. (15) present evidence that the substrate binds to the enzyme at the observed cleft with the reducing end of the substrate facing toward the C-terminal part of the enzyme. This orientation was also observed for the topologically highly similar pectate lyase C in complex with the substrate (16).

#### B. Isoforms of Polygalacturonases

The rapidly expanding family 28 of glycosyl hydrolases clearly demonstrates that many species analyzed have at least two genes encoding polygalacturonases. Thus, as for the pectic lyases, isoforms at the genetic level are plentiful. Wubben et al. (17) constructed a phylogenetic tree of 35 endopolygalacturonases of yeast and fungi which appeared to group into five monophyletic groups. Hadfield et al. (11) analyzed the plant polygalacturonases in this respect which appeared to group in three clades.

For eukaryotic polygalacturonases, many reports describe heterogeneity of polygalacturonase preparations as a result of glycosylation. To date, the N-glycosylation patterns of only two polygalacturonases have been analyzed in detail, viz., endopolygalacturonases I and II from *Aspergillus niger* (18, 19). The single N-glycosylation site in endopolygalacturonase II appeared to be heterogeneously glycosylated with glycans of the high mannose type (18), whereas of the two N-glycosylation sites of endopolygalacturonase I only one was similarly decorated as the one of polygalacturonase II and the other site was not glycosylated (19). For neither enzyme was O-glycosylation found.

In contrast to *A. niger* pectic lyases, the *A. niger* polygalacturonases all contain a prosequence in addition to the presequence normally found in secreted enzymes. The role of the prosequence is not clear but

is removed by a KEX-like protease in most cases (20, 21). Also, in *Botrytis cinerea* the prosequence was reported in four of the six endopolygalacturonase genes cloned (17).

Sheehy et al. (22) and DellaPenna et al. (23) were among the first to analyze processing of a tomato polygalacturonase. In addition to glycosylation, evidence for proteolytic processing was obtained. In addition to a presequence, a prosequence was reported as well. Moreover, Sheehy et al. (22) also observed C-terminal processing. It has been proposed that the prosequence is necessary for the targeting of the particular enzyme to a certain part of the cell wall (23), but it has also been hypothesized that the prosequence keeps the enzyme in an inactive state until the prosequence is processed at the proper location (12). As mentioned in Section II, the enzymes of clade B all have a prosequence in addition to the presequence.

#### IV. BIOCHEMICAL PROPERTIES OF POLYGALACTURONASES

In the past, several polygalacturonases have been characterized biochemically. However, the most comprehensive and in-depth analyses have been carried out for polygalacturonases from the genus *Aspergillus* and notably for the seven-membered endopolygalacturonase family from *A. niger* N400 and for exopolygalacturonase from *A. tubingensis* NW752. The variety of biochemical properties of these enzymes is such that it covers essentially most other endo- and exopolygalacturonases. The discussion of biochemical properties will therefore be confined to this group of enzymes and will be complemented with additional data for other polygalacturonases where appropriate.

##### A. *A. niger* endopolygalacturonases

An early investigation of a commercial *A. niger* pectinase preparation by Kester and Visser (24) revealed the presence of six different endopolygalacturonases with different specific activities and different modes of action (cleaving patterns) on oligomeric substrates. Using a “reverse–genetics” approach, genes encoding endopolygalacturonases I and II were cloned (21, 25), and, using the endopolygalacturonase II gene as a probe, genes encoding endopolygalacturonases A to E (1, 20, 26, 27) were cloned. All the endopolygalacturonase-encoding genes were individually overex-

pressed in view of their potential industrial application and to facilitate production, purification, and characterization (1, 20, 27, 28). Endopolygalacturonase D appeared quite different from the other *A. niger* endopolygalacturonases as it carries an 136 amino acid N-terminal extension whose function is not clear but which is not processed as evidenced by sequencing the N-terminus by Edman degradation (27).

Several basic biochemical properties of the seven enzymes are listed in Table 1. As can be seen, there is only little variation in pH optima. However, there is an enormous difference in maximal turnover, ranging from 25 U/mg for endopolygalacturonase C to 4000 U/mg for endopolygalacturonase II. For the three enzymes with the lowest turnover rates, endopolygalacturonase C, D, and E, it was proposed that polygalacturonic acid was not the natural substrate. All three enzymes still retain some activity on pectins with a low degree of esterification (DE), making it unlikely that these are the preferred substrates (Table 2). This in contrast to endopolygalacturonases A and B, which both prefer low-DE pectin.

For these latter two enzymes that is quite understandable since these enzymes are constitutively expressed, thus making their role as “scouting” enzymes which encounter primarily medium DE pectin quite likely (1). They are supposed to be involved in producing the inducers required to obtain the complete pectinase spectrum (1). The natural substrates for endopolygalacturonases C and E have yet to be identified. For endopolygalacturonase D,

**Table 1** General Properties and Kinetics of *Aspergillus niger* Endopolygalacturonases

Enzyme	M <sub>r</sub> (kDa)	pH <sup>a</sup>	S.A. <sup>b</sup> (U/mg)	K <sub>m</sub> <sup>b</sup> (mg/mL)	V <sub>max</sub> <sup>b</sup> (U/mg)

D	100	97	93	71	44	25
E	100	103	71	38	16	4

Enzymes were incubated with 0.25% (w/v) substrate in 50 mM sodium acetate buffer, pH 4.2, at 30°C.

it has been proposed that the enzyme is actually an oligogalacturonan hydrolase (27) based on the estimated number of subsites and other features (see below).

### 1. Effect of Environmental Factors

Endopolygalacturonases are generally active between pH 3.5 and pH 6.0. Some enzymes have a quite narrow pH optimum whereas others have a relatively broad pH optimum. As the majority of endopolygalacturonases have been isolated from mesophilic organisms, it is not surprising that the enzymes are also mesophilic. Many polygalacturonases tested in this respect have their highest activity between 40°C and 55°C. However, it should be noted that at these temperatures denaturation sets in. Generally, assays are performed between 25°C and 37°C.

Low-molecular-mass inhibitors for endopolygalacturonases have not been reported, although some inhibitory effect can be expected from divalent ions that interact with the substrate. The known inhibitors of polygalacturonases are the polygalacturonase inhibitor proteins (PGIPs) produced by plants.

Polygalacturonases have long been implicated in the infection process of plants by phytopathogenic microorganisms and not until recently has direct evidence of this been obtained via gene knock-out studies in *A. flavus* (29) and *B. cinerea* (30).

PGIPs belong to the leucine-rich repeat proteins and are produced by nongraminaceous monocotyledonous and dicotyledonous plants. They have been

proposed to form part of the plant's "immune system" (31). It had been known for quite some time that oligogalacturonides with degree of polymerization > 10 could effectively induce phytoalexin accumulation in plants (32). Cervone and coworkers proposed that inhibition of endopolygalacturonase activity by PGIP would increase the amount of larger oligogalacturonides and hence stimulate the phytoalexin accumulation which in turn would trigger the PGIP production (33). The effect of PGIP on endopolygalacturonase activity was demonstrated in vitro (34). Bergmann et al. (35) showed that the oligogalacturonides indeed exerted such an elicitor function by analyzing PGIP mRNA accumulation. Not only were the oligogalacturonides active in this respect, but wounding as well as infection resulted in a similar observation. Devoto et al. (36) demonstrated by using a PGIP1 promoter glucuronidase (GUS) reporter construct that of the minimally five PGIP genes present in *Phaseolus vulgaris* L. at least the PGIP1 gene is only induced by wounding and not by elicitor molecules or infection.

Since phytopathogenic fungi generally have a family of endopolygalacturonases at their disposal, different specificities of PGIPs are expected. Indeed, Desiderio et al. (37), Cook et al. (38) and Stotz et al. (39) demonstrated that the inhibition depends on the type of PGIP and the type of endopolygalacturonase. The most comprehensive study in this respect so far was carried out by Leckie and coworkers (40). They studied *P. vulgaris* PGIP1 and PGIP2 of which only the former cannot interact with the *Fusarium moniliforme* endopolygalacturonase. In a loss-of-function approach they determined that Q253 of PGIP2 was important for binding to the *F. moniliforme* endopolygalacturonase. By mutagenizing K253 of PGIP1 into Q253, PGIP1 acquired inhibitory properties toward *F. moniliforme* endopolygalacturonase. By modeling studies it was shown that K253 is exposed to the surface of the protein (40).

Stotz et al. (39) not only demonstrated the differences in specificity of PGIPs and endopolygalacturonases, they also analyzed the evolution of 22 PGIP genes and 19 fungal endopolygalacturonase genes of different origin. It was demonstrated that advantageous amino acid substitutions dominate the molecular evolution of both PGIP and endopolygalacturonases and that the proteins are likely to evolve adaptively in response to natural selection. Unlike the demonstration of Q253 to be critical for *F. moniliforme* recognition (40), this residue was not significant in the evolutionary analysis (39).

## 2. Specific Mechanism of Action

Endo- and exopolygalacturonases hydrolyze the glycosidic bond between two adjacent  $\alpha$ 1,4-linked D-galacturonic acid residues. Biely et al. (41) demonstrated that for both exoPG and endopolygalacturonase, hydrolysis proceeds with inversion of the anomeric configuration. According to the general concept of glycosyl hydrolytic action inverting hydrolases should have two acidic residues, of which one activates the water that acts as a nucleophile and the other serves as the base, spaced 9–9.5 Å apart. In neither the *E. carotovora* endopolygalacturonase (4) and *A. niger* endopolygalacturonase II 3D structures (5) nor in the *A. aculeatus* rhamnogalacturonase 3D structure (6) are acidic residues spaced at such a distance that they could play the proposed role. By site-directed mutagenesis studies of *A. niger* endopolygalacturonase II and by comparison with the phage 22 tailspike rhamnosidase, Van Santen et al. (5) and Armand et al. (15) were able to propose the catalytic mechanism. A triad of three strictly conserved Asp residues at the bottom of the substrate-binding cleft of endopolygalacturonases forms the catalytic machinery. Two Asp residues, Asp180 and Asp202 (*A. niger* endopolygalacturonase II numbering), together activate the water that acts as the nucleophile whereas Asp201 serves as the base that protonates the leaving group (15). Asp201 is assisted in its role by an adjacent His residue (His223). A His residue has long been thought to be critical for catalysis (42–44). By chemical modification Stratilova et al. (45) demonstrated the involvement of a tyrosine in catalysis of an endopolygalacturonase. Recently, Pagès et al. (46) indeed demonstrated the indirect involvement in catalysis of a strictly conserved Tyr residue (Tyr291, *A. niger* endopolygalacturonase II numbering). Replacing Tyr291 by Phe reduced the activity to 7% of the wild-type enzyme (46).

## 3. Subsites in Binding to Substrate

The *A. niger* endopolygalacturonase II was the first enzyme to be characterized with respect to number of subsites, which was estimated at four (47). More recently the entire *A. niger* endopolygalacturonase family was characterized in this respect (1, 20, 27, 28). For endopolygalacturonase E the number of subsites was estimated to be at least five, stretching from –4 to +1 (20) and subsite affinities were calculated according to the method outlined by Suganuma et al. (48). The calculation revealed that the total

contribution to the binding of the substrate by subsites –2, –1, and +1 was only small (1.1 kJ/mole). The major contribution of the substrate-binding energy, 14.4 kJ/mole, originated from subsite –3. The low affinity at subsites –2, –1, and +1 can be due to the fact that the substrates used, oligogalacturonates, are not the natural substrates for endopolygalacturonase E. For endopolygalacturonases I, II, A, B, and C, the number of subsites was estimated to be at least seven, from –5 to +2 (1, 28) and for endopolygalacturonase D the number of subsites is four, from –3 to +1 (27).

For endopolygalacturonases I and II subsite energy maps were calculated as well (28). A major difference was observed for subsite –5. At this particular subsite, quite remote from the active site, the contribution to binding of the substrate was 6 kJ/mole higher for endopolygalacturonase I than for endopolygalacturonase II. It was proposed that this higher affinity at subsite –5 is the underlying principle for the processive (or multiple attack on a single chain) behavior of endopolygalacturonase I (28). Owing to the high affinity after hydrolysis, the product remains bound from subsites –5 to –1 instead of diffusing away, and subsequently shifts to subsites –4 to +1 for another hydrolytic event. Thus, the processivity appears as an exolytic action from the reducing end and continues until the degree of polymerization of the substrate has reduced so far ( $n = 5$  for endopolygalacturonase I) that it does not cover the remote high-affinity subsite anymore. For endopolygalacturonases A, C, and D, processive behavior was observed as well (1, 27, 28). For endopolygalacturonases A and C, the minimum chain length is 6 and for endopolygalacturonase D this is 4. Upon hydrolysis of polymeric substrates the product progression of typical endoacting enzymes such as endopolygalacturonases II, B, and E is characterized by a transient increase of oligomers with  $n > 6$ , which are gradually converting into smaller products whereas for the processive enzymes the product progression typically shows a strong increase of monomers from the beginning of the reaction with hardly any transient accumulation of longer oligomers.

Of the processive *A. niger* endopolygalacturonases, endopolygalacturonase D is the most extreme in this respect. Furthermore, endopolygalacturonase D is the only *A. niger* endopolygalacturonase capable of hydrolyzing dimers. This, in conjunction with only four subsites, prompted Pařeníková et al. (27) to propose endopolygalacturonase D as an oligogalacturonan hydrolase.

## B. *A. tubingensis* Exopolygalacturonase

The *A. tubingensis* exopolygalacturonase (EC 3.2.1.67) hydrolyzes monomers from the nonreducing end of the substrate (49). Like the majority of *A. niger* endopolygalacturonases, exopolygalacturonase is optimally active between pH 4 and 5. The calculated subsite map reveals four subsites, stretching from  $-1$  to  $+3$ . Subsite  $+1$  has a very high affinity for a galacturonic acid unit ( $24.5\text{ kJ/mole}$ ) whereas subsite  $-1$  even has some repelling force ( $-1.6\text{ kJ/mole}$ ). The high affinity at subsite  $+1$  and negative affinity at subsite  $-1$  are probably why nonproductive complex formation occurs readily and why therefore the actual turnover,  $220\text{ sec}^{-1}$ , is much lower than the potential intrinsic rate ( $716\text{ sec}^{-1}$ ) (49). Also, galacturonic acid appeared to be quite a strong inhibitor ( $K_i 0.3\text{ mM}$ ).

Both the *A. tubingensis* and *A. aculeatus* exopolygalacturonase are able to release xylogalacturonic acid dimers ( $\beta$ -xylose-1,3-galacturonic acid) from apple pectin (50) or soy bean pectin (51). This ability may be a reflection of the low affinity at subsite  $-1$ . It is not known whether xylose-substituted galacturonic acid may be present at subsite  $+1$ . In view of the high affinity for galacturonic acid it is likely that this may not be the case. Körner and coworkers (52) have shown by analysis of reaction products of partially methylated galacturonic acid oligomers by mass spectrometry that *A. tubingensis* exopolygalacturonase does not hydrolyze a nonmethylated galacturonic acid from the reducing end when the following residue is methylated. However, using defined monomethylated dimers and trimers, Kester et al. (53) showed that exopolygalacturonase can accommodate such residues at subsite  $-1$  and  $+1$  albeit with reduced efficiency (< 20% of nonmethylated trimer and < 36% of nonmethylated dimer). The discrepancy between these two studies originates from the presence of galacturonic acid monomers, potent inhibitors of exopolygalacturonase, in the oligomer mixture used by Körner et al. (52). In practice, during pectin hydrolysis, exopolygalacturonase will cease action when a methylated galacturonic acid has to bind at subsite  $+1$  thus leaving a nonmethylated residue at the nonreducing end.

## C. Exo-Poly- $\alpha$ -D-Galacturonosidase

Exo-poly- $\alpha$ -D-galacturonosidase (EC 3.2.1.82) catalyzes the hydrolysis of digalacturonate from the nonreducing end of polygalacturonic acid (pectate). So far, the activity has only been detected in bacteria like

*Erwinia chrysanthemi* (54, 55), *Clostridium thermosaccharolyticum* (56), and *Ralstonia solancearum* (57).

By using a mixture of  $\Delta$ 4,5-unsaturated oligomers (generated by pectate lyase action) and saturated oligomers, Collmer et al. (54) were able to deduce that the *Erwinia* enzyme preferred hydrolysis of  $\Delta$ 4,5-unsaturated dimers, attacked the nonreducing end, and was a single-attack enzyme. The preferred action of this enzyme on unsaturated substrates is understandable in view of the enormous amount of different pectate lyases produced by this organism (see Chapter 80). Shevchik et al. (55) demonstrated that hydrolysis of saturated oligomers indeed occurs at the nonreducing end by using reduced hexagalacturonate. In addition, Kester et al. (53) showed that on purified  $\Delta$ 4,5-unsaturated trigalacturonate the enzyme is slightly more active than on the saturated counterpart (0.32 U/mL vs. 0.2 U/mL) and that the enzyme can not accommodate a methylated galacturonic acid residue at subsites  $-2$ ,  $-1$ , or  $+1$ .

For *C. thermosaccharolyticum*, Van Rijssel et al. (56) were able to show that the exopolygalacturonase activity is associated with a pectin methylesterase activity in a very large complex (1200 kDa). Although this enzyme primarily hydrolyzed dimers from the nonreducing end, the formation of trimers was observed as well. It is not known whether the formation of trimers is a result of a specific binding mode or is due to condensation or transglycosylation. The latter is highly unlikely to invert. It is therefore interesting that yet another D-galacturonan, digalacturonohydrolase, has been studied that does transglycosylate (58). This enzyme, purified from *Selenomonas ruminantium*, released dimers from tri-, tetra-, and pentagalacturonates, but at high trimer concentrations bimolecular reactions were observed. This demonstrates that the particular exopolygalacturonase acts via retention of the anomeric configuration and thus should not be included in family 28 of glycosyl hydrolases.

## D. Synthetic Substrates

Using monomethylesterified di- and trigalacturonides carrying the monomethyl group at a defined position (59), Kester et al. (53) studied the specificity of *Aspergillus* polygalacturonases. The data obtained for the *A. tubingensis* exopolygalacturonase were discussed above, as were the data for endopolygalacturonase D (27). For all six remaining endopolygalacturonases (I, II, A, B, C, and E) it was shown that at subsite  $-1$  a nonmethylated galacturonate residue is mandatory

(53). At subsite +1 only endopolygalacturonase I, II, and B were able to accommodate a methylated galacturonate albeit very poorly (activities < 0.6% compared to nonmethylated trimer). At subsite -2 all six enzymes tolerated fairly well a methylated galacturonate (activities between 6% and 38%). This was also shown by Körner et al. (52), who used partially methylated oligomers mixtures as substrate and analyzed the products of endopolygalacturonase II action by mass spectrometry.

Strictly speaking, almost all commercially available pectin compounds are synthetic substrates, as they all have undergone some chemical treatment. This holds even more for pectin series of various degree of methylation that have been either methylated by chemical treatment (acidic methanol) or demethylated by sodium hydroxide treatment or pectin methylesterase action. Especially the pectin methylesterase-treated pectins can give valuable information about substrate preference of pectic depolymerases as a blockwise distribution of methyl groups can be obtained by plant pectin methylesterase action and a random distribution by fungal pectin methylesterase. By using a series of demethylated pectins which were differently prepared, Pagès et al. (46) demonstrated that endopolygalacturonase II prefers blockwise demethylated substrate but that a single mutation (Glu252Ala) can change the preference profoundly toward less block specificity or to even more block specificity (Gln186Glu). Although these studies are based on kinetic studies (initial rates), valuable information on substrate specificity is also obtained by analyzing the products after various times of hydrolysis of pectins with various degree of methylation (52, 60, 61).

## V. APPLICATION OF POLYGALECTURONASES

Polygalacturonases have found widespread application in many industrial processes. The enzymes applied are mostly obtained from the filamentous fungi of the genus *Aspergillus*. These preparations generally contain a whole range of cell wall-degrading and -modifying enzymes and are predominantly applied in the fruit juice industry. Together with pectin methylesterase, endopolygalacturonases are essential in most of these applications e.g., clarification of fruit juices, enzymatic juice extraction, liquefaction of plant tissues (Chap. 67).

Fungal pectinase preparations containing predominantly endopolygalacturonases and which are free of

pectin methylesterase activity are used successfully for the production of pulpy nectars. These comminuted fruit juices are viscous, pulpy drinks and are usually prepared by a mechanical-thermal dispersion process. However, products prepared with enzymes are superior in cloud stability and smooth consistency and have higher contents of soluble solids and pigments. These suspensions of loose cells from fruit and vegetable tissue are obtained by weakening the cell cohesion by a limited pectin breakdown, particularly in the middle lamella. Nutrients like vitamin A or proteins are protected inside the cells. Enzyme preparations, which have only one depolymerase system (commonly Endopolygalacturonase(s)), are chosen. When endogenous pectin methylesterase is present in the fruit, blanching is indicated. Maceration can also be achieved with endopectin lyase or exopectate lyase. These enzymes might have potential application for processing of vegetables with a higher pH (62). Endopolygalacturonase(s) added to citrus concentrates will reduce the viscosity of these concentrates and contribute(s) to extend the cloud stability of citrus juices. Endopolygalacturonases can also be used for the manufacture of less calcium-sensitive pectin preparations that can be used in systems where the viscosity aspect is not important. Endopolygalacturonases will hydrolyze the galacturonan backbone preferentially in the nonesterified, calcium-sensitive regions.

Polygalacturonases are widely distributed in higher plants. They are believed to contribute to fruit softening of pears, peaches, and avocado (62, 64). Polygalacturonases and also pectin methylesterase activities are abundant in tomatoes. Ingenious systems are used in the tomato processing industry to heat-inactivate instantaneously ("hot break" process) to obtain the highly viscous juice preferred by the consumer and the high-consistency concentrated juice (tomato paste) used for sauces, soups, catsup, and similar products. When tomatoes are used for color and flavor only, and consistency is provided by other ingredients such as starch, a more easily handled, thin, "cold break" juice is the starting material for paste production. A holding time is introduced between crushing and heat treatment to ensure breakdown of the pectins by combined pectin methylesterase/polygalacturonase action (64).

## VI. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

See [Chapter 66](#) on pectic polysaccharides.

### I. INTRODUCTION

Owing to the abundance of arabinose containing structures in pectin and other plant cell wall polysaccharides, arabinose-releasing enzymes (arabinanases) play an important role in the degradation of plant material. These enzymes and the polysaccharides on which they are active have recently been reviewed (1). Arabinanases can be divided into four classes:

1. Endoarabinanases (often referred to as endoarabinases) cleave the internal bonds of the arabinan chains.
2. Exoarabinanases release terminal arabinose residues or short arabino-oligosaccharides from arabinan.
3.  $\alpha$ -L-Arabinofuranosidases release only monomeric terminal arabinose residues from arabinose containing oligo- and polysaccharides.
4. Arabinoxylan arabinofuranohydrolase, another exoacting type of enzyme specific for xylan and xylan-derived oligosaccharides. The latter enzyme will be discussed in Chapter 71.

A second group of enzymes that is important for the hydrolysis of pectin side chains are the galactose releasing enzymes (galactanases), which can be divided in three classes: endogalactanases which

cleave the internal linkages in the galactans; exogalactanases; and  $\beta$ -D-galactosidases which remove terminal galactose residues and short galacto-oligosaccharides (in the case of the exogalactanases) from galactose containing oligo- and polysaccharides. These enzymes have been identified in both prokaryotes and lower eukaryotes, as well as in some plants, and have been studied in detail. The enzymes from microbial origin are those most commonly used in food technology, particularly enzymes from species of the filamentous fungus *Aspergillus*. Therefore the emphasis in this chapter will be on these enzymes, although enzymes from other origins will also be mentioned. An overview of arabinose- and galactose-releasing enzymes from *Aspergillus* and their encoding genes can be found in recent review on plant cell wall polysaccharide degrading enzymes from *Aspergillus* (2).

The more specific experimental procedures involved in the purification and characterization of galactanases and arabinanases will be given. The different classes of enzymes will be discussed separately, followed by information about the induction of the production of these enzymes, the cooperative or synergy of these enzymes in the degradation of the polymeric substrates, and the applications of the enzymes in food technology.

## **II. EXPERIMENTAL PROCEDURES FOR THE PURIFICATION AND CHARACTERIZATION OF THE ARABINANASES AND GALACTANASES**

### **A. Purification**

Since most microbial arabinanases and galactanases are extracellular enzymes, they can be isolated from culture filtrates using classical purification techniques, such as precipitation, ultrafiltration, gel filtration, ion exchange chromatography, isoelectric focussing, and adsorption. However, some materials for affinity chromatography have been developed specifically for these enzymes. Arabinanases and galactanases are commonly produced by microorganisms during growth on crude plant cell wall material. The crude enzyme preparations obtained this way also contain many other cell wall-degrading enzymes. During growth on sugar beet pulp, which is rich in pectin, polygalacturonase and arabinanase are produced abundantly. Using chromatography over a cross linked alginate column (3), these two classes of enzymes have been efficiently separated. Divinylsulfone-substituted Sepharose and chelating Sepharose have been applied to crude enzyme preparations high in both galactanases and arabinanases. Using this material an efficient separation of arabinanases and galactanases from *A. niger* was obtained (4). This column has also been used to remove contaminating arabinanase activities during the purification of a  $\beta(1 \rightarrow 6)$ -endogalactanase (5). Crosslinked arabinan or arabinan linked to activated Sepharose 6B (6) was demonstrated to be able to bind one of the two arabinofuranosidases commonly present in crude enzyme preparations from *Aspergillus*.

### **B. Qualitative and Quantitative Determination of Activity**

Arabinofuranosidase and  $\beta$ -galactosidase activity is generally assayed by using *p*-nitrophenyl- $\alpha$ -L-arabinofuranoside and *p*-nitrophenyl- $\beta$ -L-galactopyranoside as their respective substrates. The activity of the enzymes is determined by measuring the release of *p*-nitrophenol spectrophotometrically at 400–420 nm after adjustment of the pH to 9.0.

An assay in which both arabinofuranosidase activity and endoarabinanase activity can be determined is measuring the appearance of reducing sugars from arabinans with different degrees of branching (e.g., linear arabinan, heavily branched sugar beet arabinan, and moderately branched arabinans isolated from apple

juice) (7). More advanced methods to determine arabinanase activity (including activity on polymeric substrates) use FPLC and HPLC. Methods for the analysis of the delignification activity of arabinofuranosidases (8) and action on monoterpenyl arabinofuranosylglucosides (9) have also been described but will not be discussed here.

Several methods have been described for the determination of galactanase activity. The  $\beta(1 \rightarrow 6)$ -galactanase activity was derived from the amount of  $\beta(1 \rightarrow 6)$ -galacto-oligosaccharides liberated from grape galactan (5). The amount of  $\beta(1 \rightarrow 6)$ -galacto-oligosaccharides was measured by oxidizing non-reducing terminal galactose residues using the D-galactose dehydrogenase method of Finch et al. (10). Using the same method,  $\beta(1 \rightarrow 3)$ -exogalactanase activity was measured using a galactan prepared from acacia gum (11, 12). Recently, a wide spectrum of substrates has become commercially available. These include different arabanans, galactans and arabinogalactans, as well as arabino- and galacto-oligosaccharides. Additionally, several chromogenic substrates have been developed for the rapid analysis of arabinanase and galactanase activity. McCleary (13) developed a specific assay for endoarabinanase activity using a dye-crosslinked substrate (Azurine-crosslinked linear arabinan) which is commercially available (Megazyme, Ireland). The same company also developed a similar assay for  $\beta(1 \rightarrow 4)$ -galactanase activity using Azurine-crosslinked potato galactan. In both assays the enzyme activity is measured by the amount of color released from the insoluble substrate. The same company also markets an endoarabinanase, an arabinofuranosidase, a  $\beta(1 \rightarrow 4)$ -D-endogalactanase, and a  $\beta$ -galactosidase, all purified from *A. niger*.

## **III. $\alpha$ -L-ARABINOFURANOSIDASES**

### **A. Substrate Specificity and Action Pattern**

$\alpha$ -L-Arabinofuranosidases are exoacting enzymes that remove terminal arabinofuranose residues from the nonreducing end of arabinan and arabinose containing oligosaccharides. In pectin these residues are linked via an  $\alpha(1 \rightarrow 2)$ -,  $\alpha(1 \rightarrow 3)$ - or an  $\alpha(1 \rightarrow 5)$ -linkage to arabinan and arabinogalactan side chains. Arabinofuranosidases differ with respect to their ability to release  $\alpha(1 \rightarrow 3)$ - or  $\alpha(1 \rightarrow 5)$ -linked arabinose. Two distinctly different arabinofuranosidases have been described (1). Type A is not active on polymeric substrates, only on oligomeric substrates. Type B, however, is able to release arabinose from both

oligomeric and polymeric substrates. Some  $\alpha$ -L-arabinofuranosidases are able to release arabinose not only from arabinan but also from arabinoxylan (14, 15). All arabinofuranosidases described so far are able to hydrolyze the synthetic substrate *p*-nitrophenyl- $\alpha$ -L-arabinofuranoside. This substrate can be used to distinguish between arabinofuranosidases and arabinoxylan arabinofuranohydrolases, since the latter enzyme is not able to hydrolyze *p*-nitrophenyl- $\alpha$ -L-arabinofuranoside.

## B. Properties

In general, type A arabinofuranosidases in general have a molecular weight in the range of 60–80 kDa. Some gel filtration studies assessed the molecular mass to be > 120 kDa, suggesting that these enzymes may be present as homodimers (Table 1). The native form of a type A arabinofuranosidase was demonstrated to be an octamer composed of eight subunits of 62 kDa (16). The variation in molecular weight of type B arabinofuranosidases is wider (between 34 and 94 kDa; Table 1). For these enzymes, higher molecular masses were also observed suggesting that they are also present as multimeric proteins. Nearly all fungal arabinofuranosidases have an acidic pI (between 3.2 and 6.0),

whereas the variation among bacterial arabinofuranosidases is much wider (from 3.8 to 9.0). No apparent correlation exists between the pI and A or B type arabinofuranosidases. Differences observed in the molecular mass and pI of arabinofuranosidases from the same (eukaryotic) organism are most likely due to posttranslational modifications of the enzymes, especially glycosylation. Differences in glycosylation of extracellular fungal enzymes have been observed depending on the culture conditions of the strain. This can explain, to some extent, the different molecular mass reported for the arabinofuranosidases from two *Aspergillus niger* strains (Table 1) but not the large difference in pI, indicating significant differences in the enzymes produced by the different strains.

A comparison of the kinetic properties of the two types of arabinofuranosidases is made for the well-studied enzymes from *A. niger* (1). Using *p*-nitrophenyl- $\alpha$ -L-arabinofuranoside as a substrate the  $K_m$  for AbfA and AbfB are 0.6 and 0.48 mM, respectively (Table 1). The  $k_{cat}$  for AbfA and AbfB are 262 and 243 ( $\text{sec}^{-1}$ ), respectively (1). These data indicate that despite the strong differences in their ability to hydrolyze natural substrates, their activity on *p*-nitrophenyl- $\alpha$ -L-arabinofuranoside is nearly identical. The  $K_m$  and  $k_{cat}$  of arabinofuranosidases of other organisms show differences up to a factor of 30 compared to the *A. niger* enzymes.

**Table 1** Comparison of the Properties of Some  $\alpha$ -L-Arabinofuranosidases

Organism	Type	MW (kDa) <sup>a</sup>	pI	pH <sub>opt</sub> <sup>b</sup>	$K_m$ (mM)	Ref.
<b>Bacterial</b>						
<i>Bacillus subtilis</i>	A	61		7.0		66

<sup>a</sup>MW is determined by SDS-PAGE, unless otherwise indicated (gf = gelfiltration chromatography).

<sup>b</sup>Determined using *p*-nitrophenyl- $\alpha$ -L-arabinofuranoside as a substrate.

Despite the significant differences in pI between the enzymes purified from the two *A. niger* strains (**Table 1**), nearly identical  $K_m$  values were observed.

### C. Classification and Mechanism

Based on the classification and nomenclature of the Commission of Enzymes of the International Union of Biochemistry,  $\alpha$ -L-arabinofuranosidases (EC 3.2.1.55) belong to the class of hydrolases (group 3), more specifically the O-glycosylases (subgroup .2.1.). The distinction between the two types of arabinofuranosidases from *Aspergillus niger* in the ability to hydrolyze polymeric substrates reflects the assignment of these enzymes to the different glycoside hydrolase families as described by Henrissat and Bairoch (17) at URL <http://afmb.cnrs-mrs.fr/~cazy/cazy/index.html>.

This assignment of enzymes to the different families is made based on homology of the deduced amino acid sequence derived from the genes encoding these enzymes. AbfA is assigned to family 51, whereas AbfB is assigned to family 54. The genes encoding the other purified type A or type B arabinofuranosidases have not all been isolated, so a conclusion whether this is a general correlation cannot yet be made. Families 51 and 54 contain only arabinofuranosidases, indicating that these enzymes are not very similar to other proteins. An arabinofuranosidase from family 54 has also been shown to possess  $\beta$ -xylosidase activity (18). The same is observed for some bacterial arabinofuranosidases (19–21), which have been assigned to family 43. This family also contains endoarabinanases and  $\beta$ -xylosidases.

The reaction mechanism of some members of these families has been determined. Arabinofuranosidases from families 51 and 54 work via a retaining mechanism, whereas enzymes from family 43 have an inverting reaction mechanism (17). The reaction mechanism of the arabinofuranosidase from *Pseudomonas fluorescens* subsp. *cellulosa* (22), the only member of family 62, has not been determined. This enzyme contains a putative cellulose-binding domain. Additionally, an arabinofuranosidase has been identified which contains a xylan-binding domain (23), but this enzyme has not yet been assigned to a glycosylase family.

### D. Inhibitors

L-Arabinose has been demonstrated to be a compatible inhibitor ( $K_I = 16.4$  mM) of arabinofuranosidase II from *Penicillium casulatum*, but did not affect arabinofuranosidase I from this fungus (24).

Inhibition of  $\alpha$ -L-arabinofuranosidase III from *Monilinia fructigena* was demonstrated using 1,4-dideoxy-1,4-imino-L-threitol and 1,4-dideoxy-1,4-imino-L-arabinitol (25). However, the data presented there indicated that efficient inhibition will only occur when the  $pK_a$  of the iminoalditol is below that of the acid-catalytic group of the target enzyme. Consequently these compounds will not inhibit most fungal arabinofuranosidases.

## IV. ENDOARABINANASES

### A. Substrate Specificity and Mode of Action

Endoarabinanases act on the arabinan side chains of pectins releasing arabinose oligosaccharides. They hydrolyze the internal  $\alpha(1 \rightarrow 5)$ -linkages of the main chain of arabinan resulting in arabino-oligosaccharides. The activity of this enzyme significantly enhances the activity of the  $\alpha$ -L-arabinofuranosidases and is therefore essential for an efficient degradation of arabinan. Endoarabinanases prefer unsubstituted linear substrates and therefore also benefit from the action of arabinofuranosidase (AbfB), removing the side chains from polymeric branched arabinan. Bacterial endoarabinanases produce predominantly arabinose and arabinobiose as end products (26, 27), while action of an endoarabinanase from *A. niger* results in the accumulation of arabinobiose and arabinotriose in the reaction mixture (3).

Two endoarabinanases from closely related *Aspergillus* spp. have been studied with respect to their action pattern and substrate specificity (28). The *A. aculeatus* enzyme contains six subsites, while the *A. niger* endoarabinanase contains only five subsites. Different action patterns of the two enzymes resulted in different initial hydrolysis products, but for both enzymes the predominant final hydrolysis products were arabinobiose and arabinotriose.

### B. Properties

Endoarabinanases are relatively small monomeric proteins with a molecular mass between 30 and 45 kDa (**Table 2**). The fungal endoarabinanases have an acidic pI (3.0–3.3), whereas bacterial endoarabinanases have an alkaline pI (7.9–9.3). Although many organisms produce several arabinofuranosidases, no evidence for multiple forms of endoarabinanase has been reported for any organism.

**Table 2** Comparison of the Properties of Some Endoarabinanases

Organism	MW (kDa)	pI	pH <sub>opt</sub>	Ref.
<i>Bacillus subtilis</i>	32	9.3	6.0	67
<i>Aspergillus nidulans</i>	40	3.25	5.5	61
<i>Aspergillus niger</i>	43	3.0	4.6	70

### C. Classification and Mechanism

Like the  $\alpha$ -L-arabinofuranosidases, endo- $\alpha$ -L-arabinanases (EC 3.2.1.99) belong to the O-glycosylases. The systematic name of endoarabinanase is arabinan endo-1,5- $\alpha$ -L-arabinosidase, but this name is rarely used. In this chapter this enzyme will therefore also be referred to as endoarabinanase.

Based on the sequence of the encoding genes, all these enzymes belong to family 43 of the glycoside hydrolases (17). This is a very heterogeneous family containing also (bacterial) arabinofuranosidases and  $\beta$ -xylosidases. The enzymes from this family work via an inverting mechanism (17). No three-dimensional structure has been reported for an endoarabinanase, but crystals have been obtained for the endoarabinanase produced by *Pseudomonas fluorescens* (29).

## V. EXO- $\alpha$ -L-ARABINANASES

Exoarabinanases are enzymes acting on polymeric and oligomeric substrates and have no, or very low, activity against the synthetic substrate *p*-nitrophenyl- $\alpha$ -L-arabinofuranoside. So far, two exoarabinanases have been identified. An exoarabinanase from *Erwinia carotovora* produced arabinotriose from sugar beet arabinan (30). The enzyme was specific for  $\alpha$ (1  $\rightarrow$  5)-linked arabinofuranosyl residues but did not hydrolyze linear arabinan. Therefore, this enzyme most likely releases side chains of sugar beet arabinan.

A second exoarabinanase was characterized from *A. niger* (var. *aculeatus*) (31). This enzyme produced mainly arabinobiose from sugar beet arabinan, although a small amount of arabinotriose was also detected.

Exoarabinanases have not yet been assigned a number according to the Commission on Enzymes of the International Union of Biochemistry. However, they will surely be added to the group of O-glycosylases (EC 3.2.1.-). So far no genes encoding exoarabinanases have been described, and therefore the enzyme

can also not be assigned to one of the glycosyl hydrolase families.

## VI. ENDO- AND EXOGALACTANASES

### A. Substrate Specificity and Mode of Action

Endogalactanases cleave within the galactan chains reacting with galacto-oligosaccharides, whereas exogalactanases attack the substrate from the terminal non-reducing end-releasing galactose or short galacto-oligosaccharides. While most of these enzymes work specifically by an endo- or exomechanism, some bacterial enzymes are able to work via both mechanisms (32, 33). Different types of endo- and exogalactanases have been identified with respect to their specificity for the various  $\beta$ -D-galactan linkages. These enzymes therefore have different specificities with respect to naturally occurring substrates. Type I arabinogalactans only contain ( $\beta$ (1  $\rightarrow$  4))-galactan linkages and can therefore only be hydrolyzed by  $\beta$ (1  $\rightarrow$  4)-endo- and exogalactanases. Type II arabinogalactans contain mainly  $\beta$ (1  $\rightarrow$  3)- and  $\beta$ (1  $\rightarrow$  6)-galactan linkages. The hydrolysis of pectins containing both types of arabinogalactans requires the joint action of all three types of galactanases.

In general, bacterial  $\beta$ (1  $\rightarrow$  4)-galactanases release mainly galactotriose or galactotetraose (32–36) from galactan, while some also release galactobiose (32, 36, 37). Eukaryotic  $\beta$ (1  $\rightarrow$  4)-galactanases release predominantly galactobiose and galactose from galactan (4, 38, 39). Fewer studies have been reported on galactanases working against type II arabinogalactan. They have been shown to release mainly galactose and galactobiose from the polymeric substrate (5, 12, 40).

### B. Properties

Properties of some endo- and exogalactanases are given in Table 3. The molecular mass of the enzymes differs strongly among different organisms and depends on the linkage they are active on. The  $\beta$ (1  $\rightarrow$  4)-endogalactanases from *Aspergilli* all have molecular masses  $\sim$  40 kDa and an acidic pI. The enzymes are monomers and prefer unsubstituted galactan chains as a substrate (41). The *A. niger*  $\beta$ (1  $\rightarrow$  6)-endogalactanase has a higher molecular mass (60 kDa), and its activity is inhibited by the presence of arabinose residues on the  $\beta$ (1  $\rightarrow$  6)-,  $\beta$ (1  $\rightarrow$  3)-galactan chain. Both types of endogalactanases release predominantly galactobiose, but also release some galactose, demonstrating a different action pattern

**Table 3** Comparison of the Properties of Some Endo- and Exogalactanases

Organism	Active against	Action	MW (kDa)	pI	pH <sub>opt</sub>	T <sub>opt</sub>	K <sub>m</sub> (mM)	Ref.
<i>Aspergillus aculeatus</i>	$\beta(1 \rightarrow 4)$	endo	44	2.85	4.0–4.5	45–65		41
<i>Aspergillus niger</i>	$\beta(1 \rightarrow 4)$	endo	43	4–6	4.0	50–55	0.77	52
<i>Aspergillus sojae</i>	$\beta(1 \rightarrow 4)$	endo	39.7	3.6	4.5	50	0.82	58
<i>Aspergillus niger</i>	$\beta(1 \rightarrow 4)$	exo	120	3.8	3.5	60		43
			90	4.1				
<i>Bacillus subtilis</i>	$\beta(1 \rightarrow 4)$	exo	36	7.9	6.5–7	60		37
<i>Lupinus angustifolius</i> L.	$\beta(1 \rightarrow 4)$	exo	60	7.0				74
Tomato	$\beta(1 \rightarrow 4)$	exo	75	9.8	4.5			75
<i>Aspergillus niger</i>	$\beta(1 \rightarrow 3)$	exo	62		5.0	40	1.3	76
<i>Irpex lacteus</i>	$\beta(1 \rightarrow 3)$	exo	42–51	8.2	4.6		2.13	12
<i>Aspergillus niger</i>	$\beta(1 \rightarrow 6)$	endo	60		3.5	60	4.5	5

compared to the *Aspergillus* endoarabinases. The  $\beta(1 \rightarrow 3)$ -exogalactanase from *A. niger* (11) and *Irpex lacteus* (12) differ significantly in their molecular mass (66 and 51 kDa, respectively). They are both inhibited in their activity by branching of the  $\beta(1 \rightarrow 3)$ -galactan chain.

For some galactanases transglycosylation activity has been observed. The  $\beta(1 \rightarrow 4)$ -endogalactanase from *Penicillium citrinum* produced several oligosaccharides using soybean arabinogalactan as donor, and mono- or disaccharide derivatives containing  $\beta$ -galactosyl residues as acceptors (42). The  $\beta(1 \rightarrow 4)$ -exogalactanase from *A. niger* synthesized oligosaccharides with a higher degree of polymerization when incubated with short galacto-oligosaccharides (43). A comparison was made of the transfer products of glycerol formed by *Bacillus subtilis*  $\beta(1 \rightarrow 4)$ -exogalactanase, *E. coli*  $\beta$ -galactosidase, and *P. citrinum*  $\beta(1 \rightarrow 4)$ -endogalactanase (44). The  $\beta$ -galactosidase transferred 90% of the galactose residues to the primary hydroxyl group of glycerol, whereas the  $\beta(1 \rightarrow 4)$ -endogalactanase transferred 80% of the galactose residues to the secondary hydroxyl group. The  $\beta(1 \rightarrow 4)$ -exogalactanase was less specific. Both products were formed, although the amount of transfer to the secondary hydroxyl group was approximately twice as high.

### C. Classification and Mechanism

So far, only  $\beta(1 \rightarrow 4)$ - and  $\beta(1 \rightarrow 3)$ -endogalactanases have been included in the classification and nomenclature of the Commission on Enzymes of the International Union of Biochemistry. Like all other enzymes discussed in this chapter, they belong to the group of O-glycosylases and are numbered EC 3.2.1.89

and EC 3.2.1.90, respectively. The exogalactanases and the  $\beta(1 \rightarrow 6)$ -endogalactanases should also be included in this class (EC 3.2.1.–).

For only one type of galactanases, the  $\beta(1 \rightarrow 4)$ -endogalactanases, have genes been characterized. On the basis of the sequence the encoded enzymes are all assigned to family 53 of the glycosyl hydrolases (17). These enzymes have a retaining mechanism, and for the *Pseudomonas fluorescens* subsp. *cellulosa*  $\beta(1 \rightarrow 4)$ -endogalactanase the catalytic residues have been determined (45). For the  $\beta(1 \rightarrow 4)$ -endogalactanase for *A. aculeatus* crystals have been obtained (46), but a three-dimensional structure has not yet been reported.

### VII. $\beta$ -D-GALACTOSIDASES

Endogalactanases enhance the release of monomeric galactose by  $\beta$ -D-galactosidases, which remove single-terminal galactose residues.  $\beta$ -Galactosidases have been detected in prokaryotes and lower and higher eukaryotes and are active on a wide range of substrates as discussed in other chapters of this book. This chapter will therefore only briefly mention the function of  $\beta$ -galactosidases in pectin hydrolysis.

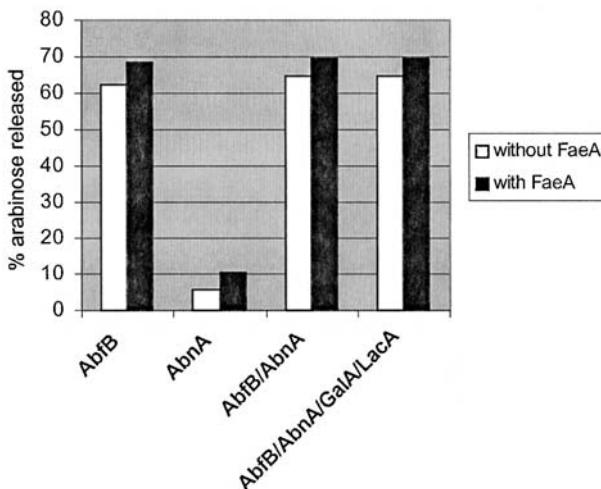

Plant  $\beta$ -galactosidases are believed to be involved in fruit ripening.  $\beta$ -Galactosidase was demonstrated to increase in parallel with an increase in tissue softness (47–49). This is most likely caused by removal of the galactose residues from pectin, thus altering the cell wall structure. The  $\beta$ -galactosidase from *A. niger* was shown to be highly active on the side chains of sugar beet pectin (15). It enhanced the activity of the *A. niger*  $\beta(1 \rightarrow 4)$ -endogalactanase, resulting in an efficient hydrolysis of the galactan chains.

$\beta$ -D-Galactosidases (EC 3.2.1.23) are also members of the O-glycosylases in the classification and nomenclature of the Commission on Enzymes of the International Union of Biochemistry. All  $\beta$ -galactosidases for which the encoding gene has been cloned have so far been assigned to family 35 of the glycosyl hydrolases (17). They work via a retaining mechanism, and contain a highly conserved region (G-G-P[LIVM]<sub>2</sub>-X<sub>2</sub>-Q-X-E-N-E-[FY]). Based on the similarity with other glycosyl hydrolases, the second glutamic acid residue most likely acts as the proton donor in the catalytic mechanism (50).

### VIII. COOPERATIVELY (SYNERGY) OF THE ENZYMES IN THE DEGRADATION OF POLYMERIC SUBSTRATES

Positive interaction among enzymes, most commonly referred to as synergy, is a general phenomenon in polysaccharide biodegradation. Synergy is important for the efficient action of both arabinofuranosidases and endoarabinanases. These two classes of enzymes positively affect each other in the hydrolysis of arabinan. Additionally, the presence of  $\beta$ -galactosidase and endogalactanase also enhances the activity of arabinanases on sugar beet pectin (15) and arabinogalactan protein (51).

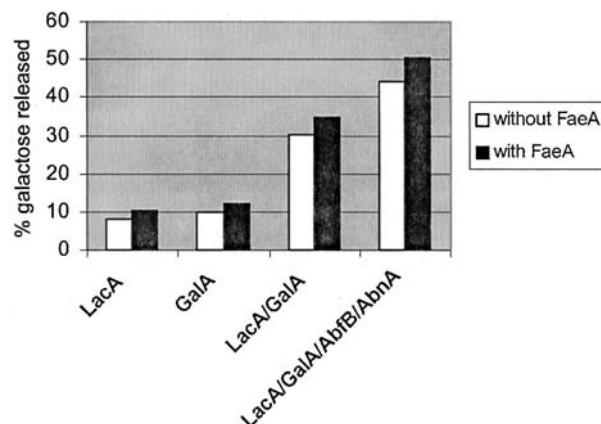

Synergy has also been reported for  $\beta(1 \rightarrow 4)$ -endogalactanase and  $\beta$ -galactosidase from *A. niger*, and for  $\beta(1 \rightarrow 4)$ -endogalactanase and endoarabinanase from *A. niger* (52). The first effect is mostly likely due to the removal of single-unit galactose side chains from the galactan backbone, whereas the second effect indicates that linear arabinan chains limit the activity of  $\beta(1 \rightarrow 4)$ -endogalactanase on galactan. A recent study (15) reported the synergy of endoarabinanase, arabinofuranosidase B,  $\beta$ -galactosidase,  $\beta(1 \rightarrow 4)$ -endogalactanase, and feruloyl esterase A from *A. niger* in the hydrolysis of the side chains of sugar beet pectin. Synergy was observed between most enzymes, although not always to the same extent. Endoarabinanase and arabinofuranosidase B positively influenced each other (Fig. 1), as did  $\beta$ -galactosidase and  $\beta(1 \rightarrow 4)$ -endogalactanase (Fig. 2). Additionally, endoarabinanase and arabinofuranosidase B strongly influenced the release of galactose by  $\beta$ -galactosidase and  $\beta(1 \rightarrow 4)$ -endogalactanase, whereas the latter two enzymes did not significantly influence arabinose release. Feruloyl esterase A, an enzyme capable of removing ferulic acid residues

**Figure 1** Synergy between *A. niger* enzymes in the release of arabinose from sugar beet pectin. AbfB, arabinofuranosidase B; AbnA, endoarabinanase; GalA,  $\beta(1 \rightarrow 4)$ -endogalactanase; LacA,  $\beta$ -galactosidase; FaeA, feruloyl esterase A. (From Ref. 15.)

from the side chains of pectin positively affected the activity of all four enzymes.

Less specific interactions have also been reported. The addition of BSA (100  $\mu\text{g}/\text{mL}$ ) had a stimulating effect on the hydrolysis of *p*-nitrophenyl- $\alpha$ -L-arabinofuranosidoside by arabinofuranosidase (51), most likely by stabilizing the enzyme in the reaction mixture.

**Figure 2** Synergy between *A. niger* enzymes in the release of galactose from sugar beet pectin. AbfB, arabinofuranosidase B; AbnA, endoarabinanase; GalA,  $\beta(1 \rightarrow 4)$ -endogalactanase; LacA,  $\beta$ -galactosidase; FaeA, feruloyl esterase A. (From Ref. 15.)

## IX. PRODUCTION OF ARABINANASES AND GALACTANASES

Arabinanases and galactanases used in food processing are mainly of microbial origin. They are in general extracellular enzymes, and are needed for the degradation of polymeric compounds to produce monomeric sugars and small oligosaccharides, which can be imported into the cell to serve as a carbon source for the organism. Some papers report intracellular arabinofuranosidases (e.g., 53), but the method used to purify these enzymes is probably not able to distinguish between intracellular enzymes and extracellular cell wall bound enzymes.

Microorganisms produce arabinanases and galactanases when grown on complex substrates, such as sugar beet pulp, wheat bran, alfalfa, (arabino)xytan, arabinan, and gum (41, 53–59). Additionally, production of the arabinanases has been observed on L-arabinose, L-arabitol, and D-xylose (60, 61). These compounds are most likely the inducing compounds, driving the expression of the arabinanase encoding genes. In *Aspergillus* the role of L-arabitol as inducer has been confirmed using an L-arabitol-accumulating mutant (62) and by Northern blot analysis of the genes encoding the arabinanases (63).  $\beta$ -Galactosidase gene expression in *A. niger* was observed on arabinose, xylose, xylan, and pectin and to a less extent on galactose and galactose containing oligo- and polysaccharides other than xylan and pectin (64). The expression on xylan and xylose could be contributed to the general xylanolytic transcriptional activator protein XlnR (64, 65), indicating that  $\beta$ -galactosidase is produced as one of the many enzymes of the xylanolytic spectrum from *Aspergillus niger*. However, expression of the  $\beta$ -galactosidase encoding gene on non-xylan-related compounds (galactose, pectin) indicates that it is also under the control of other regulatory systems.

## X. APPLICATION

Arabinases and galactanases are generally present in industrial enzyme preparations applied in the fruit industry. Fruit juices prepared with enzyme preparations which are short in arabinan-degrading enzymes are liable to cloud formation due to precipitation of polymeric linearized arabinan molecules. Enrichment of the preparations with arabinan-degrading enzymes will solve this problem. Depolymerization of arabinan and galactan type I and II in fruit juices with enzymes facilitates ultrafiltration processes by preventing mem-

brane fouling. Adequate formulations of enzyme mixtures are required (77).

### I. INTRODUCTION

#### A. Xylan—the Second Most Abundant Plant Cell Wall Component and Natural Polymer

Plant cell walls can be considered to be the main renewable resource formed in the process of photosynthetic fixation of carbon dioxide. They are composed of three major polymeric constituents: cellulose, an insoluble skeletal polysaccharide composed of  $\beta$ -D-glucopyranosyl residues linked  $\beta$ -1,4-glycosidically; hemicellulose, a series of matrix and crosslinking heteropolysaccharides that include a variety of glucans, mannans, arabinans, galactans, and xylans; and lignin, a complex polyphenol. As a part of the carbon cycle, all three constituents are degraded by specialized enzyme systems produced by microorganisms. This chapter is devoted to the enzymes that degrade the major plant hemicellulose, xylan. After cellulose, xylan is the most abundant polysaccharide in nature. Xylanolytic enzymes have been extensively reviewed in the past (1–5). Books covering xylan and xylanases exclusively have also been published (6, 7).

#### B. Occurrence of Xylanolytic Enzymes

Many bacteria, fungi, yeasts, and protozoa are able to degrade xylan (1, 8). Some of these are saprophytic soil or aqueous microorganisms, some grow aerobically, some grow at room temperature, and others show thermophilicity. Some occur in the digestive track of ruminant animals and in the intestines of wood-eating

insects (8). Most, if not all, fungal plant pathogens produce and secrete enzymes that degrade cell wall hemicellulose (9). Xylanolytic enzymes also occur in plants. The enzymes participate in the process of cell wall extension, cell division, seed germination, and other morphological and physiological events in plants. During germination endogeneous enzymes catalyze hydrolysis of these polysaccharides to remove the physical barrier imposed by the walls on the free diffusion of starch and storage protein-degrading enzymes through the germinated grains (10–12). Enzymes degrading hemicellulose polysaccharides were also reported to be present in wheat grain (13) and wheat flour (14).

#### C. Application of Xylanolytic Enzymes

The past two decades have seen a growing interest in microbial enzyme systems that degrade plant xylan, a polymer of the five-carbon sugar D-xylose. Xylose can be converted to a variety of useful products, including ethanol, the engine fuel of the future (15, 16). Enzymic saccharification of agricultural, industrial, and municipal wastes may provide sugar syrups for human and animal consumption, and carbon sources for industrial fermentations. Xylo-oligosaccharides have a variety of uses as food additives (17). Plant structural polysaccharides provide the major source of nutrients for ruminant livestock and also play an important role in animal fodder. Pretreatment of forage crops with polysaccharide-degrading enzymes improves the nutritional qual-

ity and digestibility of ruminant fodder and facilitates composting (18, 19). Enzymic hydrolysis of highly viscous arabinoxylans originating in cereal endosperms improves nutrient uptake and digestion in broiler chickens (20–23). Other applications of xylanolytic enzymes include improvement of the baking process and modification of baked products (24–30). Xylanases are also important components of enzyme systems used for liquefaction of vegetables and fruit, and for clarification of juices (3, 18). In all of the above-listed processes, microbial xylanolytic systems can be applied together with other enzymes hydrolyzing plant polysaccharides such as amylases, cellulases, and pectinases. There are, however, applications in which xylanases should not be contaminated by cellulases to preserve the polymerization degree of cellulose.

Xylanases free of cellulases have applications with important ecological implications in pulp and paper industry. They facilitate lignin extraction, reducing the consumption of toxic chemicals required for pulp bleaching (31–34). The mechanism of this process, called enzymic prebleaching or bleachbusting, is not completely understood. However, it is believed that xylanase attacks the xylan moiety of lignin-carbohydrate complexes (31). Xylanases also have potential in the purification of dissolving pulp from hemicellulose (35, 36), in the recovery of cellulose textile fibers (37), and in paper recycling (38).

#### D. Chemical Structure of Xylan

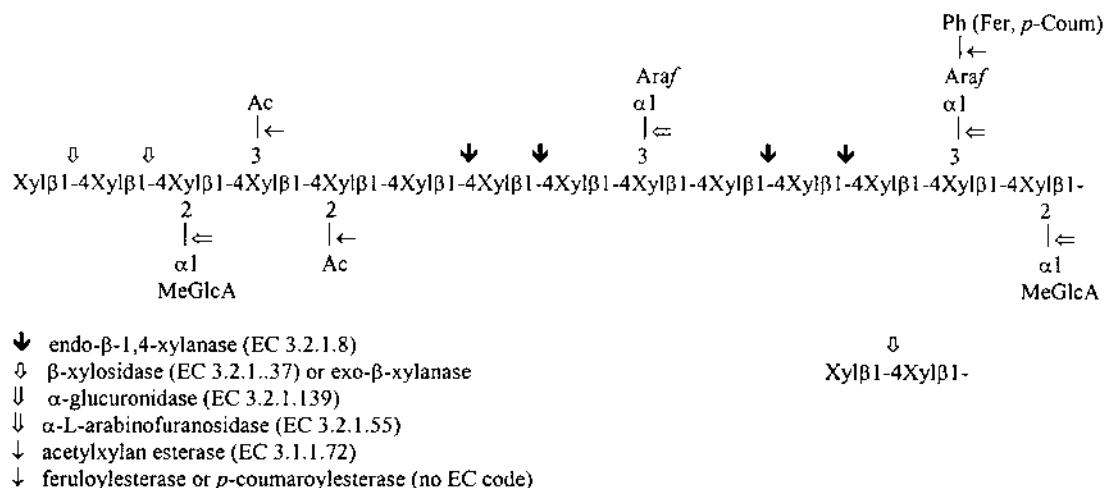

Xylan is structurally similar to cellulose, but instead of D-glucose, its main chain is built from  $\beta$ -1,4-linked xylopyranosyl residues. In contrast to cellulose, however, the xylan structure is extremely variable and depends on its source. The structure ranges from an almost linear unsubstituted chain, e.g., in some grasses, to highly branched heteropolysaccharides in cereal seeds. The prefix *hetero* indicates the presence of sugars other than D-xylose. The main chain is usually substituted to various degrees by residues of 4-O-methyl-D-glucuronic acid, D-glucuronic acid, or L-arabinofuranose, and in some cases is also esterified by acetyl groups. The substituents may be also represented by oligosaccharides and esterified by cinnamic (phenolic) acids. The principal types of xylan found in plants are well known and have been extensively reviewed (39–41). They differ in the character of their side chains as indicated in Table 1.

A hypothetical fragment of a plant xylan which shows the major structural features found in this group of hemicelluloses is depicted in Figure 1. Xylan's backbone is built of  $\beta$ -1,4-linked D-xylopyranosyl residues. In hardwood xylans the side chains are  $\alpha$ -1,2-linked 4-O-methyl-D-glucuronic acid residues and acetyl groups partially esterifying the two available hydroxyl groups of xylosyl residues. Owing to

**Table 1** Examples of Major Types of Plant Xylans

Structural type	Source	Nature of side chains	Approximate ratio Xyl:side chain subst.
Linear $\beta$ -1,4-D-xylan	Esparto grass Tobacco stalk	Substituents are rare	
O-Acetyl-4-O-methyl-D-glucuronoxylan	Hardwoods	Acetyl, 2-O- $\alpha$ -MeGlcA	Xyl:Ac:MeGlcA 10:7:1
O-Acetyl-4-O-methyl-D-glucuronoxylan	Gramineae Legumes	Acetyl, 2-O- $\alpha$ -MeGlcA Acetyl, 2-O- $\alpha$ -GlcA	Not specified
L-Arabino-4-O-methyl-D-glucuronoxylan	Softwoods	3-O- $\alpha$ -L-Araf, 2-O- $\alpha$ -MeGlcA	Xyl:Ara:MeGlcA 10:1:3:2
O-Acetyl-L-arabinoxylan	Gramineae (monocots primary walls, flours)	2-O- $\alpha$ -L-Arfa, 3-O- $\alpha$ -L-Araf Substitution of Xyl in the main chain: single and double	Xyl:Ara varies from 0.9 to 2.2 depending on source. Double substitution of Xyl with Ara is more frequent than single substitution.

**Figure 1** Hypothetical plant xylan and the enzymes required for its complete hydrolysis.

the ease of migration of acetyl groups among the hydroxyl groups, it is difficult to determine their actual distribution between positions 2 and 3. Softwood xylans are similar to hardwood xylans, but contain  $\alpha$ -1,3-linked L-arabinofuranosyl residues instead of acetyl groups. Xylans from grasses contain a smaller proportion of uronic acids, but are more highly branched with L-arabinofuranosyl residues. As indicated in Table 1, the arabinofuranosyl residues also can be linked to the main chain by  $\alpha$ -1,2-linkages, often to D-xylopyranosyl residues already substituted by  $\alpha$ -1,3-linked L-arabinofuranosyl residues. In cereals, the ratio of Xyl:Ara is low, ranging from 1 to 2.2 (44). Xylans from graminaceous plants also contain 2–5% by weight of acetyl groups and 1–2% of phenolic (cinnamic) acids esterifying the C-5 position of arabinose side chains (45). In sugar beet pectins, ferulic acid esterifies the OH-2 of L-arabinofuranose or the OH-6 of D-galactose (46). Ferulic acid [3(3-methoxy-4-hydroxy phenyl)-2-propanoic] is the major cinnamic acid found in cereals and in the Gramineae (47). In wheat bran, one of 150 of xylose residues is substituted with L-arabinose esterified with ferulic acid (45).

Ferulic acid is synthesized in plants via the shikimic pathway and is an intermediate in lignin biosynthesis (48). In some plants it has been shown to be involved in the chemical linkages between xylan and lignin, contributing to integrity of the plant cell walls. Intermolecular crosslinking may result from the dimerization of feruoyl and p-coumaroyl residues or from the formation of ester linkages between polysaccharides and lignin (49, 50).

## E. Xylanolytic System and Its Components

Depending on its complexity, the complete breakdown of xylan requires the action of several enzyme components which can be considered as a xylanolytic system (3). As depicted in Figure 1, the more complex the xylan structure, the more components of the xylanolytic system are required. The crucial enzyme for xylan depolymerization is endo- $\beta$ -1,4-xylanase ( $\beta$ -1,4-xylan xylanohydrolase; EC 3.2.1.8, abbreviated EX). EX attacks the main chain most easily and therefore most rapidly at non-substituted regions, generating nonsubstituted and branched or esterified oligosaccharides. The main chain substituents are liberated by corresponding glycosidases or esterases:  $\alpha$ -L-arabinosyl residues by  $\alpha$ -L-arabinofuranosidases ( $\alpha$ -L-arabinofuranoside arabinofuranosidase; EC 3.2.1.55), D-glucuronosyl and 4-O-methylglucuronosyl residues by  $\alpha$ -glucuronidase (EC 3.2.1.139), acetic acid, and ferulic acid and p-coumaric acid residues by corresponding esterases (EC numbers not assigned).  $\beta$ -Xylosidase (xylobiase or exo- $\beta$ -1,4-xylanase) ( $\beta$ -1,4-xylan xylohydrolase; EC 3.2.1.37) attacks xylo-oligosaccharides from the nonreducing end, liberating D-xylose.

The hydrolases removing xylan side chains have been referred to as "accessory" or "auxiliary" xylanolytic enzymes. Two categories of accessory enzymes can be recognized: those that operate on both polymeric and oligomeric substrates, and those that are active only on branched or substituted oligosaccharides generated by EXs. There is usually no sharp boundary between these groups. The enzymes operat-

ing on polymeric substrates can be distinguished from those of the second group by their ability to catalyze precipitation of the originally highly soluble branched polymeric xylan. This precipitation is due to removal of substituents that hinder the association of the xylan main chains by hydrogen bonding (analogous to that found in cellulose). This precipitation can be used for specific procedures to detect debranching enzymes in the absence of depolymerizing endoxylanases. Accessory enzymes further differ in their requirements for the fine structure of the xylan main chain and the position of the group to be removed.

#### F. Synergism of Xylanolytic Enzymes

The synergistic action of two or more enzymes during hydrolysis of xylan is evident when the rate of hydrolysis of the polysaccharide with two or more enzymes is faster than the sum of the rates of hydrolysis by individual enzymes. Several types of synergism have been recognized among the xylanolytic enzymes (51–53). The most important type concerns the cooperativity between the enzymes attacking the main chain (EXs) and enzymes that liberate side chain substituents, such as acetyl (54) and arabinofuranosyl residues (51). The action of EX releases substituted xylo-oligosaccharides, which are more readily diffusible and more favorable substrates for accessory enzymes. On the other hand, the removal of side chain substituents by accessory enzymes creates new sites on the main chain for productive binding with EX. From some accessory enzymes the cleavage of the main chain is indispensable. Individual components of xylanolytic systems are discussed below.

#### G. Analysis of Xylan Hydrolysates

It is always important to confirm that the apparent xylanolytic activity of any preparation is really connected with xylan depolymerization and not with degradation of some other polysaccharides present as impurities. This aspect is especially important for plant enzyme preparations which contain high levels of amylolytic enzymes. Almost all commercial xylan preparations contain a small amount of starch, which must be removed by  $\alpha$ -amylase treatment before testing for the presence of xylanases.

The traditional method of analyzing enzymic hydrolysates of xylan is by paper and thin-layer chromatography. A suitable solvent system for separation of D-xylose and  $\beta$ -1,4-xylooligosaccharides (linear or substituted) on Whatman No. 1 or 3 MM paper is ethyl

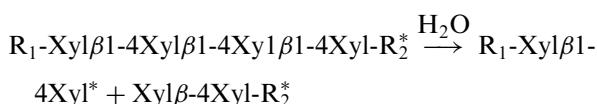

acetate–acetic acid–water (18:7:8, always v/v). A similar efficiency of separation can be achieved on thin layers of microcrystalline cellulose (Merck, Darmstadt, Germany) in ethyl acetate–acetic acid–water (3:2:2) or ethyl acetate–acetic acid–formic acid–water (18:3:1:5). These systems separate well neutral oligosaccharides, aldouronic acids, and partially acetylated xylo-oligosaccharides. Acetylated xylo-oligosaccharides show higher mobility than the corresponding deacetylated products. These systems may also be used to follow the liberation of 4-O-methyl-D-glucuronic acid, which migrates in all the above solvent systems ahead of D-xylose. The use of aniline–hydrogenphthalate reagent provides a color differentiation of the acid from xylose and xylo-oligosaccharides (orange-brown versus dark-brown colors). The reagent, which can be poured onto dry chromatograms, is prepared by dissolving 1 g of phthalic acid in 50 mL acetone followed by addition of 0.9 mL aniline. Visualization of reducing sugars is obtained on heating at 110°C for a few min.

Good separation of neutral products of xylan hydrolysis is obtained by thin-layer chromatography on silica gel (Merck) in such solvent systems as 1-butanol–ethanol–water (10:8:7), 1-propanol–ethyl acetate–ethanol–pyridine–water (7:3:3:2:1) or nitromethane–acetonitrile–ethanol–water (1:4:3:2), the last being the fastest system. Reducing sugars can be visualized with an aniline/diphenylamine reagent, consisting of a solution of aniline (2 mL) and diphenylamine (2 g) in acetone (100 mL) containing 15 mL of 85% H<sub>3</sub>PO<sub>4</sub>. Visualization of all sugars, both reducing and nonreducing, is done with 1% orcinol solution in ethanol/conc. H<sub>2</sub>SO<sub>4</sub> (9:1). Both reagents can be poured onto well-dried chromatograms, which is more convenient than spraying. The solvent system 1-butanol–ethanol–water (10:5:1) is suitable to follow the reaction of xylanases with 4-nitrophenyl  $\beta$ -xylopyranoside. 4-Nitrophenol and 4-nitrophenyl glycosides also can be detected directly under UV light (360 nm).

Other, more up-to-date methods of monitoring the enzymic hydrolysis of xylan include a variety of liquid chromatographies, such as gel permeation chromatography, ion exchange chromatography, adsorption chromatography, reversed-phase chromatography, and partition chromatography, usually in HPLC set-ups. All of these methods require the proper choice of sorbents and eluent, and sophisticated equipment. Paper and thin-layer chromatography are the most simple and least expensive separation techniques for the simultaneous analysis of a large number of samples.

## II. ENDO- $\beta$ -1,4-XYLANASE (EC 3.2.1.8)

### B. Classification

$\beta$ -1,4-Xylan xylanohydrolase, EC 3.2.1.8.

### C. Properties as Proteins

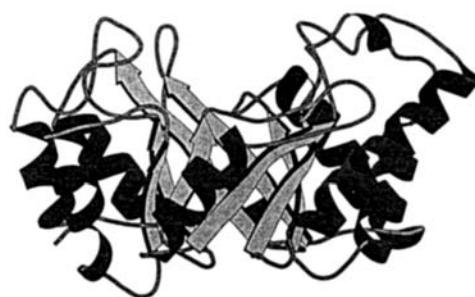

#### 1. EX Families

A careful comparison of microbial EXs on the basis of their different physicochemical properties, such as molecular mass and isoelectric point, was carried out by Wong et al. (55). This analysis indicated that these enzymes can be divided into two groups, one consisting of high-molecular-mass enzymes with low pI values, and the other consisting of low-molecular-mass enzymes with high pI values. As usual, there are exceptions, particularly concerning pI values. Interestingly, this grouping of EXs (55) was found to be in agreement with the general classification of glycanases on the basis of hydrophobic cluster analysis and sequence similarities (56–59). Hydrophobic cluster analysis is

designed to predict protein folding based on hydrophobic/hydrophilic patterns and is used to compare members of a protein group of similar functions (60). Acidic high-molecular-mass EXs ( $> 30$  kDa) were found to be assigned to glycanase family 10 (59) (formerly family F), and basic, low-molecular-mass EXs ( $< 30$  kDa), to glycanase family 11 (formerly family G). While family 10 also contains other glycosyl hydrolases, family 11 is exclusively made up of EXs.

EXs belonging to the two glycosyl hydrolase families show remarkable differences in their tertiary structures as established by crystallography (Fig. 2). Members of individual families have a similar protein folding pattern—i.e., a similar three-dimensional structure. These tertiary structures are more conserved than amino acid sequences. The most conserved region within a family appears to be the catalytic domain. EXs of family 11 appear to be smaller, well-packed molecules, formed mainly of  $\beta$ -sheets (61–64). These enzymes appear very small in their native states (65, 66). The catalytic groups are present in a cleft that accommodates a chain of five to seven xylopyranosyl residues.

The tertiary structure of EXs of family 10 (Fig. 2) is typically an eightfold  $\alpha/\beta$  barrel [ $(\alpha/\beta)_8$ ], resulting in a “salad bowl” shape (67–70). The substrate binds to a shallow groove on the bottom of the bowl, which is shallower than the substrate binding cleft of family 11 EXs (9). This feature, together with the generally greater conformational flexibility of larger enzymes, may account for the lower substrate specificity and greater catalytic versatility of family 10 EXs.

EXs of family 10

EXs of family 11

Figure 2 Tertiary structures of endoxylanases of families 10 and 11.

A comparison of the tertiary structure of EXs with other classified glycosyl hydrolases reveals that the two EX families evolved from different ancestors. EXs of family 10 are closely related to the endo- $\beta$ -1,4-glucanases of family 5, with which they share some common catalytic properties (see below). Both enzyme families 5 and 10 belong to a larger clan of enzymes possessing the eightfold  $\alpha/\beta$  barrel architecture (69, 71), known as clan GH-A (59). EXs of family 11 show a certain degree of similarity to the low-molecular-mass endo- $\beta$ -1,4-glucanases of family 12 (formerly H) (72).

## 2. Multiplicity of Forms

Genetic differences are not the only source of heterogeneity among EXs. A multiplicity of forms is frequently observed among the products of one gene. Several molecular forms of enzymes purified to homogeneity often can be revealed by isoelectric focusing. The observed multiplicity of forms may be a consequence of several factors. The most common reasons include differential mRNA processing, partial proteolysis, and variable degrees of amidation and glycosylation. Additional causes may include autoaggregation and aggregation with other proteins (51).

## 3. Multiple Domains

The molecular architectures of EXs range from a single catalytic domain to a complex arrangement of catalytic and noncatalytic domains (73–76), recently named modules (73, 74). The catalytic domain (module) includes the part of enzyme (Fig. 3) that contains the active site, i.e., the substrate-binding site in the classical sense, and the catalytic groups. Noncatalytic

domains (modules) of EXs act independently of the catalytic domain as polysaccharide-binding domains (carbohydrate-binding modules; CBMs). Catalytic domains are connected to CBMs to which they are linked by linker sequences rich in proline and hydroxy amino acids. The linkers function as flexible, extended hinge regions between functional domains (57). Originally, it was believed that CBMs increased the catalytic rate against insoluble substrates. However, later observations suggested that binding domains may also facilitate the hydrolysis of soluble polysaccharides (75, 77).

Surprisingly, there are several EXs that contain binding modules that bind exclusively to cellulose (cellulose-binding domain; CBD) and not to xylan (57, 74). This is likely related to the biological role of these enzymes in degrading plant cell walls which are predominantly built from cellulose closely associated with hemicellulose. Targeting of EX to cellulose may bring the enzyme in proximity of its substrate. There is a family of CBMs (CBD9) that are found only in EXs (73). CBMs of EX B (XlnB) from *Streptomyces lividans* and EX D from *Cellulomonas fimi* appear to be specific for soluble and insoluble xylan (75, 77). The 3D structure of this xylan-binding domain (XBD) is very similar to that of CBD. A single amino acid change converts the protein from a XBD to a CBD (75). An example of an EX containing two CBMs has been found in *Pseudomonas fluorescens* subsp. *cellulose* (78).

Nature also has designed multifunctional enzymes with two catalytic domains connected by linker sequences. Some bacteria produce bifunctional EXs containing two identical (79) or two different EX domains (80, 81). Other enzymes possess catalytic

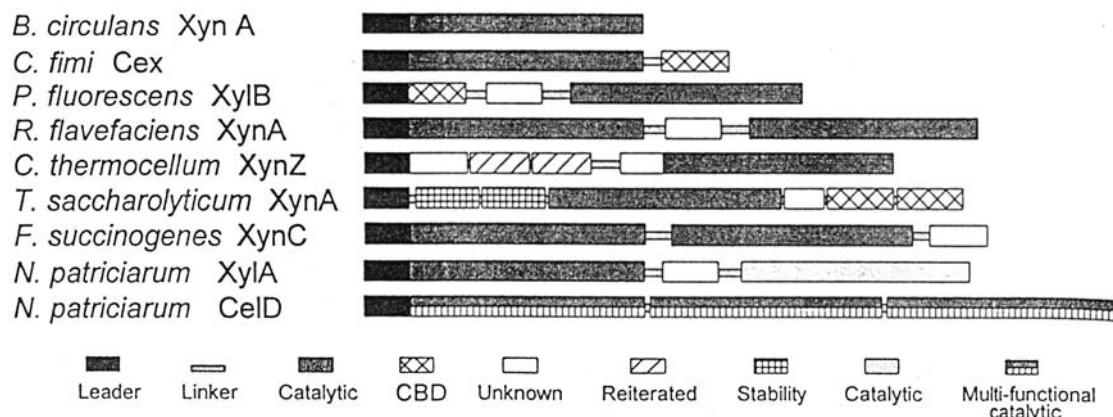

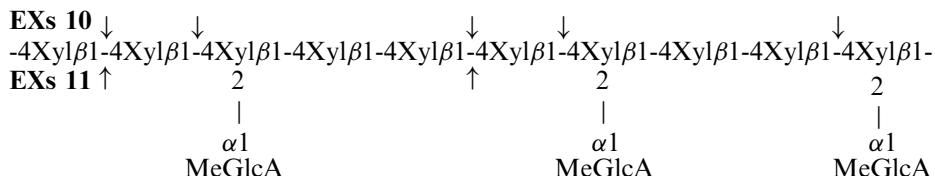

Figure 3 Molecular architecture of some endo- $\beta$ -1,4-xylanases. (From Ref. 76.)

domains of two different xylanolytic enzymes—one catalyzing the xylan depolymerization, and the other deacetylation of the xylan main chain (82–84). Such bifunctional enzymes may have an advantage over enzymes containing a single catalytic domain in the hydrolysis of native acetylated xylan. Multidomain xylanases also occur as subunits of cellulosomes and xylanosomes. These supramolecular extracellular cell-associated protein complexes of thermophilic clostridia can efficiently degrade cellulose, xylan, and related plant cell wall polysaccharides (85, 86).

#### D. Properties as Enzymes

##### 1. Catalytic Properties of EXs Belonging to Two Families

EXs belonging to glycanase family 10 hydrolyze heteroxylans and rhodymenan (a linear algal  $\beta$ -1,3- $\beta$ -1,4-xylan) to a greater extent than EXs of family 11 (87, 88). The EXs of family 10 are better able to cleave

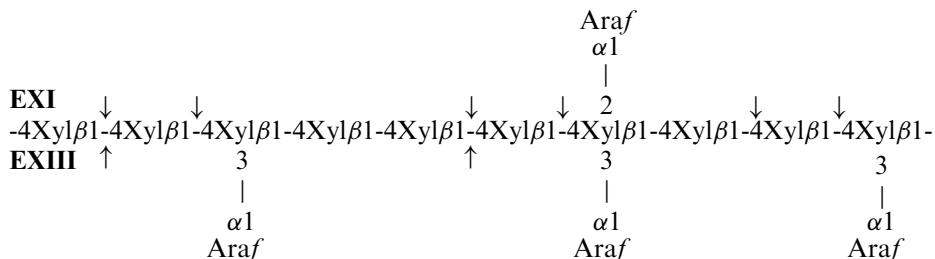

Scheme 1

glycosidic linkages in the xylan main chain that are near substituents, such as MeGlcA and acetic acid. The alteration of the xylan main chain by replacing  $\beta$ -1,4-linkages by  $\beta$ -1,3-linkages, as it is in rhodymenan, represents a more serious steric barrier for EXs of family 11 than for EXs of family 10. Consequently, EXs of family 10 liberate smaller products from 4-O-methyl-D-glucurono-D-xylan, rhodymenan, and, with

some exceptions, also from acetylxyan, than do EXs of family 11. EXs of family 10 can further hydrolyze the shortest branched or isomeric xylooligosaccharides which are released by EXs of family 11 (87).

Characterization of the shortest acidic fragments released from 4-O-methyl-D-glucurono-D-xylan after a long-term hydrolysis (88, 89) suggests which linkages are accessible to hydrolysis by the two types of EXs. EXs of family 10, unlike EXs of family 11, are capable of attacking the glycosidic linkage next to the branch and toward the nonreducing end. While EXs of family 10 require two unsubstituted xylopyranosyl residues between the branches, EXs of family 11 require three unsubstituted consecutive xylopyranosyl residues (Scheme 1). Kinetic data for cleavage of individual glycosidic linkages of the xylan main chain are not available, but time course of product analyses suggest that linkages closer to substituents are hydrolyzed more slowly than more distant linkages.

The degradation of a cereal L-arabino-D-xylan with two EXs of *Aspergillus awamori* (EXI, 39 kDa, pI 5.7–6.7, most probably a member of family 10, and EXIII, 26 kDa, pI 3.3–3.5, most probably a member of family 11) (90) is shown in Scheme 2. The cleavage site specificities L-arabinosyl-D-xylan resemble those on 4-O-methyl-D-glucurono-D-xylan. The L-arabinosyl substituents represent a more serious steric hindrance for

Scheme 2

the formation of productive complexes of the polysaccharide with EXIII. Only the larger type of the enzyme is capable of attacking the linkages between substituted and unsubstituted xylopyranosyl residues.

Studies of the action of EXs on rhodymenan are complicated by the fact that EXs of family 10 are also capable of cleaving  $\beta$ -1,3-linkages (91, 92). Generally, EXs of family 10 do not attack the polysaccharide at  $\beta$ -1,4-linkages which follow  $\beta$ -1,3-linkages toward the reducing end (91), liberating xylotriose, Xyl $\beta$ 1-3Xyl $\beta$ -4Xyl, as the shortest isomeric product EXs of family 11 liberate from rhodymenan isomeric products larger than xylotriose.

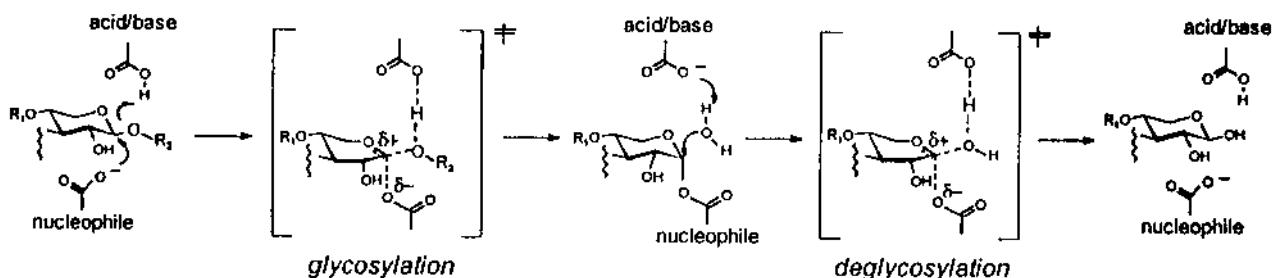

Consistent with the fact that EXs of family 10 are related to endo- $\beta$ -1,4-glucanases and some glycosidases belonging to the clan of glycosyl hydrolases GH-A (59), EXs of family 10 catalyze hydrolysis of aryl  $\beta$ -D-xylopyranosides and low molecular mass cellulase substrates. These include aryl  $\beta$ -D-cellulobiosides, aryl  $\beta$ -D-lactosides (93, 88), and cellobiooligosaccharides (94). The degradation of aryl xylosides, e.g. of 4-nitrophenyl  $\beta$ -D-xylopyranoside, also involves a complex reaction pathway including glycosyl transfer reactions leading to xylooligosaccharides and their glycosides (94, 95). The EXs of family 11 do not possess these catalytic abilities.

## 2. Mechanism of Substrate Degradation

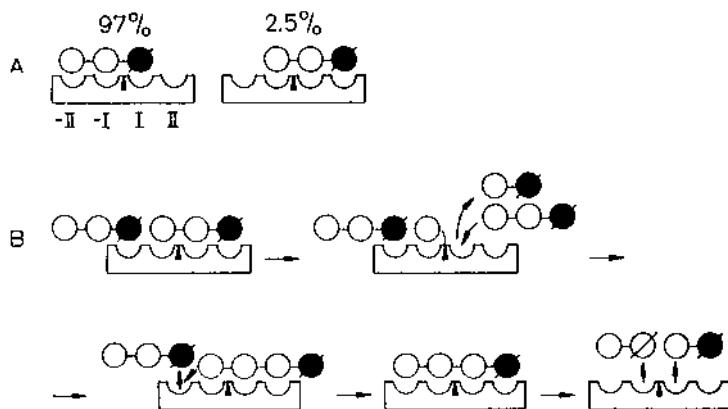

The hydrolytic reaction takes place in the active site of the enzyme consisting of the substrate-binding site and catalytic groups. Consistent with their tertiary structures, EXs of family 10 appear to have a smaller substrate-binding site than do EXs of family 11. EXs of family 11 contain a larger number of subsites (five to seven) than EXs of family 10 (four to five subsites). A subsite is a part of the binding site that interacts with one xylopyranosyl residue of the substrate. The interaction may not be only attractive, it can also be repulsive, particularly on the site of the leaving group. The number

of subsites and their binding affinities can be determined by a procedure that is called subsite mapping (96–98) which is complementary to the image of the substrate binding site provided by x-ray crystallography (99).

EXs of both families catalyze the hydrolysis of glycosidic linkages with the retention of anomeric configuration (100, 101). The reaction involves a double-displacement mechanism leading to a new reducing end with  $\beta$ -anomeric configuration (102) (Fig. 4). The catalytic amino acids in the substrate binding site divide the subsites to the left (numbered with minus Roman numbers) and to the right of the catalytic groups (numbered with positive Roman numbers) (Fig. 5). The catalytic residues have been identified as two conserved glutamate residues (in a few cases one asparate replaces a glutamate), which are located opposite each other in the active site. One residue functions as a general acid catalyst protonating the glycosidic oxygen, while the other functions as a nucleophile, attacking the anomeric center to form a covalent enzyme-glycosyl intermediate (Fig. 4). In the second step a water molecule attacks the intermediate in a general base-catalyzed process to yield the product of retained anomeric configuration (99, 103). The catalytic residues have been identified by chemical modification, site-directed mutagenesis, and use of stabilized enzyme-glycosyl intermediate (76, 103). Glycosyl transfer reactions catalyzed by both types of EXs at high substrate concentrations are also evidence for the enzyme-glycosyl intermediate. Using linear  $\beta$ -1,4-xylo-oligosaccharides as substrates, it has been established that EXs utilize multiple pathways of substrate degradation (104, 105). Unimolecular hydrolysis takes place at low substrate concentrations. Different cleavage of the substrate occurs at so-called shifted binding, which is observed at higher substrate concentrations and which is, generally, accompanied by formation of products larger than the substrate. An example of such reactions of xylotriose catalyzed by EX from *Cryptococcus albidus* is shown in Figure 5.

**Figure 4** Mechanism of hydrolysis of glycosidic linkage with endo- $\beta$ -1,4-xylanases.

**Figure 5** Possible binding and degradation of xylotriose by EX from *Cryptococcus albidus*. (A) Productive complexes at low substrate concentration and probability of their formation; (B) shifted two-one binding of xylotriose at high substrate concentration and subsequent xylosyl transfer to second xylotriose molecule to give xylotetraose, which is finally cleaved to two molecules of xylobiose. (From Ref. 104.)

At sufficiently high concentrations of xylotriose, xylobiose initially is generated as the only product of xylotriose degradation. Analogous reaction pathways are also observed with longer oligosaccharides. The main molecular and catalytic properties of EXs of families 10 and 11 are summarized in Table 2.

### 3. Xylan-Degrading Endo- $\beta$ -1,4-Glucanases

It has been unambiguously established that at least one type of endo- $\beta$ -1,4-glucanase exhibits activity on both

cellulose and xylan (106, 107). The best-known enzyme in this regard is endoglucanase I from *Trichoderma reesei*, a member of family 5 glycosyl hydrolases. The enzyme catalyzes the hydrolysis of both polysaccharides in the same active site (108). Although the enzyme belongs to the same clan as EXs of family 10, the products the enzyme generates from glucuronoxylan and rhodymenan are more similar to those liberated by EXs of family 11 (87). In *T. reesei* the enzyme is coinduced as a component of the cellulolytic and not of the xylanolytic system (3).

**Table 2** Properties of EXs of Families 10 and 11

Properties	EXs of family 10	EXs of family 11
Molecular mass	usually > 30 kDa	usually < 30 kDa
Isoelectric points	usually < 7	usually > 7
Protein fold (catalytic module)	( $\alpha\beta$ ) <sub>8</sub>	two $\beta$ -sheets and one $\alpha$ -helix
Substrate binding site	shallow groove	deep cleft
Catalytic amino acids	two glutamic acid residues (occasionally one glutamate and one aspartate)	two glutamic acid residues (occasionally one glutamate and one aspartate)
Number of subsites	4–5	5–7
Substrate specificity	less specific	more specific
heteroxylans	active	active
aryl- $\beta$ -xylosides	active	inactive
aryl- $\beta$ -cellobiosides	active	inactive
aryl- $\beta$ -lactosides	active	inactive
Stereochemistry of hydrolysis	retaining	retaining
Multiple reaction pathway at high substrate concentrations	yes	yes

## E. Qualitative and Quantitative Determination of Activity

### 1. Reductometric Assays

The most common way to follow EX activity is to determine the reducing sugars formed from selected type of xylan. Two basic procedures for determination of reducing sugars have been widely used: the Somogyi-Nelson procedure (109–111), and the 2,4-dinitrosalicylic acid (DNS) test (112–114). The methods are sufficient to prove the presence of the enzyme, to assay its activity, and to evaluate the extent of polysaccharide hydrolysis, which may be the first criteria for xylanase differentiation. The two methods for the determination of reducing sugars have been compared in an interlaboratory evaluation organized by Finnish scientists (115). Although the Somogyi-Nelson procedure is almost 10 times more sensitive than the DNS method, the latter always gives higher values of xylanase activity. When standardized with respect to substrate and procedure, the assay employing the DNS method afforded reproducible results in various laboratories with a standard deviation of 17% (115). Recently Jeffries et al. (116) reported that the differences between the Somogyi-Nelson and DNS methods are due to the fact that the first method is less reactive and the second method more reactive with xylooligosaccharides than with xylose. The prevalence of oligosaccharides among the products of xylan hydrolysis is thus why the Somogyi-Nelson method underestimates, and the DNS method overestimates enzyme activity.

The most sensitive method for photometric determination of reducing sugars is that using 2,2'-bicinchoninate (117, 118). However, it has not been widely adopted for determination of xylanase activity. Nevertheless, the method should be listed here because of its potential for miniaturization to the scale of a microplate reader (119).

#### a. DNS Xylanase Assay (115)

##### Reagents

1. Birchwood or beechwood 4-O-methyl-D-glucuronoxylan (Roth 7500, Germany; or Sigma, USA), 1% solution in 0.05 M citrate buffer, pH 5.3 (in the case of fungal enzymes or other buffers with bacterial enzymes). The solution is prepared under heating up to boiling point with stirring until the polysaccharide dissolves. Clarification by centrifugation is not necessary but may be useful. Cooled solution can be stored in the presence of 0.01–0.02% sodium azide.

2. D-Xylose, 10 mM calibration solution in 0.05 M citrate buffer, pH 5.3 (or other buffer).

3. DNS reagent prepared according to Sumner (112) or Miller (113).

*Procedure.* Preheated xylan solution (1.8 mL; 50°C) is mixed with 0.2 mL preheated enzyme solution (50°C) and incubated for 5 min at 50°C. The reaction is stopped by addition of 3 mL of the DNS reagent. The mixture is heated for 5 min at 100°C (boiling water bath) and then cooled in cold water. Absorbance of samples is measured at 540 nm against the substrate blank and the values are corrected for absorbance of the enzyme blank. Calibration samples with known amounts of xylose are prepared in the presence of the substrate.

One unit of xylanase activity is defined as the amount of enzyme liberating 1  $\mu\text{mol}$  of xylose equivalent under the experimental conditions in 1 min. (*Note:* The volume of the assay can be reduced.)

#### b. Xylanase Assay Using the Somogyi-Nelson Method (120)

##### Reagents

1. Birchwood or beechwood 4-O-methyl-D-glucuronoxylan (Roth 7500, Germany; or Sigma, USA), 0.4% solution in 0.1 M acetate buffer, pH 5.4, or 0.2% solution in 0.05 M acetate buffer (or other buffer). The solution is prepared under heating up to boiling point with stirring until the polysaccharide dissolves. The solution can be stored in the presence of 0.01–0.02% sodium azide.

2. D-Xylose, 1 mM calibration solution.

*Procedure.* Xylan solution (0.25 mL, 0.4%) is mixed with 0.25 mL enzyme solution, or 0.5 mL of 0.2% xylan solution is mixed with 10–50  $\mu\text{L}$  enzyme solution and incubated at 30°C for an appropriate time. The reaction is terminated by addition of 0.5 mL of the Somogyi reagent, mixed well, and heated for 10 min on a boiling water bath. After cooling in cold water the samples are vigorously mixed with 0.5 mL of the Nelson reagent. After 15 min standing with occasional stirring, cloudy samples are centrifuged to remove the fine precipitate. Absorbance at 560 nm of the supernatants is measured. Blanks to correct the values for reducing power of the substrate and the enzyme are run in parallel. Calibration is done in the range 0.05–0.5  $\mu\text{mol}$  of xylose. One unit of xylanase is defined similarly as above. (*Note:* Exact duration of heating at 100°C with the Somogyi reagent is critical for reproducibility of results.)

## 2. Other Xylanase Assays and Specific EX Assays

It should be noted that reductometric assays are not specific for EXs and, when used with crude xylanolytic systems or EX preparations containing other xylanolytic enzymes, they cover the overall saccharification ability of the tested enzyme preparations. Frequently, reductometric xylanase assays may not be sufficiently sensitive or may be hampered by a high background of reducing sugars in the enzyme preparations. In such cases, a viscosimetric method of xylanase assay can be recommended. This method is based on measurement of the decrease of viscosity of a soluble xylan, e.g., arabinoxylan (121) or soluble xylan derivative, like carboxymethylxylan (122, 123). Viscosity can be measured using various viscosimeters or by modern electronic devices employing vibrating metal rods. Changes in the resistance of the medium to the vibrating or rotating rods are recorded and transformed into activity units. Viscosimetric measurements are important to establish the endocharacter of glycanases. Plots of specific fluidity ( $1/\eta$ ) versus the amount of liberated reducing sugars give linear relationships, the slopes of which correspond to the randomness of the xylan attack by the enzymes (89).

Another specific EX assay employs a soluble covalently dyed xylan, Remazol Brilliant Blue–xylan (RBB-xylan), a substrate that is precipitable from aqueous solution by ethanol (124). The assay is based on the photometric determination of enzyme-released dyed fragments that remain soluble in the presence of ethanol. This method allows the determination of xylanase activity in the presence of larger amounts of reducing sugars, in membrane fractions of cells, and even in the presence of viable cells utilizing liberated xylan fragments. Limitations of the method are its sensitivity to temperature and ionic strength. Testing in 15 laboratories showed the method reproducible to  $\sim 30\%$  relative standard deviation, suggesting that RBB-xylan assay could be a useful alternative assay for xylanases (115). A number of covalently dyed soluble and insoluble xylyans are available from Megazyme (Wicklow, Ireland). The company offers also a specific tablet test for EX activity based on wheat arabinoxylan. The nephelometric assay of xylanase (125) could be suitable for differentiation of xylanases with respect to their performance on insoluble xylan.

### a. RBB-Xylan Assay (115, 124)

#### Reagents

1. RBB-xylan, solution in 0.05 M acetate buffer, pH 5.4, 5–6 mg/mL (the concentration should cor-

respond to 5 mg/mL of undyed xylan) or solution in 0.1 M acetate buffer (10–11 mg/mL).

#### 2. Ethanol, 96% or absolute.

*Procedure.* The enzyme solution or suspension (10–50  $\mu$ L) is mixed in 1.5 or 2.0 mL plastic microtest tubes with 0.5 mL of preheated (30°C) solution of RBB-xylan solution (5–6 mg/mL), or 0.25 mL of enzyme solution or suspension is mixed with 0.25 mL RBB-xylan solution in 0.1 M acetate buffer and incubated at 30°C for an appropriate time. The reaction is terminated by the addition of 1 mL ethanol to precipitate unhydrolyzed RBB-xylan and its high-molecular-weight fragments. After standing at room temperature for 20–30 min in closed test tubes, the mixtures are mixed again and centrifuged at 2500g for 1.5–3 min. The absorbance of supernatants is then measured at 595 nm against the respective substrate blank. (Note: The assay does not give direct data suitable for calculation of the enzyme activity. However, the assay can be calibrated by a reductometric assay carried out under the same experimental conditions with undyed xylan.)

## 3. Synthetic Substrates

Synthetic substrates of glycosyl hydrolases usually include chromogenic and fluorogenic glycosides which are widely used to quantify particularly glycosidases. The most common substrates are 4-nitrophenyl and 4-methylumbelliferyl glycosides. Liberation of 4-nitrophenol is followed photometrically at 405–410 nm after termination of the enzymic reaction with alkaline reagents. Fluorimetry is used to follow the liberation of 4-methylumbelliferone (excitation at 365 nm and emission at 448 nm at pH 10–11). To achieve maximal sensitivity, permitting work in the nM concentration range of substrates and products, basification of the reaction mixtures is required (126, 127).

Similar aryl glycosides of oligosaccharides derived from polysaccharides can be used as chromogenic and fluorogenic substrates of endoacting glycosyl hydrolases. Significant progress in differentiation of cellulolytic glycanases was achieved by the introduction of 4-nitrophenyl- and 4-methylumbelliferyl- $\beta$ -glycosides or cellobiose, cellotriose, and lactose (93, 128). Of these substrates, only 4-nitrophenyl- $\beta$ -cellobioside has been occasionally used for determination of activity of cellobiohydrolase. This assay is not specific, because aryl  $\beta$ -cellobiosides are attacked at the agluconic linkage also by endo- $\beta$ -1,4-glucanases (128) and EXs of family 10 (88). Liberation of the aryl aglycone from cellobio-

sides occurs also after a two-step hydrolysis of the substrate by  $\beta$ -glucosidase.

Aryl  $\beta$ -glycosides of xylo-oligosaccharides have also been described as potential substrates of EXs (129–135). However, because they have not been commercialized, their use remains very limited in spite of their great analytical potential and unusually high sensitivity. 4-Nitrophenyl  $\beta$ -xylobioside was used for characterization of substrate requirements of a non-specific  $\beta$ -xylanase from *Cellulomonas fimi* (129). 4-Methylumbelliferyl  $\beta$ -xylobioside and  $\beta$ -xylotrioside were successfully used for detection of EXs in electrophoretic gels (130) and for differentiation of EXs (133).

#### 4. Assays for Detection and Screening Purposes

A number of different procedures have been developed over the years for detection of EXs in gels. The same principles can be used both for the detection of the enzyme in electrophoretic gels and for screening of microorganisms and genetically transformed cells on solid agar media. The detection and screening techniques employ soluble xylan, insoluble xylan, soluble covalently dyed xylan, and fluorogenic  $\beta$ -glycosides of xylo-oligosaccharides.

In agar gels incorporating insoluble xylan, EX activity is visualized as the appearance of clearing zones (136). On solid growth media containing a soluble xylan-dye conjugate, such as RRB-xylan (124), xylanase-positive colonies are identified by pale-blue or colorless zones resulting from diffusion of dyed polysaccharide fragments generated by EXs (137, 138). The advantage of these two screening substrates is that the degradation of the substrate can be followed progressively without any further treatment which might prevent the isolation of the positive colonies directly from the screening plates. A replica plating is required in the case of screens employing the soluble xylan complexed with Congo Red (139, 138) or precipitation of soluble xylan with ethanol (140). Replica plating is avoided in plate assays with the fluorogenic glycosides 4-methylumbelliferyl  $\beta$ -xylobioside (Umb-Xyl<sub>2</sub>) or  $\beta$ -xylotriose (Umb-Xyl<sub>3</sub>) (130).

##### a. Procedures

*Detection of microbial producers of xylanase* (137, 138). Solid media containing 0.15–0.2% RBB-xylan (can be autoclaved) are suitable for the detection of microbial producers of extracellular EX. Surrounding colonies of EX producers, pale-blue zones are formed as a result of diffusion of secreted enzymes and enzyme-released dyed fragments of RBB-xylan.

A soluble undyed glucuronoxylan (0.1–0.2%) can be used instead of RBB-xylan. The production of EX is revealed after an appropriate time by flooding the plate first with 1 M NaCl and then with 0.1% aqueous solution of Congo Red (C.I. 22120; Sigma, Aldrich, Calbiochem). After 15 min the dye solution is poured off and areas with hydrolyzed polysaccharides are destained for 10 min with two changes of 1 M NaCl with a 20-min treatment with 5 M NaCl.

Umb-Xyl<sub>2</sub> or Umb-Xyl<sub>3</sub> gives the best results when used in the form of solutions (0.1–0.5 mM) applied to the surface of solid growth medium after colonies are clearly visible. Incorporation of the fluorogenic substrates into the solid growth media may not give straightforward results due to the rapid diffusion of the fluorogenic aglycone in comparison with the rate of colony growth.

*Semiquantitative gel diffusion assay* (141, 142). A solution of 0.15–0.2% RBB-xylan in an appropriate buffer is solidified with agar or agarose in petri dishes. Wells 4 mm in diameter are cut using a cork borer or suitably shortened disposable plastic micropipette tip and the gel is removed by suction or by a needle. Enzyme solutions (10  $\mu$ L) are pipetted into the wells, and closed dishes are left to incubate at appropriate temperature for several hours. Diffusion-zone diameters are proportional to the logarithm of enzyme concentrations.

A soluble glucuronoxylan in combination with the above described Congo Red complexing can be used for the same purpose. More sensitive and faster are similar plate assays with gels containing Umb-Xyl<sub>2</sub> or Umb-Xyl<sub>3</sub> (0.1–0.5 mM). Liberation of the fluorogenic 4-methylumbelliferone around the wells is observed under UV light (365 nm). Since the liberation of the aglycone can be a result of  $\beta$ -xylosidase action, enzyme samples should be tested in a parallel plate containing a specific  $\beta$ -xylosidase substrate, 4-methylumbelliferyl  $\beta$ -xyloside.

*Detection of EX in electrophoretic gels* (142). A warm 1.5% aqueous solution (10 mL) of RBB-xylan is mixed well with 3% molten agar in appropriate buffer (20 mL) and poured between two glass plates separated by 0.75 to 1.0-mm spacers and left to solidify. The glass plates can be covered by transparent plastic sheets, so the gel can be easily stored after glass removal. If not used immediately, the agar gel should be supplied with 0.01–0.02% sodium azide. Native PAGE or isoelectrofocusing gels (agarose or polyacrylamide) are washed twice for 5–10 min (depending on

their thickness) with a buffer corresponding to pH optimum of the tested EXs. They are then brought into contact with the RBB-xylan containing detection gel. The presence of EX leads to a change in the shade of the blue background, due to a diffusion of enzyme-released dyed fragments. The agar detection gel is then separated from the electrophoretic gel and, if needed, further incubated in a wet chamber. It is then dipped into the solvent ethanol–0.05 M acetate buffer (pH 5.4) 2:1 (v/v). Zones with enzyme-degraded substrate are destained as a result of the solubilization of dyed fragments. The background with unhydrolyzed substrate remains unchanged. The dyed fragments liberated from the blue detection gel diffuse into the separation gel, where they mark the position of the enzyme. Individual xylanase forms can be subsequently isolated from the separation gel, e.g., by electroelution.

The use of RBB-xylan enables visual monitoring of substrate hydrolysis, which is important for appropriate timing of contact between the substrate and enzymes. The detection of EXs by means of Congo Red (143) requires preliminary experimentation or knowledge of enzyme activity to terminate the reaction at the appropriate time.

The fastest procedure for the detection of EXs in electrophoretic gels can be achieved using Umb-Xyl<sub>2</sub> or Umb-Xyl<sub>3</sub> (130). Either fluorogenic substrate at a concentration of 0.1–0.5 mM can be incorporated into a 0.75 to 1-mm thick agar or agarose detection gel which is laid upon the rebuffered separation gel. A simpler approach is to bring the washed separation gel into contact with a solution of substrates on a flat glass plate. Fluorescence appears rapidly under UV light (~360 nm) in the regions of EXs. The fluorescence intensity can be enhanced by ammonium hydroxide vapors.

### III. $\beta$ -XYLOSIDASE (EC 3.2.1.37)

#### A. Chemical Reactions Catalyzed

$\beta$ -Xylosidase hydrolyzes xylobiose and higher linear  $\beta$ -1,4-xylo-oligoaccharides to monomer and also releases xylose from branched or substituted xylo-oligosaccharides produced by the action of EXs.  $\beta$ -Xylosidases vary in their affinity toward short and long oligosaccharides. Those which prefer xylobiose as a substrate are referred to as  $\beta$ -xylosidase, and those which prefer

longer oligosaccharides are referred to as exo- $\beta$ -xylosidases. A careful literature search suggests, however, that in spite of the existence of several glycosyl hydrolase families into which  $\beta$ -xylosidases have been assigned, and in spite of the fact that the enzymes behave as both retaining and inverting hydrolases, there is no sharp boundary between  $\beta$ -xylosidase and exo- $\beta$ -xylosidase with respect to their substrate preference. Therefore, this section considers all enzymes catalyzing successive removal of  $\beta$ -xylosyl residues from non-reducing termini.

#### B. Classification

$\beta$ -1,4-Xylan xylohydrolase EC 3.2.1.37.

#### C. Properties as Proteins

$\beta$ -Xylosidases are, with few exceptions, larger enzymes than EXs. Their molecular mass ranges between 26 and 360 kDa (144), and they are monomeric or dimeric proteins as shown by SDS-PAGE. Molecular masses exceeding 120 kDa usually correspond to dimeric/tetrameric aggregates. All thus far isolated enzyme species showed acidic pI values (3.25–6.1). The properties of these enzymes vary considerably, which complicates their classification. Moreover,  $\beta$ -xylosidase belongs to those xylanolytic enzymes which exhibit variable cellular localization. In several species of bacteria and yeasts, the enzyme is localized strictly intracellularly and is not glycosylated. In these organisms, xylo-oligosaccharides generated outside the cell by EXs must enter the cell by transport systems localized in plasma-membrane (3). In other organisms, like *Aureobasidium pullulans*,  $\beta$ -xylosidase is found outside and inside the cells. It remains to be established whether some organisms produce two different  $\beta$ -xylosidases. In laboratory cultures of mycelial fungi,  $\beta$ -xylosidase remains associated with mycelia during early stages of growth and is released into the media later either by true secretion or as a result of cell lysis.

Only a small fraction of known  $\beta$ -xylosidases have been classified on the basis of hydrophobic cluster analysis and comparison of amino acid sequences. They have been assigned to four glycosyl hydrolase families: 3, 39, 43, and 52 (58, 59). Family 3, which contains mainly  $\beta$ -glucosidases (EC 3.2.1.21), includes a nonspecific  $\beta$ -glucosidase/ $\beta$ -xylosidase from *Erwinia chrysanthemi* (145) and the best-known fungal  $\beta$ -xylosidases from *Aspergillus* and *Trichoderma* species (146, 147). A common feature of the members of this family is their retaining character.  $\beta$ -Xylosidases

of thermophilic bacteria have been assigned to family 39 (148–150). All  $\beta$ -xylosidases of this family are localized intracellularly and belong to retaining glycosyl hydrolases. Their molecular mass is between 55 and 60 kDa.

Family 43 contains 50 to 60-kDa  $\beta$ -xylosidases of several *Bacillus* spp. and from *Butyrivibrio fibrosolvens*. The latter enzyme has been shown to operate by a mechanism which results in inversion of the anomeric configuration (151). If the unequivocal relationship between family classification and molecular mechanism is valid, other members of family 43 should also operate with retention of the anomeric configuration.

The amino acid sequences of two *Bacillus stearothermophilus* (70–80 kDa of unprocessed precursor)  $\beta$ -xylosidases (152, 153) are so unique that they were grouped into a special family, assigned as family 52. The stereochemistry of hydrolysis by these enzymes has not been established yet. Three-dimensional structures are not available for any members of these four families. Some characteristic properties of individual  $\beta$ -xylosidase families are listed in Table 3.

#### D. Properties as Enzymes

There is limited knowledge about structure-function relationships in the glycosyl hydrolase families containing  $\beta$ -xylosidases. All  $\beta$ -xylosidases thus far described hydrolyze not only xylobiose and xylooligosaccharides but also aryl  $\beta$ -D-xylopyranosides. Consequently, 4-nitrophenyl  $\beta$ -D-xylopyranoside has become the most common substrate for  $\beta$ -xylosidase assay. There are, however, examples of aryl  $\beta$ -xylosidases which do not attack xylo-oligosaccharides. Therefore, it is always important to test the enzymes directly on xylobiose and xylo-oligosaccharides. Several  $\beta$ -xylosidases are reported also to attack polymeric xylan in an exofashion. Because of the limited

information, it is not possible to correlate the catalytic properties of enzymes with their glycosyl hydrolase families. Therefore, only the properties of best known  $\beta$ -xylosidases will be described.

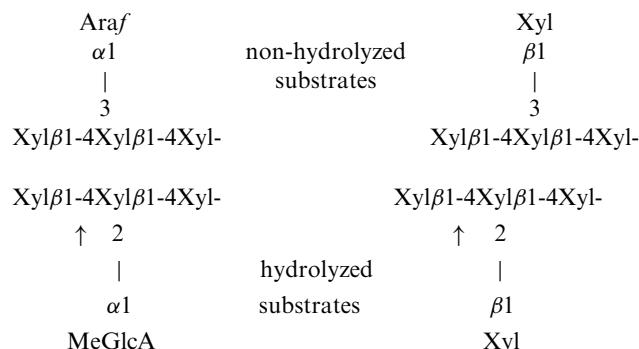

One of the best-characterized  $\beta$ -xylosidases is an intracellular enzyme from *Bacillus pumilus* (154, 155). It shows absolute specificity for  $\beta$ -xylopyranosyl residues but does not catalyze glycosyl transfer reactions. This suggests that the enzyme belongs to family 43 of glycosyl hydrolases (Table 3). The best-studied fungal  $\beta$ -xylosidases are extracellular enzymes produced by *Aspergillus* and *Trichoderma* spp., i.e., the enzymes from family 3. Their retaining character is revealed in glycosyl transfer reactions in high concentrations of xylo-oligosaccharides and 4NPh- $\beta$ -Xyl (156–159). These enzymes do not show high specificity for the glycan moiety.  $\beta$ -Xylosidases from several *Trichoderma* strains exhibit  $\alpha$ -L-arabinofuranosidase activity (160–162). This has been confirmed by cloning the *T. reesei*  $\beta$ -xylosidase gene in yeast (147). The  $\alpha$ -L-arabinofuranosidase from *T. reesei* hydrolyzes only  $\alpha$ -L-arabinofuranosides and is not able to liberate L-arabinose from arabinoxylan or arabinose-substituted xylo-oligosaccharides. Aryl  $\beta$ -xylosidase activity of *Trichoderma* strains is inhibited by D-xylose. Fungal  $\beta$ -xylosidases were shown to have a specific requirement for structural arrangement of branched oligosaccharides. The enzyme from *A. awamori* was tested on different arabinose-substituted xylooligosaccharides. The enzyme was able to remove terminal xylopyranosyl residues from the nonreducing end of branched oligosaccharides only when two contiguous unsubstituted xylopyranosyl residues were linked to single- or double-substituted xylopyranosyl residues (163). This is similar to the behavior of  $\beta$ -xylosidase from *T. reesei* (159, 164). The enzyme does not liberate  $\beta$ -1,4-xylopyranosyl residues linked to an  $\alpha$ -1,3- or  $\beta$ -1,3-substituted xylopyranosyl residue

**Table 3** Families of Glycosyl Hydrolases Containing  $\beta$ -Xylosidases

Enzyme family	Common microbial producers	Molecular mass range of listed enzymes	Stereochemistry of hydrolysis	Other enzymes in the family
3	<i>Erwinia, Aspergillus, Trichoderma</i>	60–122 kDa	retaining	$\beta$ -glucosidase
39	Thermophilic bacteria	55–60	retaining	$\alpha$ -L-iduronidase
43	<i>Butyrivibrio, Bacillus</i>	50–60	inverting	$\alpha$ -L-arabinanase EX
52	<i>Bacillus stearothermophilus</i>	70–80 (precursor)	unknown	none

(compounds of the type Xyl-4[Ara-3]Xyl- or Xyl-4[Xyl-3]Xyl-). In such compounds the substituent is apparently so close to the site of the enzymic attack (i.e., glycosidic oxygen) that the formation of the enzyme-substrate complex is sterically impaired. The  $\beta$ -1,4-glycosidic linkage becomes susceptible to the enzyme attack only if the substituent is linked to a more distant C-2 position (Scheme 3).

Scheme 3

### E. Determination of $\beta$ -Xylosidase Activity

The activity of  $\beta$ -xylosidases, which hydrolyze xylobiose, xylo-oligosaccharides, eventually linear portions of xylan, can be determined reductometrically using xylobiose and xylotriose, which are poor substrates for EXs. The sensitivity of assays can be increased by eliminating the background of oligosaccharides by their reduction to sugar alcohols with  $\text{NaBH}_4$ . The reductometric procedures described in the section devoted to EXs can be adapted for the use of xylobitol or xylotriitol as substrates. Xylobiase activity can also be determined using xylobiose as a substrate in an enzyme-coupled assay which employs  $\text{NAD}^+$ -dependent glucose dehydrogenase. The dehydrogenase is not specific for glucose and catalyzes conversion of generated xylose to xylonolactone (165, 166). The formation of NADH is followed at 340 nm to estimate  $\beta$ -xylosidase activity. Two side reactions, the oxidation of xylobiose to lactone by the dehydrogenase and hydrolysis of the lactone by  $\beta$ -xylosidase, have to be taken into consideration.

However, the most common assay of  $\beta$ -xylosidase employs 4-nitrophenyl- $\beta$ -D-xylopyranoside as a substrate. There are a great variety of conditions under which the assay can be done involving the substrate concentration, pH and type of the assay buffer, and various alkaline reagents to terminate the reaction and to shift the absorption maximum of liberated 4-nitrophenol to a visible

region of the spectrum. In a similar assay, phenyl- $\beta$ -D-xylopyranoside is used as a substrate (167). Liberated phenol is determined using the phenol reagent from the well-known Lowry procedure for protein determination.

#### 1. $\beta$ -Xylosidase Assay Using 4-Nitrophenyl- $\beta$ -D-Xylopyranoside/ $\text{Na}_2\text{CO}_3$

##### a. Reagents

1. 4-Nitrophenyl- $\beta$ -D-xylopyranoside, 4 mM solution in 0.05 M acetate buffer, pH 4.5 (or other buffer).
2. 2 M solution of  $\text{Na}_2\text{CO}_3$ .
3. 4-Nitrophenol, 2 mM stock solution in the acetate buffer; 0.2 mM calibration solution in the acetate buffer.

b. *Procedure.* Preheated substrate solution (0.9 mL, e.g., at 50°C) is mixed with 0.1 mL appropriately diluted enzyme solution and incubated for suitable time at 50°C. The reaction is terminated by addition of 1 mL of 2 M  $\text{Na}_2\text{CO}_3$ . The absorbance is measured at 410 nm against the substrate blank. The values have to be corrected for enzyme blanks if they show absorbance at 410 nm. Calibration with 4-nitrophenol is done in the range of 0.02–0.2  $\mu\text{mol}$  per assay mixture. One unit of  $\beta$ -xylosidase activity is defined as the amount of enzyme liberating 1  $\mu\text{mol}$  of 4-nitrophenol in 1 min. (Note: The assay can be miniaturized to the scale of a microplate reader.)

#### 2. $\beta$ -Xylosidase Assay Using 4-Nitrophenyl- $\beta$ -D-Xylopyranoside/ $\text{Na}_2\text{B}_4\text{O}_7$

##### a. Reagents

1. 4-Nitrophenyl- $\beta$ -D-xylopyranoside, 10 mM solution in 0.05 M acetate buffer, pH 5.0 (or other buffer).
2. Saturated solution of  $\text{Na}_2\text{B}_4\text{O}_7$ .
3. 4-Nitrophenol, 1 mM stock solution in the acetate buffer; 0.1 mM calibration solution in the acetate buffer.

b. *Procedure.* Preincubated substrate solution (0.1 mL 50°C) is mixed with 0.1 mL tested enzyme sample (50°C) in an Eppendorf test tube and incubated for appropriate time at 50°C. After addition of 1.0 mL saturated solution of  $\text{Na}_2\text{B}_4\text{O}_7$ , the absorbance is measured at 410 nm against a substrate blank. Calibration is done with 4-nitrophenol in the range of 0.01–0.1  $\mu\text{mol}$ . One unit of  $\beta$ -xylosidase activity is defined as the amount of enzyme liberating 1  $\mu\text{mol}$  of 4-nitro-

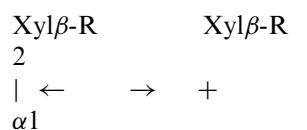

phenol in 1 min. (Note: This assay is carried out in microcentrifuge test tubes and is suitable for determination of cell-bound  $\beta$ -xylosidase activity. The cells used as the enzyme source must be separated by centrifugation before measurement.)

#### F. Assays for Screening Purposes

Detection of  $\beta$ -xylosidase activity in solid growth media or in electrophoretic gels usually involves incorporation of chromogenic and fluorogenic substrates, 4-nitrophenyl- $\beta$ -D-xylopyranoside (1–5 mM) or 4-methylumbelliferyl- $\beta$ -D-xylopyranoside (0.1–0.5 mM). Activity is revealed by flooding the growth media or gels with alkaline solutions (1 M Na<sub>2</sub>CO<sub>3</sub>, alkaline buffers) or exposing them to ammonium hydroxide vapors. Replica plating is required before alkalification when working in acidic pH regions. The liberation of 4-methylumbellifrone is revealed under UV light (360 nm). Alkalification of the solid medium or gel, e.g., exposure to ammonium hydroxide vapors, increases the fluorescence. As mentioned with fluorogenic substrates of EXs, fluorogenic glycosides for screening purposes give better results when applied as overlay at the later stages of colony development than when incorporated into growth media before inoculation.

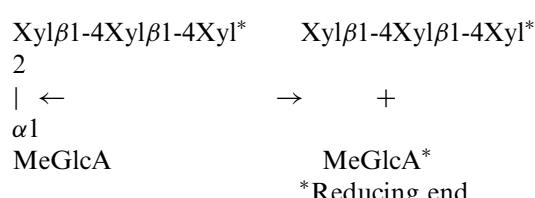

### IV. $\alpha$ -GLUCURONIDASE, 4-O-METHYL- $\alpha$ -GLUCURONIDASE (EC 3.2.1.139)

#### A. Chemical Reactions Catalyzed

$-\text{R} = 1\text{-4Xyl, } 1\text{-4Xyl}\beta 1\text{-4Xyl, } 1\text{-4Xyl}_n$

One of the best substrates

#### B. Classification

$\alpha$ -D-Glucuronidase (EC 3.2.1.139).

#### C. Occurrence of $\alpha$ -Glucuronidase

$\alpha$ -Glucuronidase activity has been detected in cellulolytic and xylanolytic systems of a variety of fungi (168–176), actinomycetes, and bacteria (177–184). Two reports mention  $\alpha$ -glucuronidase in snail digestive juice (184, 185). There is no report on the occurrence of the enzyme in plants. In most microorganisms  $\alpha$ -glucuronidase was found to be secreted into culture medium. However, there are examples in which the enzymes have been found confined to the cells (172, 180, 181).

#### D. Properties as Proteins

$\alpha$ -Glucuronidase has been purified from a relatively small number of microorganisms. All eukaryotic  $\alpha$ -glucuronidases, with the exception of the enzyme from *Agaricus bisporus* (196), are monomeric enzymes with molecular masses between 91 and 150 kDa. Their isoelectric points are acidic, between values 4.6 and 5.3 (146). The  $\alpha$ -glucuronidase purified from the snail *Helix pomatia* (185) also shares these properties. Bacterial  $\alpha$ -glucuronidases are usually found as dimers with subunits of a molecular mass  $\sim$  70 kDa. PI values of bacterial enzymes are similar to those of fungal enzymes.  $\alpha$ -Glucuronidase from the thermophilic bacterium *Thermotoga maritima* shows a variable oligomeric structure depending on the salt concentration (183).

So far only five amino acid sequences of  $\alpha$ -glucuronidases are known, all based on gene sequencing (146, 176). The sequences show a high degree of similarity (40–60% identity) and have been assigned to a separate glycosyl hydrolase family 67, which does not contain any other hydrolases. A three-dimensional structure of  $\alpha$ -glucuronidase has not been reported; however, the enzyme from *Bacillus stearophilus* has been successfully crystallized and subjected to x-ray analysis (186).

#### E. Properties as Enzymes

$\alpha$ -Glucuronidases seem to belong to those accessory xylanolytic enzymes that do not operate on polymeric substrates. With exception of  $\alpha$ -glucuronidase from *Thermoascus aurantiacus* (170),  $\alpha$ -glucuronidases failed to liberate 4-O-methyl-D-glucuronic (MeGlcA) acid or

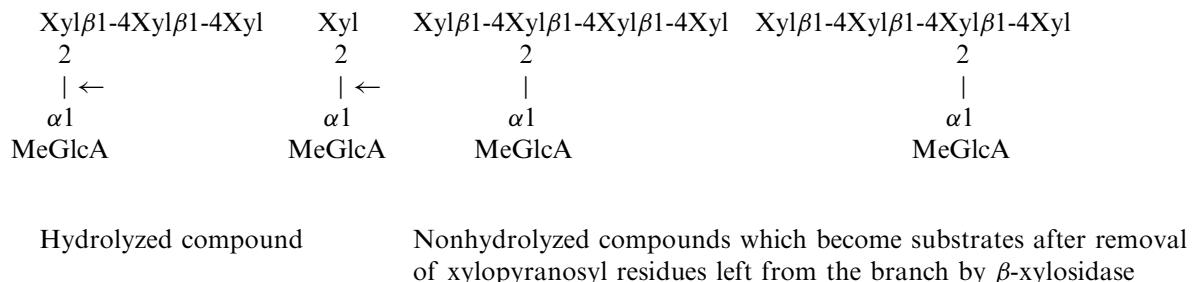

D-glucuronic acid at an appreciable rate from polymeric substrates. In a few cases, an extremely low rate was found. However, it should be stressed that even a slight contamination of  $\alpha$ -glucuronidase by EX and  $\beta$ -xylosidase would generate polysaccharide fragments that would serve as  $\alpha$ -glucuronidase substrates.  $\alpha$ -Glucuronidases, regardless of their eukaryotic or prokaryotic origin, are very selective toward the structure of aldouronic acids. They are capable of removing MeGlcA or GlcA from aldouronic acids in which MeGlcA or GlcA residues are linked to a single xylopyranosyl residue or to a nonreducing terminal xylopyranosyl residue of xylo-oligosaccharides. Such fragments can be generated from glucuronoxyan by the action of EXs of family 10 or by the action of a combination of EXs of family 11 and  $\beta$ -xylosidase (Scheme 4) (88, 187).

5.0 for fungal enzymes.  $K_m$  values for aldouronic acids as substrates were reported in the range of 0.14–0.95 mM.

The stereochemistry of hydrolysis of glycosidic linkage by  $\alpha$ -glucuronidase was recently investigated with purified *Aspergillus tubingensis* enzyme, which belongs to family 67 of glycosyl hydrolases. By NMR spectroscopy it has been established that the enzyme uses a single displacement reaction mechanism, leading to inversion of the anomeric configuration (189). Based on this finding, inverting character can be expected with other  $\alpha$ -glucuronidases.

#### F. Determination of $\alpha$ -Glucuronidase Activity

As mentioned above, the activity of  $\alpha$ -glucuronidase cannot be determined directly on glucuronoxyan or

Scheme 4

An interesting question related to the substrate specificity of  $\alpha$ -glucuronidase is whether the enzyme is specific for GlcA or MeGlcA. The enzyme from *Aspergillus niger* hydrolyzed GlcA-Xyl<sub>3</sub> about two times faster than MeGlcXyl<sub>3</sub> (172). This example suggests that the 4-O-methyl group in the acid is not decisive for the action of the enzymes.

A surprising property of microbial  $\alpha$ -glucuronidases is their inability to hydrolyze 4-nitrophenyl- $\alpha$ -D-glucuronide, a compound that could otherwise serve as a convenient chromogenic substrate. The only  $\alpha$ -glucuronidase capable of hydrolyzing this compound was the snail enzyme (185). Microbial  $\alpha$ -glucuronidases require uronic acid to be linked to at least one xylopyranosyl residue, which can be in the form of an aryl glycoside as in 4-nitrophenyl-2-O-(methyl-4-O-methyl- $\alpha$ -D-glucuronosyl)- $\beta$ -D-xylopyranoside (188).

Optimal pH values for bacterial  $\alpha$ -glucuronidases are in the range of 5.4–6.5 and in the range of 3.5–

a related polymeric substrate. Glucuronoxyan can be used for the  $\alpha$ -glucuronidase assay only in the presence of xylan-depolymerizing enzymes which generate aldouronic acids of the required structures (190). The most common substrate for  $\alpha$ -glucuronidase assays are linear aldouronic acids obtained by enzymic or acid hydrolysis of glucuronoxyan. From such aldouronic acids, liberation of MeGlcA is usually followed by determination of the reducing power of the free uronic acid by a modification of the Somogyi copper reagent and the Nelson phosphomolybdenic acid reagent according to Milner and Avigad (191). The method is quite specific for uronic acids and suffers only slightly from the presence of neutral reducing sugars. The assay could be affected by some salts (citrate, phosphate), however. Alternative methods include HPLC determination of free MeGlcA (173, 174) or the equivalent amount of xylo-oligosaccharides (169), or GLC of trimethylsilyl

oxim derivatives of uronic acids (178, 179, 182, 184). Unfortunately, there is no direct  $\alpha$ -glucuronidase assay available that would utilize a chromogenic substrate. As we have already mentioned, 4-nitrophenyl- $\alpha$ -glucuronide does not serve as substrate of microbial  $\alpha$ -glucuronidases. Recently, a new  $\beta$ -xylosidase-coupled  $\alpha$ -glucuronidase assay has been introduced that uses 4-nitrophenyl-2-O-(4-O-methyl- $\alpha$ -D-glucuronosyl)- $\beta$ -D-xylopyranoside (NPh-Xyl-MeGlcA) (188). Liberation of MeGlcA from the compound yields an equimolar amount of 4-nitrophenyl- $\beta$ -xylopyranoside. In the presence of excess of  $\beta$ -xylosidase to hydrolyze the xyloside, the amount of liberated 4-nitrophenol becomes a measure of  $\alpha$ -glucuronidase activity (Scheme 5).

of the developed reaction mixture with water. Some authors stop the reaction by boiling and clarify the mixture by centrifugation before addition of the copper reagent (146.).

## 2. $\beta$ -Xylosidase-Coupled Assay of $\alpha$ -Glucuronidase (188)

### a. Reagents

1. 4-Nitrophenyl-2-O-(4-O-methyl- $\alpha$ -D-glucuronosyl)- $\beta$ -D-xylopyranoside (NPh-Xyl-MeGlcA), prepared by alkaline deesterification of its methyl ester (191, 192), 4 mM solution in 0.05 M acetate buffer, pH 5.0.

**Scheme 5**

### 1. Determination of $\alpha$ -Glucuronidase Activity Using the Milner-Avigad Copper Reagent

#### a. Reagents

1. A mixture of aldotriuronic and aldotetrauronic acid (ratio  $\sim$  8 : 2) (Megazyme, Ireland), a solution 2 mg/mL in 0.05 M acetate buffer pH 5.0.
2. Copper reagent prepared according to Milner and Avigad (191).
3. Arsenomolybdate reagent of Nelson reagent (110).
4. D-Glucuronic acid, 1 mM calibration solution in 0.05 M acetate buffer (calibration in the range 0.02–0.2  $\mu$ mol).

*b. Procedure.* Enzyme (0.04 mL) is added to a preheated solution of aldouronic acids (0.16 mL, 40°C) and incubated at 40°C for an appropriate time. The reaction is stopped by adding 0.6 mL of the copper reagent. The mixture is heated in a boiling water bath for 10 min and then cooled in an ice-water bath. Subsequently 0.4 mL of the Nelson reagent is then added and after mixing the absorbance at 600 nm is measured against the substrate blank. One unit of  $\alpha$ -glucuronidase is defined as the amount of enzyme liberating 1  $\mu$ mol of glucuronic or 4-O-methylglucuronic acid per 1 min under the selected assay conditions. (Note: The original procedure (191) involves dilution

2. Recombinant  $\beta$ -xylosidase of *Aspergillus niger* produced in *Saccharomyces cerevisiae* (191), a solution 2 U/mL of 0.05 M acetate buffer, pH 5.0 (one unit of  $\beta$ -xylosidase is defined as the amount of enzyme liberating 1  $\mu$ mol of 4-nitrophenol from 4-nitrophenyl- $\beta$ -D-xylopyranoside).

3. Saturated solution of  $\text{Na}_2\text{B}_4\text{O}_7$ .
4. 4-Nitrophenol, 1 mM solution in the acetate buffer, calibration in the range 0.01–0.1  $\mu$ mol.

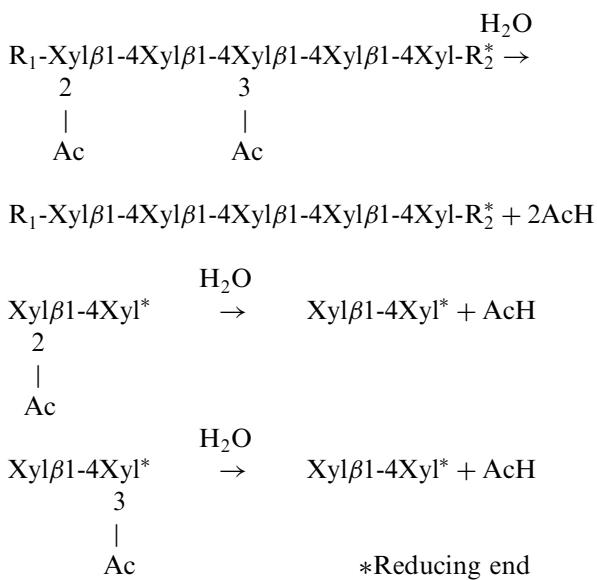

*b. Procedure.* 0.1 mL of 4 mM solution of NPh-Xyl-MeGlcA is mixed with 0.1 mL of the  $\beta$ -xylosidase solution (200 mU per reaction mixture), preheated to 37°C, and the reaction is started with addition of 5–20  $\mu$ L of the tested enzyme solution. After 10 min or longer incubation at 37°C 1 mL saturated solution of  $\text{Na}_2\text{B}_4\text{O}_7$  is added and the absorbance is measured at 410 nm. An alternative procedure is to add 0.1 mL enzyme solution to 0.05 mL double-concentrated substrate and  $\beta$ -xylosidase solution in 0.1 M acetate buffer. One unit of  $\alpha$ -glucuronidase is the amount of enzyme required to release 1  $\mu$ mol of 4-nitrophenol. (Note: The assay was applied to three different  $\alpha$ -glucuronidases. Their  $K_m$  values for NPh-Xyl-MeGlcA were in the range 0.21–0.58 mM, which is in the range of  $K_m$  values of  $\alpha$ -glucuronidases for aldouronic acids. The new substrate is still not commercially available.)

## G. Assays for Screening Purposes

No direct in situ detection of  $\alpha$ -glucuronidases has been reported.

## V. ACETYLXYLAN ESTERASE (3.1.1.72)

### A. Chemical Reactions Catalyzed

Acetylxylan esterases (AcXEs) are components of microbial xylanolytic and cellulolytic systems which are able to remove acetyl groups esterifying D-xylopyranosyl residues of xylan main chain at positions 2 or 3 (193–195). AcXEs also deacetylate partially acetylated xylo-oligosaccharides. The enzyme action on polysaccharide substrates creates new sites on the xylan main chain, suitable for productive binding with depolymerizing EXs. This effect is reflected in a clear cooperativity of the two enzymes during acetylxylan degradation, a typical example of enzyme synergy (54, 196, 197). Acetylxylan degradation with EXs proceeds faster and to a higher degree in the presence of AcXEs (54). Deacetylation of xylo-oligosaccharides makes the oligosaccharides fully susceptible to the action of  $\beta$ -xylosidase.

### B. AcXE Substrates

The substrate similar to the native O-acetyl-4-O-methyl-D-glucurono-D-xylan present in plant cell walls can be prepared by dimethylsulfoxide extraction

of hardwood holocellulose, e.g., birchwood or beechwood holocellulose (198, 199). An analogous polysaccharide of a lower polymerization degree (average DP  $\sim 25$ ) and acetyl content of 13% can be obtained as a nondialyzable fraction of a water-soluble, noncellulosic polymer by steaming birch at 200°C for 10 min (200). An aqueous thermochemical treatment of hardwood leads to a similar material with a higher acetyl content (201). Since none of the above-mentioned AcXE substrates are commercially available and their isolation is difficult or dependent on availability of special equipments, some authors have replaced natural acetylxyan by a chemically acetylated polysaccharide. A widely used method of chemical acetylation of xylan was published by Johnson et al. (202). There are also examples of the use of fully chemically acetylated hardwood xylan as a substrate for AcXE (203, 204). As will be shown below, a majority of AcXEs can be assayed on a variety of aryl acetates which serve as substrates of nonhemicellulolytic acetyl esterases and lipases.

### C. Classification

Acetylxyan esterase (EC 3.1.1.72).

### D. Properties as Proteins

AcXEs show the greatest diversity in molecular organization among all components of microbial xylanolytic systems. On the basis of amino acid sequence similarity AcXEs have been assigned to seven families of 13 so far recognized families of carbohydrate esterases (73, 205) (Table 4).

The best-known fungal AcXEs from *Aspergillus*, *Penicillium*, *Schizophyllum* and *Trichoderma* spp. can be found in carbohydrate esterase families 1 and 5 together with bacterial acetylxyan esterases. The majority of these represents one catalytic domain of bifunctional acetylxyan-degrading enzymes. Diverse AcXEs of the anaerobic fungus *Neocallimastix patriciarum* (214) can be found in families 2, 3, and 6. AcXEs produced by *Streptomyces* are grouped in family 4 together with similar AcXE modules of bacterial bifunctional enzymes. Their sequences are similar to those of nodulating proteins (NodB) from *Rhizobium* spp. and with some yeast enzymes, identified as chito-oligosaccharide and chitin deacetylases (205).

Fungal AcXEs, and some bacterial enzymes, are usually monomeric enzymes, while some AcXEs from thermophilic anaerobic bacteria occur as oligomers of smaller subunits (224). As already mentioned, numer-

**Table 4** Families of Carbohydrate Esterases Containing Acetylxyilan Esterases

<sup>a</sup>Assignment based on a sequence of fifty NH<sub>2</sub>-terminal amino acids (226).

<sup>b</sup>This may be the only family, members of which do not attack synthetic low-molecular-mass substrates, such as aryl acetates (226).

Source: <http://afmb.cnrs-mrs.fr/~pedro/CAZY/db.html>.

ous enzymes have modular architecture. Some of AcXEs, such as those from *Pseudomonas fluorescens* (209) or *Trichoderma reesei* (221), contain cellulose-binding domains (CBDs) separated from the catalytic domain by linker regions. Others, like AcXE from *Streptomyces lividans* (217), contain a xylan-binding domain (77). AcXE of *Cellulomonas fimi* is a part of a bifunctional enzyme which contains both CBD and XBD (82). The two-catalytic module architecture, represented by various combinations of EXs linked to AcXEs, is very common particularly among acetylxyilan-degrading bifunctional enzymes of ruminal anaerobic bacteria (212). AcXE domains of such bifunctional enzymes can be found in carbohydrate esterase families 1, 2, 3, and 4 (Table 4). With the bifunctional EX-AcXE enzyme from *Clostridium thermocellum* (83) it has been demonstrated that the two catalytic domains act synergistically in the degradation of acetylxyilan. This observation again suggests that the production of an enzyme having both debranching and depolymerizing activity can be a great advantage for a microorganism competing for a carbon source with microorganisms using separate enzyme components.

AcXEs existing as single-domain enzymes have a molecular mass in the range of 23–48 kDa and acidic or neutral pI values. There does not seem to be a special relationship between these two parameters and their assignment into carbohydrate esterase families (Table 4).

Three-dimensional structures are known only for AcXEs belonging to family 5. Crystallization has been reported for AcXEII from *P. purpurogenum* (227) and AcXE from *T. reesei* (228). The protein from *P. purpurogenum* shows an  $\alpha/\beta$  hydrolase fold, similar to that of cutinase (227). Cysteine residues form five S-S bridges which makes the structure very rigid and tightly packed. The substrate binding site appears to be small and able to accommodate only an acetyl group, thus giving a relatively high substrate specificity to the enzyme.

## E. Properties as Enzymes

### 1. Substrate Specificity

Substrate specificity of AcXEs is one of the least-clarified aspects of this xylanolytic component. There is very limited knowledge on the structure-function rela-

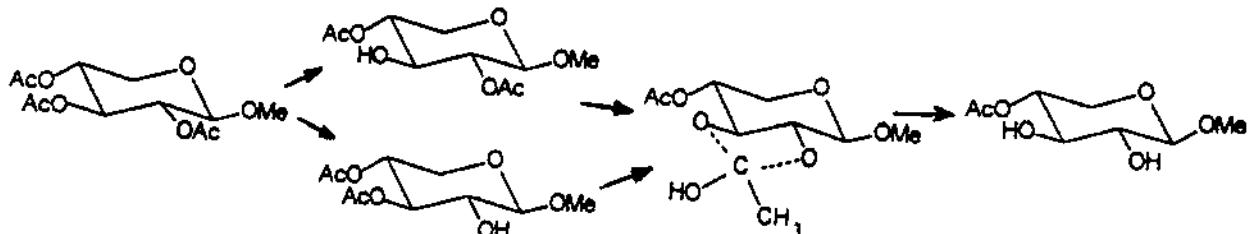

tionship of these enzymes, particularly considering that they have been assigned to seven different families (**Table 4**). The situation is complicated because there are esterases and lipases which cannot be strictly considered as components of xylanolytic systems, but which could participate in the later stages of acetylxyylan degradation, by deacetylation of xylooligosaccharides. It is known that nonhemicellulolytic esterases and lipases operate quite efficiently on low-molecular-mass acetylated carbohydrates (226, 229). As a consequence, we shall limit the discussion here to the catalytic properties of enzymes that deacetylate polymeric substrates as such or coinduced with other plant cell walls hydrolyzing enzymes.

Several lines of evidence suggest that there are two major types of acylesterases that participate in acetylxyylan degradation (197). They differ in their affinity toward polymeric and oligomeric substrates. The enzymes that perform well on polymeric substrates are capable of causing precipitation of xylan from solution due to deacetylation (207, 226). The removal of acetyl groups results in the association of xylan molecules into insoluble aggregates. This property is very typical of AcXEs of family 4 (**Table 4**), which appear to be most specific for acetyl xylan and do not hydrolyze low-molecular-mass substrates such as 4-nitrophenyl- or 4-methylumbelliferyl acetate (226). The enzymes of other families share properties compatible with general acylesterases and acylesterases (226). They are active on a variety of synthetic aryl acetates and acylates (226). This second group of enzymes do not perform well on polymeric acetylxyylan but are more active on acetylated oligosaccharides generated from acetylxyylan by EXs (197, 226, 230). Thus EXs would synergistically facilitate the release of acetic acid in concert with this type of acylesterases. Additional studies are also required to define the specificity of AcXEs with respect to the type of polysaccharide that they deacetylate. There are indications

that at least some AcXEs are quite specific for acetylxyylan (197, 230).

## 2. Specificity for the Position of the Acetyl Group in the Main Chain

Xylose residues in xylan are acetylated at positions 2 and/or 3, and the acetyl groups are more or less evenly distributed between these positions. This raises questions of whether the AcXEs are capable of releasing acetyl groups bound only at one position or at both positions, and to what extent is deacetylation influenced by the migration of acetyl groups between positions 2 and 3. Studies of three AcXEs on acetylated methyl glycosides showed the regioselective removal of acetyl group from positions 2 and 3 (229, 231, 232). AcXE from *S. commune* AcXE exhibited a preference for position 3 (229), while the *T. reesei* AcXE deacetylated the model compounds sequentially, first at position 2 and then rapidly at position 3 (231). *S. lividans* AcXE worked almost simultaneously on positions 2 and 3, essentially catalyzing a double deacetylation of compounds at both positions (232). Two methyl xylopyranoside diacetates, which had a free hydroxyl group at position 2 or 3, i.e., the derivatives that most closely mimicked monoacetylated xylopyranosyl residues in acetylxyylan, were deacetylated by 1 or 2 orders of magnitude faster than 2,3,4-tri-O-acetyl- or 2,3-di-O-acetyl- $\beta$ -D-xylopyranoside. These observations explained the double deacetylation. The second acetyl group was removed immediately after the first one. An implication of these results is that the deacetylation mechanism of positions 2 and 3, when the neighboring positions 3 and 2 are nonacetylated, might involve an enzyme-catalyzed formation of a five-member transition state intermediate (**Scheme 6**). Such intermediates are believed to be involved in the spontaneous migration of acetyl group along the glycopyranoid ring in aqueous media. If this hypothetical

**Scheme 6**

mechanism is experimentally confirmed, the question of regiospecificity of AcXE at positions 2 and 3 will become irrelevant.

### 3. Reaction Mechanism

The inactivation of AcXEs with phenyl methyl sulfonyl fluoride (221, 227) and the occurrence of the serine sequence GXSXG in active site of AcXEs (195) suggest that AcXEs utilize a catalytic mechanism similar to lipases and serine proteases. This mechanism involves two major elements, a nucleophilic serine and a general acid-base catalyst, usually a histidine. It remains to be established whether all types of AcXEs contain the serine motif (GXSXG) in their catalytic site.

## G. Determination of AcXE Activity

The most specific AcXE assay employs as substrates hardwood acetylxylyans extracted either by DMSO or obtained by steaming wood. The naturally occurring acetylxylyan can be replaced by chemically acetylated xylyan. In the presence of EXs, both types of polysaccharides are also suitable for enzymes that prefer acetylated xylo-oligosaccharides as substrates. The amount of released acetic acid can be determined by HPLC chromatography, or enzymically using the Boeringer Test Combination No. 148,261. Practically all HPLC procedures employ for analysis of acetic acid a Bio-Rad (Richmond, CA) Aminex HPX-87H column eluted with 0.01 N H<sub>2</sub>SO<sub>4</sub> (193, 202), connected to a refractometric detector. Glycerol may be recommended as internal standard. The conditions of AcXE assay on acetylxylyan vary considerably among different laboratories. Typical conditions include a substrate concentration in the range of 0.2–10%, pH in the range of 5.0–7.0, and temperature in the range of 30–75°C.

Since most AcXEs exhibit general acetylesterase activity [the exception is family 4 (226)], their activity also can be determined using chromogenic or fluorogenic acetylesterase substrates such as 4-nitrophenyl acetate,  $\alpha$ - or  $\beta$ -naphthyl acetate, and 4-methylumbelliferyl acetate. Examples of selected AcXE assays are given below.

### 1. AcXE Assay on Acetylxylyan (202, 233)

#### a. Reagents

1. Acetylxylyan obtained from hardwood by DMSO extraction or steaming, or chemically acetylated xylyan, 10% solution or suspension in 0.4 M potassium phosphate buffer, pH 6.0 or 6.5.

2. 1 N H<sub>2</sub>SO<sub>4</sub>.
3. Acetic acid, 0.–1.0% (w/v).
4. Glycerol, 1% (w/v).

b. *Procedure.* One volume of acetylxylyan solution or suspension is mixed with one volume of enzyme solution and incubated at 50°C. At time intervals, 0.2-mL aliquots are taken, mixed with 10  $\mu$ L of 1 N H<sub>2</sub>SO<sub>4</sub> to stop the reaction, clarified by a short centrifugation, and supernatants analyzed for acetic acid by HPLC. Standards of acetic acid are analyzed under the same conditions. Glycerol can be used as an internal standard at 0.1% or 0.2% concentration. One unit of AcXE is defined as the amount of enzyme liberating 1  $\mu$ mol of acetic acid per minute. (*Note:* Termination of the reaction is done by heating of the sample at 100°C in case the acetic acid is determined enzymically (200).)

### 2. Acetylesterase Assay on 4-Nitrophenyl Acetate (233)

#### a. Reagents

1. 4-Nitrophenyl acetate, saturated solution in 0.2 M potassium phosphate buffer, pH 6.5 (freshly prepared solution).
2. 4-Nitrophenol, 1 mM standard solution in 0.2 M potassium phosphate buffer, pH 6.5.

b. *Procedure.* A volume of 10–50  $\mu$ L appropriately diluted enzyme solution is mixed with 1 mL clarified saturated solution of 4-nitrophenyl acetate in a 1 cm light-path microcuvette and incubated at 22°C. Absorbance at 410 nm is measured at time intervals against a substrate blank. Alternatively, the absorbance can be followed continuously. The amount of substrate hydrolyzed is calculated from a calibration curve prepared using 4-nitrophenol in the 0.05–0.3  $\mu$ mol/mL range in 0.2 M phosphate buffer. The reaction cannot be terminated chemically because of the labile nature of the substrate. One unit of acetylesterase activity is defined as the amount of enzyme liberating 1  $\mu$ mol of 4-nitrophenol in 1 min.

### 3. Acetylesterase Assay on 4-Nitrophenyl Acetate (202)

#### a. Reagents

1. 4-Nitrophenyl acetate, 50 mM solution in DMSO (stable at 4°C), 2 mM solution in water prepared freshly by diluting 1 volume of the DMSO solution with 24 volumes of water.

2. 0.1 M potassium phosphate buffer, pH 6.5.

3. 4-Nitrophenol calibration solution in 0.05 M phosphate buffer.

b. *Procedure.* Enzyme present in 1.5 mL of 0.1 M phosphate buffer is mixed with 1.5 mL of 2 mM solution of 4-nitrophenyl acetate and incubated at 25°C. The increase in absorbance at 410 nm is measured against a substrate blank. Enzyme activity is calculated from the slopes of absorbance versus time and calibration values of 4-nitrophenol obtained under the same conditions. One unit of acylesterase activity is defined as above.

#### 4. Acylesterase Assay on $\alpha$ -Naphthyl Acetate (234)

##### a. Reagents

1.  $\alpha$ -Naphthyl acetate, 1 mM solution in 0.05 M sodium citrate buffer, pH 5.3.

2. Fast Corinth V Salt (Sigma F-6389), 0.1% solution in 1 M acetate buffer, pH 4.3, containing 10% Tween.

3.  $\alpha$ -Naphthol, calibration solution in the citrate buffer.

b. *Procedure.* Enzyme solution (0.2 mL) is incubated with 1.8 mL  $\alpha$ -naphthyl acetate solution at 50°C for 10 min, after which 1 mL dye solution is added. The absorbance at 535 nm is read exactly 10 min after addition of the dye. The calibration curve is constructed under the same conditions.

#### E. Fluorimetric Acylesterase Assay on 4-Methylumbelliferyl Acetate (235)

a. *Reagents.* 4-Methylumbelliferyl acetate, 10 mM solution in methanol. 0.5 M potassium phosphate buffer, pH 6.5.

b. *Procedure.* 4-Methylumbelliferyl acetate solution (10  $\mu$ L) is mixed with 10  $\mu$ L phosphate buffer and made up to 100  $\mu$ L with the enzyme sample and water. After an appropriate time of incubation at 40°C, the mixture is diluted with 2.9 mL distilled water. The fluorescence is measured at an excitation wavelength of 330 nm and an emission wavelength at 445 nm using 4-methylumbellifrone as the calibration standard. One unit of esterase is defined as 1  $\mu$ mol of the product formed per minute. (*Note:* A much less sensitive acylesterase assay using 4-methylumbelliferyl acetate is a photometric assay which exploits the fact that 4-methylumbellifrone shows considerable absorbance at 354 nm (not an absorption maximum) while its acetate does not absorb at this wavelength (224).)

## H. Assays for Screening and Detection Purposes

All substrates used for AcXE assays can also be employed for detection of the enzyme in gels. Detection of AcXE using polymeric acetylxyan is based on the precipitation of the polysaccharide due to deacetylation (207). This approach is applicable only in those cases when the AcXEs located in the gel are free of EXs, which would prevent the precipitation by hydrolyzing the deacetylated polymer. Such a situation occurs after separation of EXs from AcXEs by electrophoretic methods. This means that precipitation of acetylxyan can be used for screening purposes only in the case of naturally occurring and recombinant strains that do not produce EXs.

For initial screens of microorganisms and transformants producing AcXEs belonging to other families than family 4 (Table 4), it is possible to use chromogenic and fluorogenic aryl acetates, such as  $\alpha$ - or  $\beta$ -naphthyl acetate and 4-methylumbelliferyl acetate (214). An alternative is to screen for the production of enzymes clearing of milky solid media containing insoluble per-O-acetylated carbohydrates, e.g., penta-O-acetyl-D-glucose (236). Subsequent screening of positive colonies for the ability to deesterify acetylxyan itself is necessary. The principles outlined above can be used for detection of AcXEs in electrophoretic gels.

##### 1. Detection of AcXE in Gels Using Acetylxyan as a Substrate (233)

An approximately 1-mm-thick flat 1.5–2.0% agarose gel containing 0.5–2.0% of acetylxyan (DMSO extracted or obtained by steaming wood) and 0.01% sodium azide in 0.1 M phosphate buffer, pH 6.5, is prepared by casting between glass plates. Visualization of AcXE is carried out by superimposing the detection and rebuffered separation gel in a plastic bag and incubating at 30–50°C until cloudy areas appear. The precipitate forms in both the separation and detection gels because of cross-diffusion of enzyme and substrate. The method fails when esterase is located close to EXs. Gels with precipitates are photographed in diffuse light similarly as immunoprecipitation bands.

##### 2. Detection of Acylesterase in Gels by $\alpha$ -Naphthyl Acetate (237)

A solution of 20 mg  $\alpha$ -naphthyl acetate in 4 ml of N,N'-dimethylformamide is mixed with 36 mL of a solution of 20 mg of Diazo Blue R (Sigma) in 0.05

M phosphate buffer, pH 7.4. An electrophoretic or isoelectrofocusing gel is washed with 0.1 M phosphate buffer, pH 7.4, for 15 min. The gel is then placed in a freshly prepared substrate-dye solution and incubated for 1 h at 40°C. The reaction is stopped by decanting the staining solution and covering the gel with a solution of 2% acetic acid.

### 3. Detection of Acetyleresterase Using 4-Methylumbelliferyl Acetate (233)

A flat detection agarose gel containing 0.1% 4-methylumbelliferyl acetate in 0.1 M phosphate buffer is freshly prepared. The gel is placed in contact with a washed electrophoretic gel and incubated at room temperature until a bright fluorescent zone appears under UV light at 360 nm on both separation and detection gels. An alternative procedure is to bring the separation gel into contact with a saturated solution of 4-methylumbelliferyl acetate in 0.1 M phosphate buffer on a glass plate.

## VI. $\alpha$ -L-ARABINOFURANOSIDASE (EC 3.2.1.55)

### A. Chemical Reactions Catalyzed

3 (2)

$\alpha$ 1

Araf

3(2)

$\alpha$ 1

Araf

$\alpha$ -L-Arabinofuranosidase is a component of hemi-cellulolytic systems that participates in hydrolysis of plant polysaccharides built from or containing nonreducing terminal  $\alpha$ -L-arabinofuranosyl residues (44, 238). Such polysaccharides have been recognized as part of pectic substances, gum exudates, and wood and cereal hemicelluloses (239). The pectic substances mainly include L-arabinan and various types of L-ara-

bino-D-galactans. Other natural substrates of  $\alpha$ -L-arabinofuranosidase are glycosylated terpenols of grape, important precursors of grape and wine aromas. Many of these terpenols are linked to disaccharide moieties in which the nonreducing terminal sugar is frequently L-arabinofuranose. Thus,  $\alpha$ -L-arabinofuranosidase can be used for enhancement of wine flavor by the release of free terpenols (240–242).

Since the enzymes degrading arabinans and arabinogalactans were specifically covered in Chapter 70, here we shall focus on  $\alpha$ -L-arabinofuranosidases involved in the degradation of polysaccharides containing main chains built from  $\beta$ -1,4-linked xylopyranosyl residues, specifically, softwood arabinoglucuronoxylans and cereal arabinoxylans. Some of these enzymes, particularly those which attack low-molecular-mass fragments of these polysaccharides, participate in the degradation of all types of L-arabinose-containing polysaccharides. However, there are  $\alpha$ -L-arabinofuranosidases specific for arabinoxylans. In the softwood polysaccharide the L-arabinofuranosyl residues are linked to the main chain  $\alpha$ -1,3- or  $\alpha$ -1,2 glycosidically as single substituents. Cereal arabinoxylans contain, in addition to  $\alpha$ -1,3- and  $\alpha$ -1,2-linked L-arabinofuranosyl residues as single substituents, doubly arabinosylated xylopyranosyl residues of the main chain.

### B. Properties as Proteins

Fungal  $\alpha$ -L-arabinofuranosidases occur mostly as monomeric enzymes with molecular masses between 32 and 84 kDa and pI values between 3.2 and 7.5 (44). The majority of described fungal enzymes are products of *Aspergillus* spp. (146), and have pI values ~ 3.5. Bacterial and *Streptomyces*  $\alpha$ -L-arabinofuranosidases frequently occur as oligomers, form dimers up to octamers, with subunits of molecular mass between 33 and 75 kDa. pI values were reported in the range of 3.8–9.0.

Some  $\alpha$ -L-arabinofuranosidases show modular architecture similar to other xylanolytic enzymes. Interesting in this regard is  $\alpha$ -L-arabinofuranosidase from *T. reesei* (244, 245). Two different forms of the enzyme have been isolated from a culture fluid of the fungus. The 25-kDa form corresponds to the catalytic domain only (245). The 53-kDa form, the first form of the enzyme described (244), also contains a noncatalytic xylan-binding domain (245). The large 53-kDa form can be converted to the shorter one by proteolytic digestion (245).  $\alpha$ -L-Arabinofuranosidase from *P. fluorescens* was reported to contain a cellulose-binding

domain in the N-terminal portion of the polypeptide chain (246). A xylan-binding domain was detected in C-terminal region of  $\alpha$ -L-arabinofuranosidase B from *S. lividans* (247). The enzymes containing the noncatalytic polysaccharide-binding domains are specific for release of L-arabinofuranose from polymeric substrates.

### C. Properties as Enzymes

Microbial  $\alpha$ -L-arabinofuranosidases can be divided into three different groups according to substrate specificities (239). The groups seem to coincide with three different glycosyl hydrolase families into which  $\alpha$ -L-arabinofuranosidases belong (Table 5).

The enzymes that perform best on short  $\alpha$ -1,5-linked arabinooligosaccharides and are active on 4-nitrophenyl- $\alpha$ -L-arabinofuranoside (NPh-Araf) and inactive on polymeric substrates are grouped in family 51. They include both fungal and bacterial  $\alpha$ -L-arabinofuranosidases of molecular mass 57–72 kDa, which catalyze the hydrolysis of the glycosidic linkage with retention of the anomeric configuration (248). These are apparently the enzymes designed to degrade more arabinans rather than arabinoxylans.

Family 54 includes mainly fungal  $\alpha$ -L-arabinofuranosidases (M.m. 49–53 kDa) which exhibit somewhat broader substrate specificities than the enzymes of family 51. The 54 family  $\alpha$ -L-arabinofuranosidases

attack not only NPh-Araf and arabinose-containing oligosaccharides, but also polymeric substrates such as arabinoxylans and arabinoglucuronoxylans (239). These enzymes catalyze hydrolysis of  $\alpha$ -1,5-,  $\alpha$ -1,3- and also  $\alpha$ -1,2-linked terminal L-arabinofuranosyl residues with retention of the anomeric configuration (248).

The family 62 of  $\alpha$ -L-arabinofuranosidases (Table 5) includes enzymes which preferentially attack polymeric substrates, i.e., arabinoxylans. The best-known members of this family are enzymes from *Aspergillus* spp., assigned as AXHs (249),  $\alpha$ -L-arabinofuranosidase B from *Streptomyces lividans* (247), and an enzyme from *Ps. fluorescens* subsp. *cellulosa* having a modular architecture (246). The enzymes show a clear preference for  $\alpha$ -1,2-linked and  $\alpha$ -1,3-linked  $\alpha$ -L-arabinofuranosyl residues of arabinoxylan main chain. However, the enzymes of this family do not remove  $\alpha$ -L-arabinofuranosyl residues from doubly substituted xylopyranosyl residues.

An arabinofuranose-releasing enzyme of novel substrate specificity was isolated from *Bifidobacterium adolescentis* DSM 20083 (250). This enzyme specifically releases terminal arabinofuranosyl residues linked  $\alpha$ -1,3 to xylopyranosyl residues of main chains that also carry  $\alpha$ -1,2-linked arabinofuranose. Wood and McCrea (251) reported the occurrence of a hydrolase releasing feruloylated L-arabinofuranosyl residues from wheat straw arabinoxylan. Additional evidence

**Table 5** Families of  $\alpha$ -L-Arabinofuranosidases and Differences in Their Properties

Family	Producing microorganism	Molecular mass (kDa)	Hydrolyzed substrates	Mechanism of hydrolysis	Ref.
51	<i>A. niger</i> (enz. A) <i>Bacillus</i> <i>Streptomyces</i> <i>Thermotoga</i> <i>Clostridium</i>	57–72	NPh- $\alpha$ -Araf, arabinooligosaccharides (enzymes are inactive on polymers)	Retaining	205
54	<i>A. niger</i> (enz. B) <i>T. reesei</i> <i>Ewericella nidulans</i> <i>Synchocystis</i> sp.	49–53	NPh- $\alpha$ -Araf, arabinooligosaccharides, arabinoxylan (attack mainly on $\alpha$ -1,3-linked Araf, no attack on double arabinosylated xylopyranosyl residues.)	Retaining	205, 253
62	<i>Aspergillus</i> (AXH) <i>Streptomyces</i> (enz. B), <i>Ps. fluorescens</i>	47–59	arabinoxylan (the enzymes remove $\alpha$ -1,3- and $\alpha$ -1,2-linked L-Araf residues, no attack on double arabinosylated xylopyranosyl residues)	Unknown	246, 247, 249

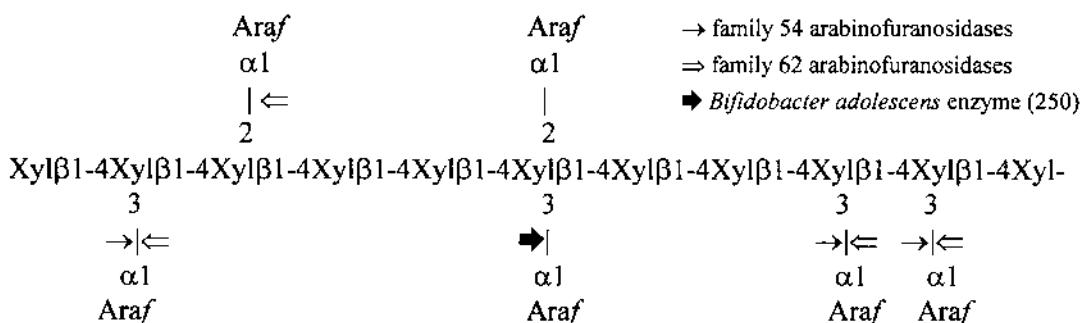

Source: Refs. 44, 205.

for hydrolysis of substituted arabinofuranosyl residues has been reported for  $\alpha$ -L-arabinofuranosidase from *A. terreus* (252). The mode of action of enzymes operating on high-molecular-mass arabinoxylans and their relationship to glycosyl hydrolase families is illustrated in Scheme 7. Based on the complexity of structures of plant arabinoxylan, one can anticipate the discovery of arabinofuranosidases with other substrate specificities.

(pH 4.0) or in other buffer depending on the pH optimum of the assayed enzyme.

2. 1.0 M sodium carbonate.

*b. Procedure.* 4-Nitrophenyl  $\alpha$ -L-arabinofuranoside solution (0.9 mL) is mixed with 0.1 mL of the enzyme sample, incubated at 50°C or an appropriate time, and the reaction is stopped by addition of 0.5 mL of 1 M solution of Na<sub>2</sub>CO<sub>3</sub>. Liberated 4-nitrophenol is

### Scheme 7

#### D. Determination of $\alpha$ -L-Arabinofuranosidase Activity

As indicated in **Table 5**, two families of  $\alpha$ -L-arabinofuranosidases can be assayed easily using the chromogenic substrate 4-nitrophenyl  $\alpha$ -L-arabinofuranoside or the fluorogenic substrate 4-methylumbelliferyl  $\alpha$ -L-arabinofuranoside. One should be aware of the fact that these substrates can also be attacked by  $\beta$ -xylosidases of family 43, which exhibit aryl  $\alpha$ -L-arabinofuranosidase activity (**Table 3**). Therefore, it is imperative to confirm the identity of the enzyme by determining its ability to release arabinose from arabino-substituted xylans or xylooligosaccharides (5).  $\alpha$ -L-Arabinofuranosidases of family 62 must be assayed on natural substrates, arabinoxylans, and oligosaccharides derived from arabinoxylans. Released arabinose is determined using HPLC or as reducing sugar. Examples of determination of  $\alpha$ -L-arabinofuranosidase activity are given below.

### 1. $\alpha$ -L-Arabinofuranosidase Assay Using 4-Nitrophenyl $\alpha$ -L-Arabinofuranoside (244)

### *a Reagents*

a. Reagents  
1. 4-Nitrophenyl  $\alpha$ -L-arabinofuranoside, 2 mM solution in 0.05 M sodium citrate phosphate buffer

measured spectrophotometrically at 400 nm. One unit of  $\alpha$ -L-arabinofuranosidase activity is defined as the amount of enzyme liberating 1  $\mu\text{mol}$  of 4-nitrophenol in 1 min. (Note: The literature offers a variety of modification of the above procedure with respect to buffer, substrate concentration, and the reaction terminating agent. Termination of the reaction using a saturated solution of sodium tetraborate is recommended.)

## 2. Fluorimetric Assay of $\alpha$ -L-Arabinofuranosidase (254)

#### a. Reagents

1. 4-Methylumbelliferyl  $\alpha$ -L-arabinofuranoside, 10 mM solution in dimethyl formamide.
  2. 0.02 M acetate buffer, pH 4.5.
  3. 0.2 M sodium carbonate buffer, pH 10.0.
  4. 4-Methylumbelliferone.

*b. Procedure.* Enzyme solution, 5–20  $\mu$ L, is made up to 200  $\mu$ L with 0.02 M acetate buffer (pH 5.5) containing 4  $\mu$ L of 10 mM solution of the substrate in dimethyl formamide. To monitor the enzymic activity 20- $\mu$ L aliquots of the reaction mixture are diluted with 2 mL sodium carbonate buffer, and the liberated 4-methylumbelliferyl is determined fluorimetrically.

One unit is defined as the amount of enzyme that releases 1  $\mu$ mol of 4-methylumbelliferyl  $\alpha$ -L-arabinofuranoside (255) per minute.

3. Assay of 1,4- $\beta$ -Arabinoxylan  
Arabinofuranohydrolase (249)

a. *Reagent.* Arabinoxylan (wheat, rye, or oats; Megazyme), 0.1% solution in 0.05 M acetate buffer, pH 5.0.

b. *Procedure.* The solution of oats spelt arabinoxylan is mixed with a small volume of enzyme solution, incubated at 30°C for an appropriate time, and analyzed for L-arabinose by HPLC.

4. Assay of 1,4- $\beta$ -Arabinoxylan  
Arabinofuranohydrolase (247)

a. *Reagents*

1. Arabinoxylan (wheat, rye, or oats; Megazyme), 1.0% solution in 0.05 M acetate buffer, pH 5.0.
2. p-Hydroxybenzoic acid anhydride (PANBAH) reagent for determination of reducing sugars (256).

b. *Procedure.* 0.9 mL of 1.0% arabinoxylan solution is mixed with 0.1 mL appropriately diluted enzyme and incubated at 55°C. The reaction is stopped by transferring 0.1 mL of the sample to 0.3 mL of the PANBAH reagent and heating for 5 min at 95°C. The reducing sugars are determined spectrophotometrically at 405 nm using L-arabinose as standard. One unit of enzyme activity is defined as the amount of enzyme that releases 1  $\mu$ mol of arabinose per minute.

**E. Assays for Detection and Screening Purposes of  $\alpha$ -L-Arabinofuranosidases of Families 51 and 54**

$\alpha$ -L-Arabinofuranosidases which hydrolyze aryl  $\alpha$ -L-arabinofuranosides can be detected in electrophoretic gels or in screening growth media using two substrates: fluorogenic 4-methylumbelliferyl  $\alpha$ -L-arabinofuranoside (255), or chromogenic 5-bromo-3-indolyl- $\alpha$ -L-arabinofuranoside (254). Specific procedures how to apply these glycosides can be found in the section devoted to endo- $\beta$ -1,4-xylanases. With the first substrate, which is commercially available, the presence of the enzyme results in the liberation of 4-methylumbelliferyl, which shows a strong fluorescence under UV light (~360 nm). The fluorescence can be enhanced by alkaline agents, e.g., exposing the gels to ammonium hydroxide vapors. The hydrolysis of 5-bromo-3-indolyl glycoside results in the forma-

tion of an intensely colored indigo precipitate. The glycoside was suggested for use in cloning experiments in which  $\alpha$ -L-arabinofuranosidase will be used as a reporter gene (254).

## ACKNOWLEDGMENT

The author thanks Dr. Timothy D. Leathers from the Biopolymer Unit of the USDA, ARS, in Peoria, IL, for generous help with English in this chapter.

## Enzymes with Activity Toward Xyloglucan

Jean-Paul Vincken

Wageningen University, Wageningen, The Netherlands

### I. INTRODUCTION

Xyloglucans are plant cell wall polysaccharides, which belong to the hemicellulose class; i.e., they can bind to cellulose. They are the most abundant hemicellulose in the walls of many nongraminaceous species. Xyloglucans can function both as a structural and as a reserve polysaccharide. In the primary cell wall, xyloglucans can crosslink cellulose fibers, yielding a network that determines to a large extent the strength of the wall. This complex usually constitutes approximately half of the amount of wall polysaccharides, the cellulose (30%) being a bit more abundant than the xyloglucan (20%). Plants possess many enzymes to remodel this network. Certain degradation products of xyloglucan may serve as signaling molecules, the activity of which can be regulated by various glycosidases. Structural xyloglucans are also important from a food industry point of view. They are an important target for fungal enzymes in applications, which aim at a complete degradation of the plant cell wall, such as the "liquefaction process" for fruit juice manufacturing. Further, xyloglucans might play a role in determining the shelf life of fruits and vegetables.

Xyloglucans can also be deposited in the secondary cell walls of seeds of several species, such as *Tamarindus indica*, *Tropaeolum majus*, *Hymenaea courbaril*, and *Copaifera langsdorffii*. The seeds can contain > 50% xyloglucan. Upon germination of

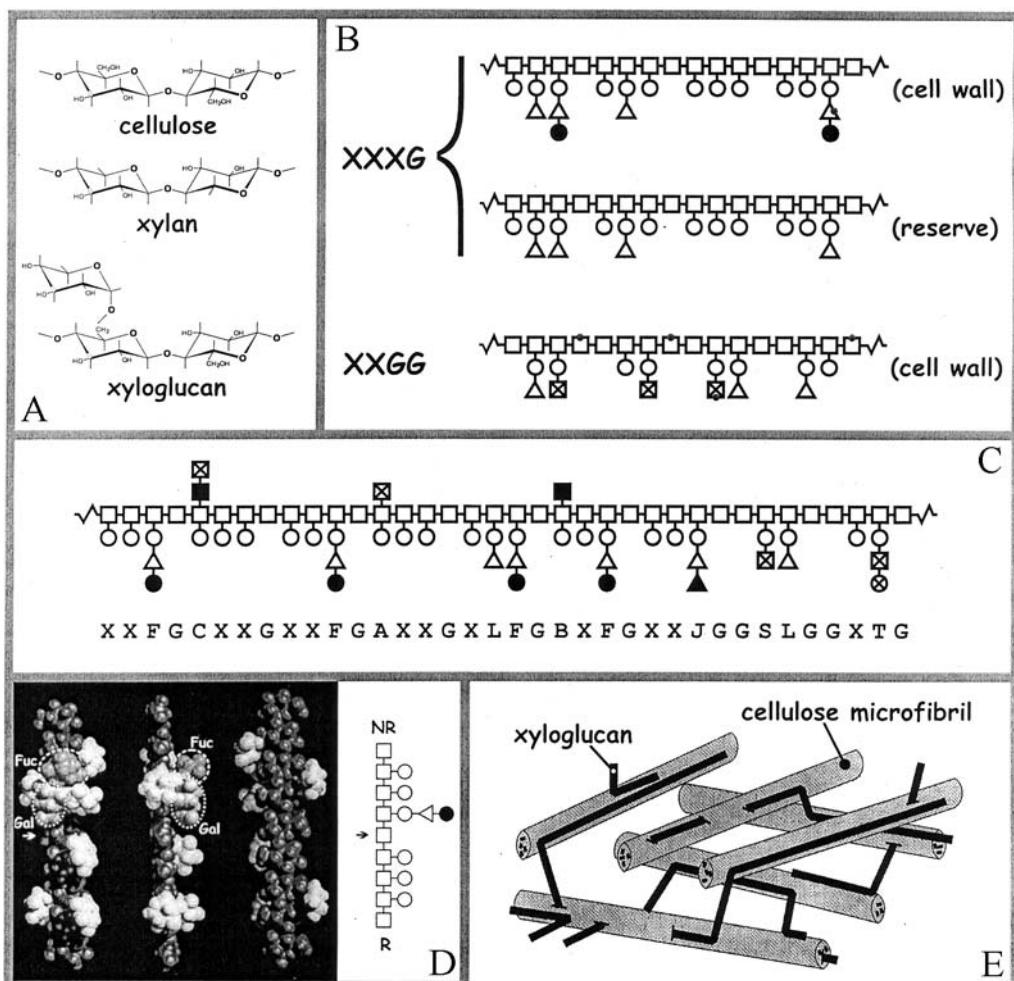

these seeds, a battery of enzymes is induced to mobilize the xyloglucan food reserves of the hypocotyl. The storage xyloglucans, in particular, are used as food ingredients or in pharmaceutical applications. The decoration (or side-chain configuration) of these xyloglucans determines to a large extent their functional properties. Depending on the application, the decoration may be adjusted by using enzymes of either plant or fungal origin. With the discovery of the first enzymes in xyloglucan biosynthesis, it may be possible in the future to realize these structural modifications in the plant itself. Biosynthetic enzymes using nucleoside-diphosphate sugars will not be discussed in this chapter.

In the paragraphs below, the structural variations of xyloglucans will be reviewed first. As we will see later, substitution determines the rate at which xyloglucan molecules are degraded. Subsequently, the anchoring of xyloglucan in the plant cell wall will be discussed. Some background information on this is provided, because certain enzyme purification procedures and enzyme assays make use of these principles. The following sections deal with (plant and microbial) enzymes involved in degradation or modification of xyloglucan. After this, a number of methods for activity measurements are summarized. These methods deal predominantly with the determination of transferase activity, because these assays follow different procedures from those used for degradative enzymes. Finally, a few applications in the food industry will be described.

## II. STRUCTURE AND PROPERTIES OF XYLOGLUCANS

Xyloglucans are polysaccharides with a highly branched  $\beta$ -(1  $\rightarrow$  4)-GlcP or cellulosic backbone. Most side chains contain  $\alpha$ -XylP residues, which are attached to the 6-position of the Glc residues (Fig. 1A). The  $\alpha$ -XylP residues are distributed in the glucan backbone according to regular patterns. In principle,

two general branching patterns can be distinguished, XXXG and XXGG (see Fig. 1B) (1). Thus, xyloglucans seem to have a subunit length of four glucosyl residues in common. In the XXXG-type xyloglucans (most nongraminaceous species), three contiguous Glc residues are branched, followed by an unbranched one. The XXGG-type xyloglucans (solanaceous plants) contain clusters of two branched Glc residues, which alternate with a sequence of two "bare" Glc residues.

**Figure 1** (A) Structure of the cellobiosyl building unit of cellulose, the xylobiosyl building unit of xylan, and a trisaccharide XG subunit of xyloglucan. Note that glucose and xylose are very similar except for C-6. (B) Two general branching patterns of xyloglucans, XXXG and XXGG. Small shaded circles represent acetyl groups. (C) Hypothetical (nonexisting) molecule showing the different structural elements encountered in xyloglucans. G =  $\beta$ -D-GlcP; X =  $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP; L =  $\beta$ -D-GalP-(1  $\rightarrow$  2)- $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP; F =  $\alpha$ -L-FucP-(1  $\rightarrow$  2)- $\beta$ -D-GalP-(1  $\rightarrow$  2)- $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP; S =  $\alpha$ -L-Araf-(1  $\rightarrow$  2)- $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP; A =  $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP-(2  $\leftarrow$  1)- $\alpha$ -L-Araf; B =  $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP-(2  $\leftarrow$  1)- $\beta$ -D-XylP; C =  $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP-(2  $\leftarrow$  1)- $\beta$ -D-XylP-(3  $\leftarrow$  1)- $\alpha$ -L-Araf; J =  $\alpha$ -L-GalP-(1  $\rightarrow$  2)- $\beta$ -D-GalP-(1  $\rightarrow$  2)- $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP; T =  $\beta$ -L-Araf-(1  $\rightarrow$  3)- $\alpha$ -L-Araf-(1  $\rightarrow$  2)- $\alpha$ -D-XylP-(1  $\rightarrow$  6)- $\beta$ -D-GlcP. (D) Flat backbone conformation of the xyloglucan heptadecamer GXXFGXXXG [adapted from (4)]. NR, nonreducing end of the polymer; R, reducing end. (E) Schematic representation of a part of the cellulose-xyloglucan network in the primary cell of plants [adapted from Roberts and McCann (9)].

An exception to this rule is the xyloglucan from *Hymenaea courbaril*, which contains similar amounts of XXXG- and XXXXG-type subunits (2). Another exception might be the xyloglucan from certain gramineous species (rice, barley), which are thought to have a degree of branching of 40% or lower (1).

The variation in xyloglucan structure is much larger than the two general branching patterns suggest. The xyloglucan skeleton can be decorated with many different residues. However, the sequence in which these residues occur in the side chain is very consistent. In 1993, a concise nomenclature was developed to unambiguously designate xyloglucan structures (3). A xyloglucan molecule is named by partitioning the backbone into segments consisting of a single glucosyl residue and its pendant side chains. Each segment is given a specific code letter, depending on the side chain configuration. For example, the letters G and X refer to the unbranched  $\beta$ -D-Glc<sub>p</sub> residue and the  $\alpha$ -D-Xyl<sub>p</sub>(1 → 6)- $\beta$ -D-Glc<sub>p</sub> segment, respectively. The letter F refers to the  $\alpha$ -L-Fuc<sub>p</sub>(1 → 2)- $\beta$ -D-Gal<sub>p</sub>(1 → 2)- $\alpha$ -D-Xyl<sub>p</sub>(1 → 6)- $\beta$ -D-Glc<sub>p</sub> segment of the fucosylated nonasaccharide (XXFG) commonly found in xyloglucans. The different structural elements which are currently known are summarized in the hypothetical (nonexisting) xyloglucan molecule in Figure 1C.

The variation in xyloglucan structure is not only species dependent, but also relates to the physiological state of the cell wall of that particular species (1). Xyloglucans that are present as storage polysaccharides in seeds are of the XXXG type. Unlike the xyloglucan derived of the primary cell wall, these are not fucosylated (Fig. 1B). Depending on their origin, they contain different proportions of XXXG, XLXG, XXLG, and XLLG. In addition to these, the primary cell wall xyloglucan can contain the fucosylated oligosaccharides XXFG, XLFG, and XFFG, as well as larger oligosaccharides with the more rare segments A, B, and C. Smaller oligosaccharides, like FG, GFG, XFG, and XXG, also occur, but these are most likely a result of postdepositional modification by endogenous enzymes. Finally, the galactosyl residue of the F elements can be acetylated.

The XXGG-type xyloglucans have so far only been found in solanaceous plants (potato, tomato, tobacco) (1). Fucosylated trisaccharide side chains are not present in these xyloglucans. Instead, they possess a fair amount of arabinosyl-containing disaccharide side chains. It seems that all combinations of the elements X, L, and S can occur (XX, LX, XL, LL, SX, XS, SS, SL, and LS). The structural elements A, B, and C have not been demonstrated in the XXGG type. Acetyl

groups can be attached to the C-6 position of Glc residues, mainly as in XX(G-ac)G, and to a minor extent as in (G-ac)XXG. Further, acetyl groups can be present on the C-5 of terminal arabinosyl units.

Despite their heavily branched nature, xyloglucans can interact intimately with cellulose. Molecular modeling studies with the heptadecamer GXXFGXXXG have shown that xyloglucan molecules can adopt a so-called flat-backbone conformation, which facilitates their binding to cellulose (4, 5). In this conformation, the xylosyl residues point outwards in an alternate fashion (Fig. 1D). The fucosylated side chain folds onto the backbone toward the nonreducing side, whereas the opposite face of the molecule is relatively flat. The structure of the side chains plays an important role in the interaction with cellulose. The fucosylated sidechain in particular seems to induce the flat-backbone conformation. Indeed, binding studies have shown that fucosylated xyloglucans display a higher affinity binding than nonfucosylated xyloglucans (5, 6). This may be consistent with the function of these xyloglucans in the plant cell wall. The former is encountered as a crosslinker of cellulose microfibrils in the primary wall. The latter serves as a reserve polysaccharide in the secondary wall of seeds, which needs to be easily accessible to glycanases during germination. At the moment, the binding characteristics of XXGG-type xyloglucan are unknown, as is the contribution of arabinosyl substitution to binding. Next to the side chain configuration, the length of the xyloglucan molecule is also an important parameter for interaction with cellulose. It has been shown that molecules composed of (at least) four oligosaccharide binding units (equivalent to a backbone length of 16 Glc residues) bind quantitatively to cellulose (7, 8).

The cellulose-xyloglucan network comprises ~50% of the primary cell wall (width ≈ 75 nm). The wall is flanked by a plasma membrane and a middle lamella, and can accommodate three to four lamellae of cellulose microfibrils (diameter 5–12 nm; indeterminate length). The microfibrils in one layer run parallel, and no weaving between layers is observed (9). Xyloglucans coat the cellulose surface; they are also incorporated in the microfibrils during the synthesis of the wall. The length of individual xyloglucan molecules (30–400 nm) generally exceeds the distance between lamellae many times, which suggests that these polysaccharides can interlink several microfibrils (Fig. 1E). Typically, xyloglucans seem to be built of blocks of 30 nm repeats (10); one such repeat corresponds to ~60 Glc residues (or 15 xyloglucan oligosaccharides), which is similar to the length of a

crosslink or the distance between two lamellae. The attachment of xyloglucan to cellulose provides important mechanical properties such as extensibility, which can not be realized with cellulose alone (11).

### III. ENZYMIC DEGRADATION OF XYLOGLUCANS

Over the years, many xyloglucan hydrolases of both fungal and plant origin have been described. In this section, most attention will be devoted to endoglucanases, which can rapidly depolymerize xyloglucan. Next to these, a number of exoacting enzymes will be reviewed, the majority of which only act on oligosaccharides (such as xyloglucosidase,  $\alpha$ -xylosidase, and  $\alpha$ -fucosidase).  $\beta$ -Galactosidase is an exception to this, and can be used to adjust the physical properties of polymeric xyloglucan. Hydrolases with the ability to split off  $\alpha$ -L-Araf from XXGG-type xyloglucan have not been described so far.

#### A. Endoglucanase

In the older literature endoglucanases are sometimes referred to as cellulases or  $C_x$  factor. In principle, both cellulase and  $C_x$  are a collective noun for a group of enzymes, including endoglucanases, which have in common that they hydrolyze  $\beta$ -D-Glc<sub>p</sub>-(1 → 4) linkages. Endoglucanases have long been characterized by their activity on carboxymethyl cellulose (CMC). Unfortunately, determination of xyloglucanase activity is not a common practice, and for many well-characterized cellulases it is not known if they are able to degrade xyloglucan. However, it is important to realize that not every endoglucanase is a xyloglucanase (12). Recently, an endoglucanase with xyloglucanase, but no CMCase, activity has been described (13). This suggests that there are at least two types of xyloglucanases—a highly specific one, and one with a more promiscuous substrate specificity.

Bacteria and fungi usually possess several endoglucanases. For instance, the fungus *Trichoderma reesei* has four endoglucanases—EGI, EGII, EGIII, and EGV—of which at least two have xyloglucanase activity (EGI and EGIII; for EGV this has not been determined) (12). With this set of different endoglucanases, *Trichoderma* seems very well equipped to efficiently degrade plant cell wall cellulose, i.e., cellulose that is coated with hemicellulose (14). The variety of endoglucanases in plants is even larger than that in microbial

sources. *Arabidopsis thaliana* alone already contains > 12 endoglucanases (15). Virtually nothing is known about the substrate specificity of these enzymes.

Microbial endoglucanases are often modular proteins; i.e., they are composed of separate domains, which are connected by linker peptides (16). The substrate specificity of the endoglucanase resides in the catalytic core. One or more cellulose-binding domains (CBDs) determine whether the enzyme can attach itself to, and degrade insoluble substrates like cellulose. The fact that EGI from *Trichoderma reesei* has a CBD, whereas EGIII has not, shows that xyloglucanases with and without CBD can occur naturally. So far, no plant endoglucanases with a CBD have been described (15). However, these enzymes can contain (putative) signal sequences for cell attachment or membrane anchoring. This implies that the action of the endoglucanases with a signal sequence is restricted to specific locations within the wall.

As we have seen above, the answer to the question whether an endoglucanase has xyloglucanase activity lies in the topology of the catalytic core. These catalytic cores can be grouped in families, based on similarities in apparent secondary structures of proteins (<http://afmb.cnrs-mrs.fr/~pedro/CAZY/>). In principle, cores with very low amino acid sequence identity can be attributed to the same glycosyl hydrolase family; i.e., the fold of the core proteins seems to be much better conserved than their sequence. Within one family, the catalytic mechanism (retaining or inverting) of the hydrolysis reaction is the same. So far, endoglucanases with xyloglucanase activity have been attributed to two families-7 and 12 (both retaining). Important characteristics of enzymes belonging to these families are summarized in Table 1.

Typically, the *Trichoderma reesei* EGI and EGIII can cleave both xyloglucan and xylan (12), suggesting that the presence of CH<sub>2</sub>OH groups or a xylosyl residue protruding from the backbone do not matter for these enzymes (see also Fig. 1A). However, EGII from *Aspergillus aculeatus* is highly specific for xyloglucan and is unable to degrade xylan (13). This shows that activity toward xylans is not a common feature of xyloglucanases.

Another important conclusion from Table 1 is that the substrate specificity of endoglucanases is not conserved within each family. For instance, family 12 contains many different kinds of endoglucanases. Either they are mainly active on CMC, or they are active only on xyloglucan. Also, there are endoglucanases, which can degrade both substrates. This suggests that only subtle changes in the structure of endoglucanases can

**Table 1** Overview of Selected Endoacting Enzymes with Activity Toward  $\beta$ -(1  $\rightarrow$  4)-D-Glucans

determine whether these enzymes have xyloglucanase activity. Probably, it is important that the substrate-binding groove is lined with the appropriate amino acid residues at certain positions; this may determine whether the xylosyl side chains on the glucan backbone are tolerated in the groove. Also, xylosyl groups may be involved in the molecular recognition of the substrate by xyloglucanases. From the examples above it is clear that the family classification does not have a predictive value with respect to the substrate specificity of endoglucanases. The xyloglucanase activity of each individual endoglucanase should be verified experimentally. There are a number of reports showing that there are enzymes in plant extracts that have xyloglucanase activity. Possibly, some of these xyloglucanases will be classified in family 9. At this moment, there is no experimental evidence supporting this remark. It is interesting to note that the enzymes of family 9 act with an inverting mechanism. This

means that xyloglucanase activity may not be reserved to retaining enzymes.

In the previous paragraphs it was shown that the structure of xyloglucan determines the properties of these molecules, such as binding to cellulose surfaces. Next to this, the structure also greatly influences the enzymic digestibility; i.e., the nature of the sidechains determines how fast xyloglucan is degraded by endoglucanases. It is difficult to relate the tolerance to particular side chains to individual endoglucanases, because most studies have been carried out with rather crude mixtures of enzymes from *Trichoderma*.

In Figure 2 a number of rules that seem to have a general validity are summarized. The presence of fucosylated side chains can hinder cleavage by the endoglucanase (17). Two adjacent fucosylated side chains as in XFFGXXXG can give partial resistance to endoglucanase, meaning that prolonged incubations are needed to generate the constituent oligosaccharides XFFG

**Figure 2** Overview of xyloglucan structures, which (a) are easily cleaved by endoglucanases (solid arrow), (b) are partially resistant to endoglucanase (thin arrow), and (c) are completely resistant to endoglucanases (thin arrow with cross). For details on xyloglucan structure, see Figure 1C. Small shaded circle on open box (bottom right structure) represents an acetyl group attached to a glucosyl residue.

and XXXG (18). Molecular modeling studies suggest that, in solution, the fucosylated side chain folds toward the reducing end of the molecule, i.e., over the linkage to be cleaved (4). This probably decreases the accessibility of the glucan backbone to endoglucanases.

The presence of A elements adjacent to unsubstituted glucosyl residues (as in XXFGAXXG or XXAGXXFG) blocks cleavage by endoglucanases completely (19). In *Solanaceous* spp., two vicinal unbranched glucosyl residues can occur as in XSGGXXGG (20). In this case the endoglucanase has a choice in "cleavable linkages," either XSG  $\downarrow$  GXXGG or XSGG  $\downarrow$  XXGG. The presence of other structural elements (L or S) at the position of the X elements probably influences the preference of the endoglucanase for a particular linkage. There is some evidence indicating that the presence of acetyl groups (as in XS(G-ac)GXXGG) inhibits cleavage of the adjacent glycosidic bond (21).

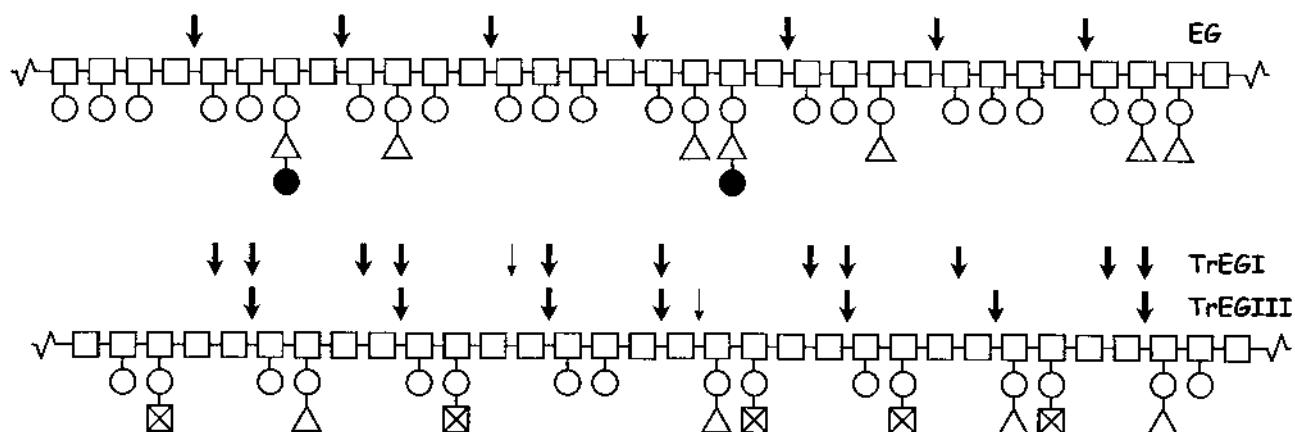

Because most xyloglucans are of the XXXG type, not many people have realized that endoglucanases may actually display differences in their mode of action towards xyloglucan. When it appeared that *solanaceous* xyloglucans were less heavily substituted than others, and that they had a regular branching pattern (XXGG type), it became possible to investigate this (20). It was demonstrated that two endoglucanases from *Trichoderma reesei*, EGI and EGIII, respond differently to substitution of the glucan backbone (Fig. 3). EGI predominantly released an XXGG type of oligosaccharide, whereas EGI also released GXG and XXG types of oligosaccharides (20). At this moment it is unknown whether the promiscuity of

EGI and the higher specificity EGIII are common features of, respectively, family 7 and 12 endoglucanases.

From the above it is clear that the activity of endoglucanases toward xyloglucan is greatly affected by the fine structure of the polysaccharide. Much more work remains to be done to establish the structure-function relationships of endoglucanases, and to answer the important question of what determines whether an endoglucanase has xyloglucanase activity.

## B. Glucosidase

Many of the glycosidases described to date play a role in mobilizing seed reserves upon germination. The  $\beta$ -glucosidase from *Tropaeolum majus* is probably the best-characterized one described in the literature (22). Therefore, the discussion of glucosidases will be restricted to this enzyme. The enzyme belongs to glycosyl hydrolase family 3 (retaining), and shows strong sequence homology to  $\beta$ -glucan exohydrolase from barley. The glucosidase contains two highly conserved motives, SDW—(24 aa)—GIDM, in which the aspartates have been implicated as the catalytic residues. Several  $\beta$ -linked glucose disaccharides were tested as a substrate. From this it was concluded that the enzyme hydrolyzes the various linkages at different rates: (1  $\rightarrow$  3)  $>$  (1  $\rightarrow$  4)  $>$  (1  $\rightarrow$  2)  $>$  (1  $\rightarrow$  6). Xyloglucan oligosaccharides were also tested as a substrate. The glucosidase was active against GXXG, GXLG, and GXG, but not against XXXG, XXLG, XLXG, XLLG, GLXG, or GLLG. Thus, the enzyme requires an unsubstituted glucosyl residue at the nonreducing end of the oligosaccharide. Next to this, the sidechain configuration of the penultimate glucosyl residue at the

**Figure 3** Schematic illustration of mode of action of endoglucanases (EGI and EGIII) from *Trichoderma reesei* on two different types of xyloglucan (XXXG and XXGG). For details on xyloglucan structure, see Figure 1C.

nonreducing end is important. Enzyme action is inhibited when this side chain contains a galactosyl residue. Another important observation is that the glucosidase shows transglycosylation activity with cello-oligosaccharides, but not with xyloglucan oligosaccharides. The cello-oligosaccharide transglycosylation products can be extended with Glc-(1 → 4)- $\beta$ -, and possibly with Glc-(1 → 6)- $\beta$ .

### C. Xyloglucosidase

This enzyme is discussed in a separate paragraph, because contrary to glucosidase it seems to have a requirement for xylosyl side chains. Xyloglucosidase was purified from a preparation of *Aspergillus oryzae* (23) and is often used for structural characterization ("sequencing") of xyloglucan oligosaccharides. It releases isoprimeverose ( $\alpha$ -D-Xylp-(1 → 2)- $\beta$ -D-GlcP) from the nonreducing terminus of XXXG ( $\rightarrow$  XXG + X), XXG ( $\rightarrow$  XG + X), or XG ( $\rightarrow$  G + X) oligosaccharides. Glucose release from cellobetraose is considerably slower (~50 times), which demonstrates that the enzyme is rather specific for xyloglucan. Also PNP- $\beta$ -Glc was a very poor substrate. Xyloglucosidase is unable to bypass galactosyl-containing side chains. It is unclear if this enzyme is active toward polysaccharides, because the polymeric substrates tested contain galactosyl residues. A similar activity is present in a preparation from *Irpex lacteus* (known under the commercial name Driselase), which is used by many plant researchers (24, 25). As of now, no such enzymes from plant origin are known.

### D. Xylosidase

$\alpha$ -Xylosidases have been purified from *Pisum sativum* (26) as well as from *Tropaeolum majus* (27), and the two enzymes were shown to have very similar properties. The enzyme releases the xylosyl residue attached to the non-reducing glucosyl residue of a xyloglucan oligosaccharide (for instance XXXG → GXXG + Xyl). No measurable amounts of xylose were split off from polymeric xyloglucan, which shows that no internal xylosyl residues are removed. However, the release of one xylosyl residue from the nonreducing terminus can not be excluded. The  $\alpha$ -xylosidase may play a role in "deblocking" the nonreducing termini to facilitate  $\beta$ -glucosidase action. Contrary to a number of micro-

bial  $\alpha$ -xylosidases (28–32), PNP- $\alpha$ -Xyl and isoprimeverose were not substrates for the plant  $\alpha$ -xylosidases.

### E. Galactosidase

Both fungal and plant  $\beta$ -galactosidases have received attention. The fungal enzymes are sometimes used for structural characterization of xyloglucan oligosaccharides. The plant enzymes play a role in mobilization of seed reserves, together with the XET (see further), glucosidase, and xylosidase. York and coworkers (33) demonstrated that the  $\beta$ -galactosidase from *Aspergillus niger* catalyzed the following reactions: XLXG → XXXG and XLLG → XXLG. The enzyme was not capable of degalactosylating sidechains at the penultimate glucosyl residue at the reducing end, under the conditions used. Similar results have been reported for a plant  $\beta$ -galactosidase from *Copaifera langsdorffii* (34). The activity of this enzyme toward polymeric xyloglucan and other galactosyl-containing substrates was not further investigated. The substrate specificity of  $\beta$ -galactosidase from *Aspergillus oryzae* seems to be different. This preparation was successfully used to remove all galactosyl residues from three-oligo fragments of tamarind xyloglucan (8). The  $\beta$ -galactosidase from *Tropaeolum majus* was active toward PNP- $\beta$ -Gal as well as polymeric xyloglucan (35). Unfortunately, the exact specificity was not further investigated. It is unknown if this enzyme is capable of removing both galactosyl residues from, for instance, XLLG-building blocks.

### F. Fucosidase

Fucosidases have received some interest from plant researchers because it has been suggested that particular fucosylated xyloglucan oligosaccharides have biological activity (so-called oligosaccharins). The  $\alpha$ -fucosidase from *Pisum sativum* has rather narrow substrate specificity. The enzyme recognizes  $\alpha$ -L-Fucp-(1 → 2)- $\beta$ -D-Galp-(1 → structures in xyloglucan oligosaccharides. No activity toward PNP- $\alpha$ -Fuc or polymeric xyloglucan was observed (36). It appeared that 6-O-acetylation of subterminal galactose of a synthetic substrate enhanced fucosidase activity. Interestingly, 6-O-acetylated XXFG naturally occurs as a building unit of sycamore cell wall xyloglucan (37). This enzyme probably plays a role in controlling the half-life of certain oligosaccharins (XXFG), which antagonize

auxin-induced growth. Fucosidases from other sources have also been described, but these will not be discussed here.

#### IV. XYLOGLUCAN ENDOTRANSGLYCOSYLASE AND RELATED ENZYMES

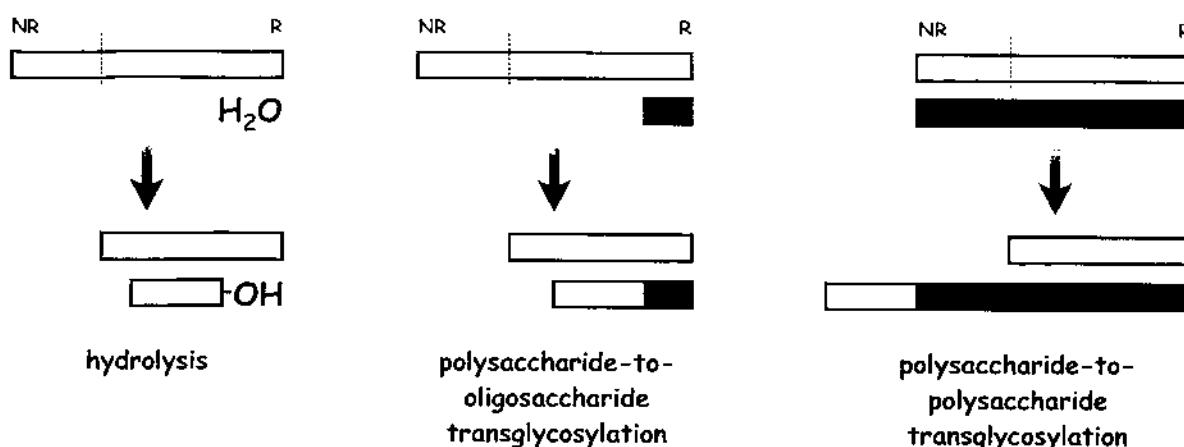

A separate section has been devoted to xyloglucan endotransglycosylase (XET), mainly because it is a very interesting enzyme from an enzymological point of view. The enzyme occurs throughout the plant kingdom, although some plants (for instance tomato) seem a richer source than others (38). XET or XET-related (referred to as XTR) proteins probably play a role in a number of important plant processes: (a) anchoring newly (synthesized and) deposited xyloglucan into the plant cell wall; (b) ripening; and (c) mobilization of seed reserves (39, 40). In the older literature, XET is sometimes referred to as xyloglucan-specific endoglucanase, oligosaccharide-activatable endoglucanase, or endo-xyloglucan transferase (EXT or EXGT).

XET catalyzes the cleavage of a xyloglucan molecule (**donor** substrate), and attaches the nonreducing moiety of this molecule to an **acceptor**, either water (hydrolysis reaction) or another xyloglucan molecule (transferase reaction of transglycosylation). Only XXXG-type donor molecules have been tested so far, and these are cleaved by XET at a similar position as by endoglucanases. The acceptor can be an oligosaccharide or a polysaccharide. The three possible reactions of XET are shown in Figure 4. During polysaccharide-to-polysaccharide endotransglycosyla-

tion, the molecular-weight distribution of xyloglucan molecules broadens, but no net change in molecular weight is observed (38, 41). Polysaccharide-to-oligosaccharide transglycosylation results in a large decrease in molecular weight. This reaction has practically the same effect as endohydrolysis catalyzed by endoglucanases.

Experiments with plant extracts have shown that XET is highly specific for xyloglucan. Only xyloglucan serves as a donor substrate, whereas carboxymethyl cellulose and cellulose are not recognized (38). Several oligosaccharide have been tested as acceptor substrates. No transglycosylation was observed with cellobiose, cellotetraose to cellohexaose, laminarihexaose, FG, XGG, and GXG (38, 41–43). Some xyloglucan oligosaccharides appeared to be more efficient than others (efficiency in decreasing order XLLG, XXXG and XXFG) (38). In a separate study it was shown that XXXG was a better acceptor than XXG (42). From this it was concluded that XET requires two adjacent xylosyl residues as in XXG, which is the smallest acceptor molecule.

XET proteins can be purified relatively easily from a crude mixture of proteins, such as a plant extract. Two procedures have been described; both are based on the fact that XET can form a relatively stable enzyme-substrate complex with polymeric xyloglucan. In the first procedure, the molecular weight of XET is increased "artificially" by adding polymeric xyloglucan, which nests in the active site. Subsequently, the XET-xyloglucan complex is purified by size exclusion chromatography. Finally, XET is released from the polymer by addition of xyloglucan oligosaccharides, followed by a second chromatography step (44). The second pro-

**Figure 4** Schematic illustration of three reactions that can be catalyzed by XET. NR, nonreducing end of the polymer; R, reducing end. Vertical dotted line represents site of cleavage by XET.

cedure utilizes the affinity of xyloglucan for cellulose (45). The enzyme-substrate complex is adsorbed to cellulose. Subsequently, XET is released by addition of xyloglucan oligosaccharides.

Sequence comparisons have shown that the different XETs can be assigned to the same family as bacterial  $\beta$ -(1  $\rightarrow$  3)(1  $\rightarrow$  4)-glucanases, namely glycosyl hydrolase family 16 (39, 40). Reactions catalyzed by members of this family proceed with retention of configuration, which is in line with the fact that this family contains many transferases. The three-dimensional structure of two *Bacillus*  $\beta$ -glucanases has been solved (46, 47). The enzymes are compact proteins with a sandwichlike jellyroll architecture. A groove, where the actual catalysis takes place, spans the concave side of the molecule. The other side of the enzyme contains a  $\text{Ca}^{2+}$ -binding site, which probably plays a role in stabilizing the protein together with one disulfide bridge. Because bacterial  $\beta$ -glucanases and XET have been assigned to the same family, it is expected that certain structural characteristics (e.g., fold) will also apply for XET. XET has been suggested to contain at least one disulfide bond, which appears to be important for maintaining enzyme activity. Most XETs contain a consensus sequence of **DEIDFEFLG**. Bacterial  $\beta$ -glucanases contain a sequence very similar to this, **DEIDIEFLG**. The DEIDIE residues are located along the bottom of the active site of these enzymes. The second glutamate (E) in this motif has been implicated as one of the catalytic residues of the enzyme. For XET it has been shown that the first glutamate is important for enzyme activity (48).

The sequence of many XETs or XET-related proteins have been described. For *Arabidopsis* it has been shown that it contains  $> 20$  different XET (or XET-related) genes. The various XET sequences can be classified into four subgroups (I through IV) (40). Most sequence divergence is found in the carboxy terminal part of the proteins. *Arabidopsis* sequences are present in groups I–III, suggesting that plants have acquired specialized XETs to catalyze particular processes. Group III XETs differ from the enzymes in the other groups in that they have a C-terminal extension and a putative (N-linked) glycosylation site at a different position in the protein. Enzymes from these groups will be discussed in more detail below. Group IV only contains two barley XET sequences, and will not be discussed further.

The biochemical properties of two XETs in group I have been mapped. Unfortunately, different experimental procedures/conditions were used, which

makes it difficult to make an extensive comparison. The enzymes have a high transferase activity in common, and they do not seem to catalyze the hydrolysis reaction (see Fig. 4). Both fucosylated and nonfucosylated xyloglucan can be used as donor. The activity of the *Vigna angularis* XET decreases dramatically when the donor substrate becomes shorter (41). Only very little activity was found on donor substrates of 10 kDa (approximately eight-oligo fragments). Possibly, this preference for high-molecular-weight xyloglucan is related to the conformation of xyloglucan in solution, but this requires further investigation. Similar observations have been made by Tabuchi et al. (49), but in this case the activity cannot be related to a sequence. The EXGT from *Arabidopsis thaliana* prefers the acceptor substrate XLLG over XXXG. XXXG seems to be preferred over XXFG (50).

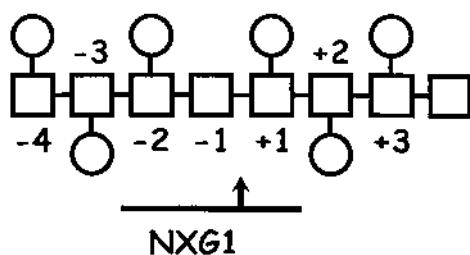

Three group II XETs from *Arabidopsis thaliana* have been characterized biochemically: TCH4, Meri-5, and XTR9 (50, 51). These enzymes have a pH optimum between 6.0 and 6.5, and have low (if any) hydrolytic activity. TCH4 and XTR9 have a relatively low temperature optimum of 18°C, whereas Meri-5 is most active at 28°C. TCH4 and Meri-5 are not influenced by fucosylation of the donor substrate. In contrast to this, XTR9 has a clear preference for nonfucosylated donor substrate. The three XETs prefer XLLG over XXXG and XXFG as an acceptor substrate. However, only XTR9 seems to prefer XXFG over XXXG. Further, XTR9 has a lower  $K_m$  value for the XLLG acceptor and is significantly inhibited by high levels of XLLG. The activity of TCH4 and Meri-5 is abolished upon removal of N-linked glycosylation, whereas the activity of XTR9 is unaffected by such treatment.

The best-characterized member of group III is nasturtium (*Tropaeolum majus*) XET, often referred to as NXG1 (52). This enzyme is characterized by its relatively higher preference for water as acceptor substrate; i.e., it can catalyze hydrolysis reactions next to trans-glycosylation reactions. It is unlikely that NXG1 requires high-molecular-weight donor substrates. This enzyme plays a role in the mobilization of xyloglucan reserves in seeds during germination, and has long been regarded as a xyloglucan-specific endoglucanase. Typically, the highly conserved active site motif is slightly different in NXG1 (and also in other members of group III), **DELDIEFLG** instead of **DEIDFEFLG** (40). In principle, one could say that the bacterial  $\beta$ -glucanases hold an intermediate position between NXG1 and most other XETs with respect to this motif (compare with motif above). In addition, the

group III XETs have a small loop of three extra amino acids upstream of this motif. At the moment it is still unclear whether these special NXG1 features are responsible for its relatively high hydrolytic activity. The substrate specificity of NXG1 was investigated by Fanutti et al. (52). A xylosidase (see previously) was used to tailor the specific substrates GXXGXXXG and GLLGXLLG, which were subsequently treated with NXG1. It appeared that GXXGXXXG was converted to GXXGGXXGXXXG and XXXG. GXXG( $\downarrow$ )G $\downarrow$ XXGXXXG could be cleaved as indicated (cleavage site between brackets is likely but does not follow unambiguously from the experiments). GLLGXLLG was converted to GLLGGLLGXLLG and XLLG. GLLG( $\downarrow$ )GLLGXLLG was degraded in a different manner as GXXGGXXGXXXG (cleavage site between brackets is likely but does not follow unambiguously from the experiments). From these and other experiments a number of important conclusions with respect to donor and acceptor substrate specificity could be drawn:

1. NXG1 can use acceptor substrates, which do not carry a xylosyl residue on the nonreducing glucosyl residue.
2. NXG1 does not require xylosyl substitution at glucose residues  $-4$ ,  $-2$ ,  $+1$ , and  $+3$  (for nomenclature see Fig. 5).
3. Xylosyl substitution at  $+2$  (and possibly  $-3$ ) is a requirement for NXG1.
4. Galactosyl substitution of a xylosyl residue at  $+1$  prevents, and at  $-2$  modifies, chain cleavage by NXG1.

The overview above shows that there can be important differences in the properties of XETs, even within one subgroup. Much more research is needed to understand the structure-function relationships of XETs.

**Figure 5** Xyloglucan fragment illustrating the pattern of xylose substitution of the glucan backbone around the site of chain cleavage (arrow). For details on xyloglucan structure, see Figure 1C. For significance of numbering, see text. (From Ref. 52.)

Important questions to be answered are “what determines the hydrolytic activity of some XETs?” and “what underlies the requirement for high molecular weight donor substrates for some XETs?” For family 12 endoglucanases, we have discussed already (see previous section) that subtle differences between these enzymes can determine whether or not they have xyloglucanase activity. In analogy to this, it may be expected that particular amino acid substitutions underlie donor and acceptor substrate specificity of XETs. In addition, it remains to be established whether XETs can display a different mode of action toward XXXG-type or XXGG-type xyloglucan.

## V. DETERMINATION OF ENZYME ACTIVITY ON XYLOGLUCANS

Many different assays can be used for studying conversions of xyloglucans. Simple reducing end-group analysis can point out whether enzymes or enzyme extracts contain xyloglucanase activity. It should be realized that xyloglucans contain relatively few “cleavable” glycosidic linkages (less than one out of seven!). As a result of this, it may be necessary to use higher substrate concentrations than one would use for unbranched substrates (to avoid substrate limitation). High-performance size exclusion chromatography (HPSEC) with refractive index (RI) detection may be used to determine differences in molecular-weight distributions. High-performance anion exchange chromatography (HPAEC) with an electrochemical detection unit is suitable for monitoring the release of oligosaccharides from a polymer. Appropriate reference oligosaccharides cannot be obtained commercially, and should be purified by oneself. Mass spectrometry (MS) is a very useful tool in structural elucidation of reaction products. In particular, liquid chromatography/tandem-mass spectrometry (LC-MSMS) in combination with  $^{18}\text{O}$ -labeling of reaction products may detect differences in mode of action between two endoglucanases. In this case, incubations are done in the presence of  $^{18}\text{O}$ -labeled water; tandem-MS is used to “sequence” the individual oligosaccharides (53).

Reducing end-group assays are not applicable for determining XET activity (except for NXG1-like enzymes catalyzing hydrolysis reactions), because the number of reducing ends remains constant during transglycosylation. Several methods to quantify the transglycosylation activity of XET have been described. These protocols are all based on a polysac-

charide-to-oligosaccharide transglycosylation. Three methods are discussed below.

1. Xyloglucan oligosaccharides are radiolabeled by exchanging the hydrogen at the reducing terminus of the molecule with  $^3\text{H}$  (39, 40). Radiolabeled oligosaccharides are subsequently incorporated into polymeric xyloglucan by transglycosylation. The radiolabeled products are sufficiently long to be adsorbed on a piece of filter paper (cellulose). After a washing step to remove the unreacted  $^3\text{H}$ -oligosaccharides, the transglycosylation activity can be simply measured by counting the radioactivity of the filter paper with a scintillation counter.

2. In the second method, the xyloglucan (acceptor) oligosaccharides are tagged at the reducing end with a UV or fluorescent label (e.g., 2-aminopyridine) (39, 40). The transglycosylation reaction produces fluorescent xyloglucans with an increased molecular weight. These are separated by HPSEC, and quantified by a fluorescence or UV detector. It may be advantageous to couple a RI detector to the HPSEC/UV system in order to visualize a shift in molecular-weight distribution of the polymeric xyloglucan.

3. The third method is probably the easiest, because it does not involve radiolabeling or complicated derivation procedures of the acceptor oligosaccharides. The method is based on the fact that xyloglucans with a molecular weight  $> 10$  kDa form a blue-green complex with iodine, whereas fragments  $< 10$  kDa remain unstained (54). XET activity can be determined colorimetrically by measuring the disappearance of the blue-green-colored iodine:xyloglucan complex in the presence of xyloglucan acceptor oligosaccharides at 620 nm.

For a more qualitative analysis of XET action LC-MSMS is a valuable analytical tool (see previous paragraph) (53). This method could, for instance, be used to detect differences in mode of action of various XETs.

## VI. APPLICATIONS IN THE FOOD INDUSTRY

Enzymes with activity toward xyloglucan can be used in a number of processes which are relevant for the food industry. Most applications are related to processing of vegetables and fruits. Other applications are more at the ingredient level. Some examples in which enzymic modification of xyloglucans can play a role will be discussed below.

Many processes in the food industry aim at a complete degradation of the plant cell wall (the so-called liquefaction process). For instance, in fruit juice manufacturing enzyme preparations are applied to increase juice yield. Also the recovery of important metabolites from plant material can be facilitated by using mixtures of cell wall-degrading enzymes. In many cases, xyloglucanases are an important component of these cocktails. In apple cell wall degradation, a *Trichoderma reesei* endoglucanase with xyloglucanase activity works particularly well with pectinases (55). The ratio of various endoglucanases in commercial enzyme preparations also deserves attention. It is known for quite some time that cellulose is most efficiently degraded by a mixture of glucanases: endoglucanase and cellobiohydrolase (CBH). The endoglucanase produces new chain termini for the CBH to work on. It is less known that efficient degradation of cell wall-embedded cellulose (i.e., cellulose which is coated with xyloglucan) requires (at least) one more glucanase, namely xyloglucanase. The xyloglucanase increases the accessibility of cellulose by removing its xyloglucan coating (14).

In the previous sections, we have seen that many endoglucanases and XETs can be present in plant tissues. It has been suggested that these enzymes may act in concert during fruit ripening. In this process, the EG generates xyloglucan oligosaccharides, which are subsequently used as acceptor substrates by XET in a polysaccharide-to-oligosaccharide transglycosylation (56). As a result of this, xyloglucan will be more rapidly depolymerized. This rapid breakdown of xyloglucan may be related with fruit softening, although also other enzymes like pectinases are known to play an important role in this process. It is expected that the shelf life of fruits can be extended when these enzyme activities can be kept at a low level. It has also been shown that the level of XET in apple fruit can be an important factor in the liquefaction process. The endogenous XET may act in concert with exogenous (fungal) endoglucanases (57, 58). The endoglucanases generate xyloglucan oligosaccharides on the outside of the apple tissue. These oligosaccharides diffuse into the tissue and serve as acceptor substrates for XET. "High-XET" apple fruit could be processed much faster than "low-XET" apple fruit, because it is degraded from both the inside and the outside during liquefaction. This may explain observations by the industry that the processing time can vary from one fruit batch to another.

Xyloglucans, which are stored in the secondary cell wall of seeds (for instance, tamarind seed), are often used as a viscosifier in the food industry. The gelling

properties of these polysaccharides can be modulated by treatment with  $\beta$ -galactosidase from plant (59) or fungal origin (60). Removal of  $\sim 40\%$  of the galactosyl residues from xyloglucan resulted in self-association of the polymers, and consequently the formation of a gel. These gels have unique properties in that they can be liquefied at low ( $\sim 30^\circ\text{C}$ ) and high temperatures ( $\sim 100^\circ\text{C}$ ); i.e., there are two sol-gel transition points (60). Possibly,  $\alpha$ -xylosidases can also be useful to adjust the gelling properties of xyloglucan. However, at this moment there are no such enzymes with activity toward polymeric xyloglucan.

The special properties of XET have already been mentioned in a previous paragraph. For industrial applications the low activity of (most?) XETs toward xyloglucans with a molecular weight  $< 10 \text{ kDa}$  (approximately eight oligosaccharides) is particularly interesting. These enzymes have the potential to tailor low-viscosity xyloglucan fragments, which still have the ability to bind to cellulose. Possibly, such molecules can be used in the future to engineer cellulose-xyloglucan composites with specific properties (58).

## Enzymes Degrading Rhamnogalacturonan and Xylogalacturonan

Jean-Paul Vincken, Alphons G. J. Voragen, and Gerrit Beldman

*Wageningen University, Wageningen, The Netherlands*

### I. INTRODUCTION

In a previous section of this book (Chap. 66), the structure of pectin was discussed in detail. Besides homogalacturonans (often referred to as the smooth regions of pectin), also branched or hairy regions occur (1). The hairy regions are composed of a collection of polysaccharides: rhamnogalacturonan (RG), xylogalacturonan (XGA), arabinan, and (arabino)galactan. This chapter deals with carbohydrases having activity toward the former two. Both polysaccharides can be referred to as heterogalacturonans. A third heterogalacturonan present in plant cell walls, rhamnogalacturonan II, has a very complex structure. At this moment, no enzymes with activity toward this polysaccharide have been characterized. Homogalacturonan-degrading enzymes, as well as arabinan- and galactan-degrading enzymes, are described elsewhere in this book (Chap. 70).

In comparison with homogalacturonan-degrading enzymes, enzymes with activity toward RG and XGA are newcomers in the field of carbohydrates. Reasons for this are the following: (a) industrial interest in these enzymes has only recently been roused by new fruit juice manufacturing techniques (see further); (b) the enzymes are usually minor components of commercial enzyme preparations used by the food industry; (c) substrates for these enzymes are often difficult to obtain from commercial resources; and (d) the enzymes produce complex mixtures of degradation products, requiring sophisticated analytical tools for

identification. It is expected that the interest in these enzymes will continue to grow, because they may also be important in tailoring bioactive oligosaccharides. With the completion of the *Arabidopsis* genome-sequencing project, plant biologists have obtained clues that homologs of the enzymes discussed in this chapter are also present in plants; these enzymes may be involved in remodeling plant cell wall structure during development.

As a consequence of their fairly recent discovery, the picture of RG- and XGA-degrading enzymes is rather incomplete when compared to that of the more classical pectinases such as endopolygalacturonase (endoPG), endopectin lyase (endoPL), and endopectate lyase (endoPAL). Much less sequence information is available for these enzymes, and systematic studies to delineate the principles underlying their structure-function relationships still have to get started. Pectinases can be assigned to various enzyme families. This family classification is based on similarities in apparent secondary structure characteristics of proteins (<http://afmb.cnrs-mrs.fr/~pedro/CAZY/>) and is updated regularly. In principle, pectinases with very low amino acid sequence identity can be attributed to the same family; i.e., the fold of the proteins seems to be much better conserved than their sequence. Within one family, the catalytic mechanism (retaining or inverting) and the three-dimensional structure of the protein are thought to be similar.

A selection of classes of pectin-degrading enzymes is summarized in Table 1. Enzymes with activity toward

**Table 1** Overview of Galacturonan-Degrading Enzymes<sup>a</sup>

Enzyme	Organism	Fam.	No. entries	Comments
<b>endoPG</b>	<i>Aspergillus niger</i>	GH28	7 <sup>b</sup>	3D structure available
<b>exoPG</b>	<i>Aspergillus tubingensis</i>	GH28	1	Active toward xylogalacturonan
<b>endoXGH</b>	<i>Aspergillus tubingensis</i>	GH28	1	Homologous to endoPG, presumably requires xylosyl sidechains for activity
put. PG	<i>Arabidopsis thaliana</i>	GH28	~ 55	Very limited biochemical data available, sequences cluster in various groups
<b>endoRGH</b>	<i>Aspergillus niger</i>	GH28	2	RGHs differ in the presence of a C-terminal extension, 3D structure of <i>Aspergillus aculeatus</i> RGH is available

<sup>a</sup>Enzymes with activity against rhamnogalacturonan are in boldface. For more details, see text.

<sup>b</sup>Number indicates that family GH28 contains seven different endoPGs from *Aspergillus niger*. EndoPGs from many other species are also members of this family, but these are not shown.

branched galacturonans are shown in boldface. Glycosyl hydrolase family 28 (GH28) is a particularly large family, comprising enzymes with a very divergent substrate specificity. Hydrolases with activity toward homogalacturonan, XGA, and RG are present within this family. Further, GH28 contains many putative proteins from plant origin. An interesting observation is that *Arabidopsis* members of GH28 outnumber those derived from one fungus (e.g., *Aspergillus niger*). It remains to be established whether these *Arabidopsis* proteins represent an array of different pectinases with activity toward the various galacturonan-containing polymers in plants. Surprisingly, galacturonan lyases are distributed over as many as seven different families (L1–L4 and L9–L11). Also in this case the *Arabidopsis* genome-sequencing effort has provided clues on the possible existence of an abundance of plant galacturonan

lyases (L1 and L4). Again, at present the plant enzymes have not been characterized. Despite the large differences in substrate specificity (homogalacturonan, XGA, and RG) and catalytic mechanism (hydrolase versus lyase), it turns out that the three-dimensional structures of pectin-degrading enzymes are very similar (2). All the enzymes investigated so far possess the characteristic right-handed parallel  $\beta$ -helical structure, which has been discussed for homogalacturonan-degrading enzymes elsewhere in this book. In this chapter, we will focus on microbial enzymes, because there are currently no biochemical data available for the plant enzymes. XGA-degrading enzymes will be discussed first, followed by RG-degrading enzymes. Subsequently, a few words will be said on the detection of enzyme activity toward heterogalacturonans. Finally, applications with relevance to the food industry will be discussed.

## II. ENZYMIC DEGRADATION OF XYLOGALACTURONANS

In the literature, there are a number of reports describing a homogalacturonan with  $\beta$ -D-Xylp-(1 → 3) side chains (3, 4). This polysaccharide is referred to as xylogalacturonan (XGA). Besides the xylosyl branches, methoxyl groups can be attached to the O-6 of GalA residues (3). So far, the presence of XGA in plants seems to be confined to reproductive organs (fruits, seeds) (5), such as apple (3), pea (4), and watermelon (6), and to exudates from *Astragalus* trees (7, 8). It seems that the degree of xylosylation of the homogalacturonan backbone can differ with the origin of the XGA. For instance, in apple XGA three out of four GalA residues carry a xylosyl sidechain, whereas in watermelon XGA this is only one out of four. In apple, XGA seems to be covalently linked to RG (3); for other species, this has not been investigated in so much detail.

### A. Exopolygalacturonase

Exopolygalacturonase (exoPG) from *Aspergillus aculeatus* was the first enzyme of which activity toward unesterified XGA was demonstrated (9). This enzyme is not specific for XGA, as (unesterified) homogalacturonans are also degraded, with GalA as the only

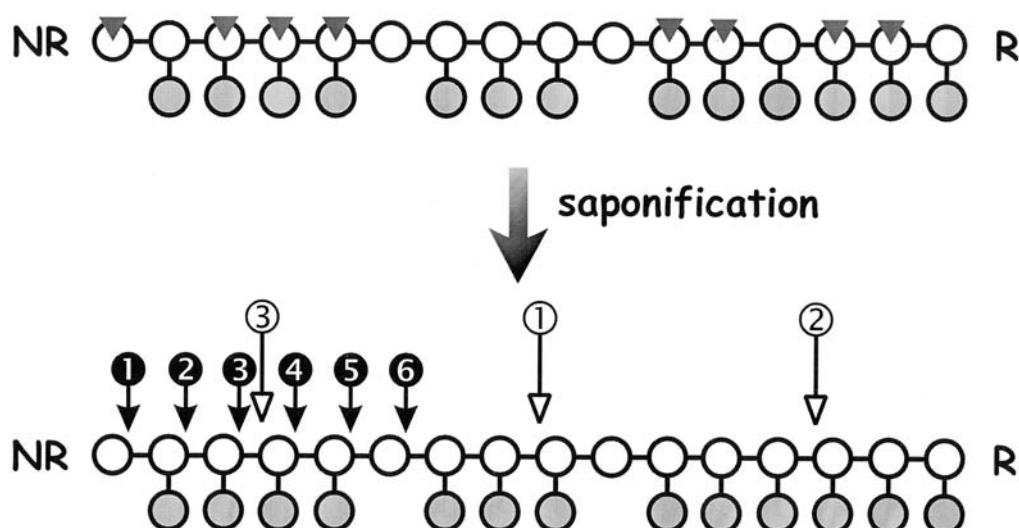

product. The exoPG can release Xyl-GalA disaccharides and monogalacturonic acid from the nonreducing terminus of xylogalacturonan (see Fig. 1). Thus, it seems that the *A. aculeatus* exoPG is tolerant to xylosyl substitution of the homogalacturonan backbone, a feature also encountered in other *Aspergillus* exoPGs (10).

### B. Endopolygalacturonase

EndoPGs can also show activity toward saponified XGA; however, this seems to depend greatly on its degree of xylosyl branching. Apple XGA (saponified) was resistant to all endoPGs tested, including endoPGI and edoPGII from *Aspergillus niger*. The less branched watermelon XGA can be degraded to GalA, GalA<sub>2</sub>, GalA<sub>3</sub>, and a series of Xyl-containing oligogalacturonides by a commercial endoPG preparation (6). Oligogalacturonides with a Xyl:GalA ratio of 1:4 and 1:5 seem to be abundant in the XGA digest. These results suggest that endoPGs are not as tolerant to xylosyl substitution as exoPG. They require a number of contiguous, unbranched GalA residues (presumably more than three) for activity.

### C. Endoxylogalacturonan Hydrolase

Very recently, an endoacting enzyme with activity toward XGA was discovered by screening an

**Figure 1** Schematic illustration of xylogalacturonan degradation by exopolygalacturonase (closed arrowheads) and endoxylogalacturonan hydrolase (open arrowheads). Both enzymes are hindered by the presence of methoxyl groups. Numbers indicate 1st, 2nd, 3rd, etc., cleavage of the substrate by the enzyme. Open circles represent α-D-GalpA residues, shaded circles β-D-Xylp residues, and small closed triangles methoxyl groups. NR indicates the nonreducing end; R, the reducing end.

*Aspergillus tubingensis* expression library in the yeast *Kluyveromyces lactis* (11). A modified gum tragacanth (saponified and treated with dilute acid; Xyl:GalA ratio of 1:2) was used as a substrate, and activity was detected using a reducing end-group assay (12). Amino acid sequence comparisons have shown that endoxylgalacturonan hydrolase (endoXGH) is a GH28 member, just like endoPG, exoPG, and endorhamnogalacturonan hydrolase (endoRGH). Typically, it shares the highest homology with exoPG, which is in accordance with its substrate specificity (11). EndoXGH can degrade saponified apple hairy regions (containing XGA); the disaccharide Xyl-GalA and an unknown oligosaccharide are the main end products of this treatment. Digestion of the modified gum tragacanth results in a complex mixture of many xylosylated oligogalacturonides (11). The low activity of endoXGH toward unesterified homogalacturonan and its much higher activity toward saponified XGA suggest that the enzyme has a requirement for xylosyl side chains (contrary to exoPG, which has a tolerance to xylosyl branches). Therefore, it is believed that endoXGH cleaves XGA between two xylosylated GalA residues (see Fig. 1), but this needs to be further substantiated.

#### D. Other Enzymes

It seems likely that more enzymes exist with activity on XGA. In apple hairy regions, XGA can be highly esterified with methoxyl groups. This polymer can not be deesterified by pectin methylesterase (PME) (3), suggesting that this enzyme is also hindered by xylosyl side chains, just like endoPG (10). At this moment it is unknown whether nature offers PMEs which are tolerant to xylosyl branching. The Xyl-GalA disaccharide can be cleaved by  $\beta$ -xylosidase (10). It is unknown whether this enzyme is also active toward polymeric XGA. Possibly, XGA may become digestible by endoPG after treatment with an appropriate  $\beta$ -xylosidase.

### III. ENZYMIC DEGRADATION OF RHAMNOGALACTURONANS

Rhamnogalacturonan (RG, also referred to as RG-I) is the second heterogalacturonan of which the enzymic degradation is described in this chapter. This polysaccharide can have a backbone composed of as many as 100 repeats of the disaccharide [ $\rightarrow$  2]- $\alpha$ -L-Rhap-(1  $\rightarrow$  4)- $\alpha$ -D-GalpA-(1  $\rightarrow$ ) (5). The rhamnosyl residues can be substituted at O-4 with single unit [ $\beta$ -D-Galp-

(1  $\rightarrow$  4)] or longer neutral sidechains. The latter are often referred to as the “hairs,” and are mainly composed of galactosyl and/or arabinosyl residues. The GalA residues can be acetylated at the O-2 and/or O-3 position. This section will focus on the enzymes which are required to convert RG to its constituent monosaccharides.

#### A. Endoacting Rhamnogalacturonan-Degrading Enzymes

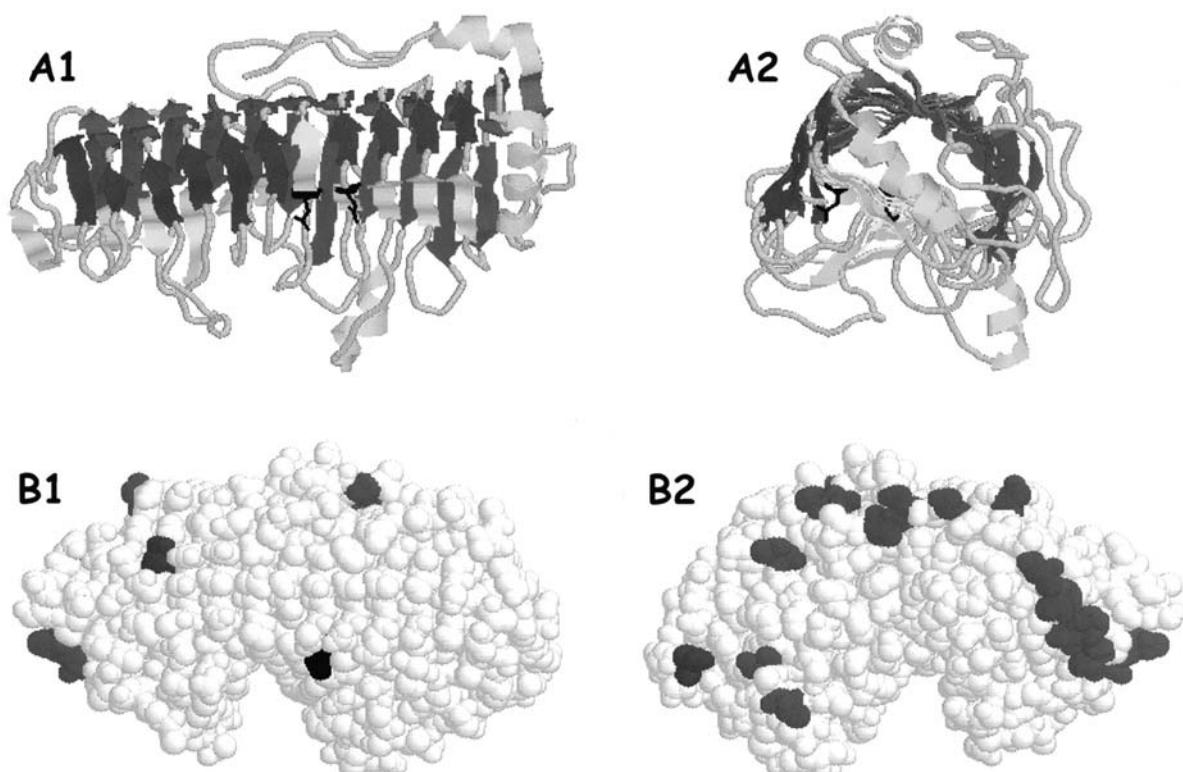

The first rhamnogalacturonan-degrading enzyme was discovered during fractionation of a commercial enzyme preparation derived from *Aspergillus aculeatus* (13). The enzyme acted exclusively on RG, and showed no activity on homogalacturonan. A few years later, this enzyme, as well as another rhamnogalacturonase from *A. aculeatus*, was cloned. The enzymes were termed RGaseA and RGaseB, respectively (14, 15). It appeared that the two enzymes differed in their catalytic mechanism. RGaseA is a hydrolase, meaning that it cleaves the RG backbone with the concomitant uptake of a water molecule. Degradation of RG by RGaseB follows a  $\beta$ -eliminative reaction; a double bond is formed between C-4 and C-5 of the nonreducing GalA residues of the reaction products (16, 17). This reaction can be monitored spectrophotometrically at 235 nm. Therefore, RGaseA and RGaseB were renamed to endorhamnogalacturonan hydrolase (endoRGH) and endorhamnogalacturonan lyase (endoRGL), respectively. Thus, it seems that fungi have acquired a similar set of enzymes for RG degradation as for that of homogalacturonan (endoPG, endoPAL, endoPL).

Over the years, a number of new sequences have been added to the sequence databases. The GH28 family contains four entries of endoRGHs: the one from *A. aculeatus* (14, 15); rhgA and rhgB from *A. niger* (18); and one from *Botryotinia fuckeliana* (19). Note that *A. niger* rhgB is not related to *A. aculeatus* RGaseB. Comparison of the primary structure of the enzymes reveals a number of regions, some of which are pectinase specific, and some of which are endoRGH specific (19). Typically, rhgB from *A. niger* and endoRGH from *B. fuckeliana* contain C-terminal extensions, which are not present in the two other RGHs. It is currently unknown whether this extension affects the properties of the enzymes. The endoRGLs have so far been assigned to two polysaccharide lyase families. The *A. aculeatus* endoRGL belongs to family L4, whereas the recently discovered *Pseudomonas cellulosa* endRGL forms a new family

(L11), together with the uncharacterized proteins YesW and YesX from *Bacillus subtilis*, and PSP from *Streptomyces coelicolor* (20). It is interesting to note that the *P. cellulosa* endoRGL is equipped with a cellulose-binding module, which is very uncommon for pectinases. The significance of this is unknown. The *P. cellulosa* endoRGL differs from the one from *A. aculeatus* in having a higher pH optimum (9.5 vs. 6) and an absolute requirement for  $\text{Ca}^{2+}$ .

The three-dimensional structure of the *A. aculeatus* endoRGH has been solved (21), and appears to be very similar to that of other pectinases (2). EndoRGH folds into a large right-handed parallel  $\beta$  helix (four parallel  $\beta$  sheets), with a core composed of 13 turns of  $\beta$  strands (see Fig. 2) (21). The potential active site is a groove, oriented almost perpendicular to the helical axis. Four amino acids with acidic side chains are located in the groove. Of these, Asp156 and Asp180

are presumably the catalytic ones. The distance between Asp156 and Asp180 is  $\sim 10\text{\AA}$ , which is consistent with the spacing between catalytic residues generally found for inverting enzymes. Another striking feature of endoRGH is its high degree of glycosylation. The enzyme contains almost 6 kDa of carbohydrates on a total molecular mass of 52 kDa. As a result of this, endoRGH is highly water soluble. *N*-glycan trees [ $\text{Man}\alpha 1\text{-}6(\text{Man}\alpha 1\text{-}3)\text{Man}\beta 1\text{-}4\text{GlcNAc}\beta 1\text{-}4\text{GlcNAc}$ ] are linked to Asn32 and Asn299. The C-terminus of the molecule (amino acid residues 367–422) contains all *O*-linked glycosylation sites (Thr, Ser), which are monosubstituted with mannosyl residues. Figure 2 clearly shows that the glycosylation sites are not uniformly distributed over the enzyme. Despite the fact that the structure of endoRGH has been solved, the important question of which structure-function relationships determine whether an GH28 member has

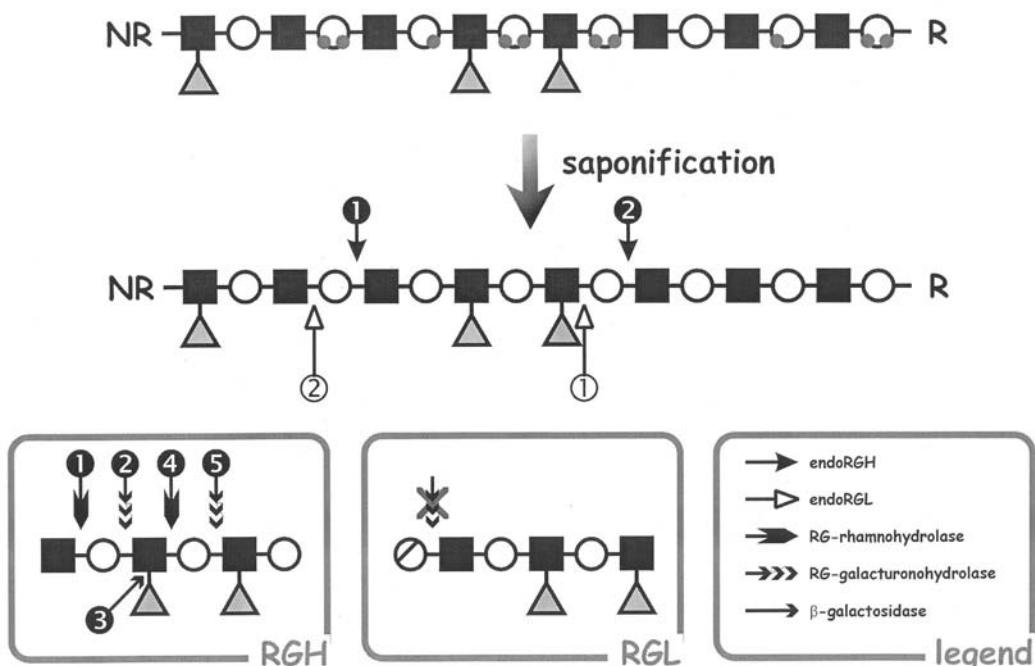

**Figure 2** The three-dimensional structure of *A. aculeatus* endoRGH. (A1) Cartoon indicating the four parallel  $\beta$  sheets; the putative catalytic amino acids, Asp156 and Asp180, are indicated as black “sticks.” (A2) View into the superhelix of the molecule at a 90° rotation to A1. (B1) Space-filling model of endoRGH (similar view as with cartoon A1) clearly showing the substrate-binding groove of the enzyme in which the catalytic residues (in black, only one visible) are located. The illustration also shows that endoRGH is heavily glycosylated. Amino acids with *O*-linked glycosylation (Thr, Ser) and those with *N*-linked glycosylation (Asn) are shown in black. (B2) View of endoRGH at a 180° rotation to B1 to show that glycosylation is confined to one side of the molecule.

endoPG or endoRGH activity remains to be answered. At this moment, no structural information is available for endoRGL.

Detailed structural characterization of reaction products has shown that endoRGH and endoRGL cleave the RG backbone at different positions (17, 22–24). The oligomeric products of *A. aculeatus* endoRGH consist of two or three Rhap-GalpA disaccharide units, with a rhamnosyl at the nonreducing end and a galacturonosyl residue at the reducing end (22, 23). The rhamnosyl residues can be substituted with single units of galactose. The two *A. niger* endoRGHs release a similar set of oligosaccharides from saponified hairy regions (this is a RG preparation containing arabinan and galactan side chains, after treatment with alkali to remove acetyl groups) as the *A. aculeatus* enzyme (18), but the ratio between the various oligosaccharide products is different for the three enzymes. It seems as if *A. niger* rhgB accumulates the largest products of the three endoRGHs, including a number of larger oligosaccharides that have not yet been characterized. The oligosaccharides produced by *A. aculeatus* endoRGL differ from those formed by endoRGH in that they contain an unsaturated GalpA residue ( $\Delta 4,5\text{GalpA}$ )

at the nonreducing end, and a Rhap at the reducing terminus (17, 24). Similar products are released from saponified hairy regions by the *P. cellulosa* rgl11A (20). In addition, this enzyme seems to produce smaller fragments, presumably with a  $\Delta 4,5\text{GalpA-Rhap}$  disaccharide backbone. The difference in specificity of endoRGH and endoRGL are illustrated in Figure 3.

From the formation of oligomeric products discussed above, it might be concluded that endoRGH and endoRGL are active toward a similar part of the RG backbone. However, it is possible that the various RG-degrading enzymes recognize parts of the backbone. When the same saponified hairy regions are degraded with various RG-degrading enzymes, different shifts in the molecular-weight distribution of the polymeric products are evidenced (14, 20). Removal of the arabinan hairs from saponified hairy regions increased the catalytic efficiency of *A. aculeatus* endoRGL, whereas removal of galactan hairs decreased the efficiency (24). The *P. cellulosa* rgl11A can degrade a galactosylated oligosaccharide with a  $[\text{Rhap-GalpA}]_3$  backbone, whereas this oligosaccharide is not degraded anymore after treatment with a  $\beta$ -galactosidase (20). These examples show that side

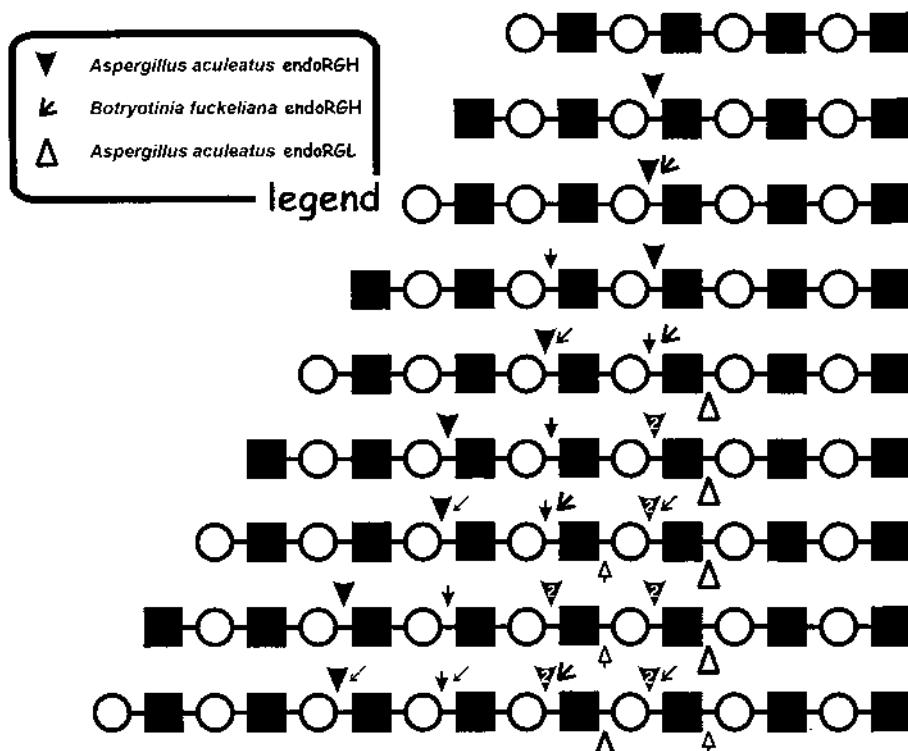

**Figure 3** Schematic illustration of enzymes involved in the degradation of rhamnogalacturonan. Both endoRGH and endoRGL are hindered by the presence of acetyl groups. Numbers indicate 1st, 2nd, 3rd, etc., cleavage of the substrate by the enzyme. Open circles represent  $\alpha$ -D-GalpA residues, closed boxes  $\alpha$ -L-Rhap residues, shaded triangles  $\beta$ -D-Galp, and small shaded circles acetyl groups. NR indicates the nonreducing end; R, the reducing end.

chains may play an important role in molecular recognition. The various RG-degrading enzymes may differ considerably in their *tolerance to side chains*, or they may even have a *requirement for side chains*.

From a quantitative analysis of the total number of polymeric and oligomeric reaction products the number of splits an enzyme makes per encounter with its substrate can be estimated. It appears that endoRGH and endoRGL from *A. aculeatus* differ in their degree of multiple attack: 4.0 and 2.5, respectively (24). This implies that endoRGL is a more "randomly acting" (or less processive) enzyme than endoRGH. Linear RG oligosaccharides have been used to further substantiate the *mode of action* of RG-degrading enzymes. Such substrates can be prepared by treating pectin with dilute acid, and subsequent fractionation of the forthcoming fragments by chromatography (25).

The linkage between Rha and GalA is more easily hydrolyzed by acid than the one between GalA and Rha. As a result of this, the linear RG oligosaccharides carry a rhamnosyl residue at their reducing terminus.

Figure 4 summarizes the mode of action of three different enzymes toward linear RG oligosaccharides of different length. Both endoRGHs require a backbone of at least nine or ten glycosyl residues for activity, whereas endoRGL requires longer ones (12 glycosyl residues). The *A. aculeatus* endoRGH prefers to cleave four or five glycosyl residues away from the nonreducing terminus of the oligosaccharide, and shows multiple attack toward the substrates offered (26). The *B. fuckeliana* enzyme cleaves five or seven glycosyl residues away from the reducing terminus of the substrates (19). The activity of this enzyme is distributed over a number of linkages, instead of consistently attacking the same linkage of a particular substrate (see Fig. 4). In this case, it may be more appropriate to speak of bond cleavage frequencies. The *B. fuckeliana* endoRGH does not show processivity. The *A. aculeatus* endoRGL prefers to cleave the smaller substrates four residues from the reducing rhamnose. The longest oligosaccharide (DP 16) is cleaved at 6 units from the reducing terminus. These examples demonstrate that

**Figure 4** Mode of action of *Aspergillus aculeatus* and *Botryotinia fuckeliana* endoRGH and *Aspergillus aculeatus* endoRGL on degalactosylated rhamnogalacturonan oligosaccharides of various length. Thick arrows indicate preferred cleavage sites; less preferred sites are indicated with thinner arrows. Closed arrowheads marked with "2" indicate the second cleavage site of the enzyme. Open circles represent  $\alpha$ -D-GalpA residues; and closed boxes  $\alpha$ -L-Rhap residues.

RG-degrading enzymes can differ considerably in their mode of action.

### B. Rhamnogalacturonan Rhamnohydrolase

RG-rhamnohydrolase was purified from a commercial pectinase preparation (27). Characteristic of this enzyme is its absolute preference for terminal rhamnosyl residues (1,4)-linked to  $\alpha$ -galacturonosyl residues (see Fig. 3). The enzyme was unable to split *p*-nitrophenyl- $\alpha$ -rhamnoside. The RG-rhamnohydrolase can degrade the products formed by endoRGH, together with the enzymes mentioned in the following paragraphs. Prior to the action of the rhamnohydrolase, removal of galactosyl residues from the RG oligosaccharides is required. At this moment, no sequence information on this enzyme is available, and consequently the enzyme has not been attributed to a glycosyl hydrolase family. The enzyme acts with inversion of the anomeric configuration (28).

### C. Rhamnogalacturonan Galacturonohydrolase

The RG-galacturonohydrolase can act in concert with RG-rhamnohydrolase in the degradation of products released from hairy regions by endoRGH (see Fig. 3). This enzyme has a striking specificity for the release of galacturonosyl residues from the nonreducing end of RG oligosaccharides (29). Oligogalacturonides were not degraded by the enzyme. Also, no activity was detected toward the products released from hairy regions by endoRGL, showing that the enzyme is unable to release  $\Delta$ 4,5GalpA residues. From kinetic experiments with linear RG oligosaccharides it could be concluded that low-molecular-weight substrates were hydrolyzed with the highest catalytic efficiency. At this moment, no sequence information for RG-galacturonohydrolase is available, and it is therefore unknown whether this enzyme has homology with for instance exoPG. The initial product of hydrolysis was  $\beta$ -galacturonic acid, showing that RG-galacturonohydrolase is an inverting enzyme (28).

### D. Synergism in Rhamnogalacturonan Degradation

Many enzymes are involved in the degradation of hairy regions. Endogalactanase, endoarabinanase, arabinofuranosidase, and  $\beta$ -galactosidase may all facilitate the action of RG-degrading enzymes, as has been indicated in the paragraphs above. These enzymes are dealt with in more detail elsewhere in this book.

Another important enzyme for the degradation of RG in its natural setting is RG acetyl esterase (RGAE). This enzyme specifically can remove 70% of the acetyl groups present in hairy regions; acetyl esters present in homogalacturonans are not hydrolyzed (30). Acetyl groups hinder the action of both *A. aculeatus* endoRGH and endoRGL. When hairy regions are incubated with a combination of endoRGH and RGAE, a more extensive decrease of the molecular weight is found than with endoRGH alone (31). Similar results were obtained with endoRGL. RGAE is discussed in more detail in the esterase section of this book (Chap. 67).

## IV. DETERMINATION OF ENZYME ACTIVITY ON HETEROGLACTURONANS

Many different assays can be used for studying conversion of rhamnogalacturonans. Simple reducing end-group analysis can point out whether enzymes or enzyme extracts contain RG-degrading activity. In the case of lyase activity, spectrophotometric measurements at 235 nm is a convenient option (17, 24). High-performance size exclusion chromatography (HPSEC) with refractive index (RI) detection may be used to determine differences in molecular-weight distributions (13, 14). High-performance anion exchange chromatography (HPAEC) with an electrochemical detection unit is suitable for monitoring the release of oligosaccharides from a polymer (14, 23, 24). Appropriate reference oligosaccharides cannot be obtained commercially, and should be purified by oneself. Mass spectrometry (MS) is a very useful tool in structural elucidation of reaction products. In particular, liquid chromatography/tandem mass spectrometry (LC-MSMS) in combination with  $^{18}$ O-labeling of reaction products may detect differences in mode of action between two rhamnogalacturonases. In this case, incubations are done in the presence of  $^{18}$ O-labeled water; tandem-MS is used to "sequence" the individual oligosaccharides (32).

## V. APPLICATIONS IN THE FOOD INDUSTRY

Degradation of branched pectins, hairy regions, or heterogalacturonans is at this moment probably

mainly applied in fruit juice manufacturing, in particular when the juice is made by the so-called liquefaction process (33). In this process, fruit cell walls are extensively degraded by a mixture of pectinases, hemicellulases, and cellulases. Eventually, the cells cannot withstand the osmotic pressure anymore, and collapse. The cell content (juice) is thus released without pressing, and can be obtained by centrifugation. A final clarification step is done by ultrafiltration. Besides enormous economical benefits (juice yields up to 100%), this process has also introduced some new technological problems, which are mainly due to the fact that more soluble cell wall fragments are released into the juice. A serious problem in the liquefaction process is the membrane fouling during the final clarification step. In apple juice manufacturing, polymeric cell wall material accumulates at the membrane, and consequently the flux through the membrane is reduced.

The material causing the fouling consists predominantly of hairy regions. Experiments in our laboratory have shown that addition of endoXGH, endoRGH, and endoRGL (and RGAE) helps in maintaining the flux through ultrafiltration membranes, and minimizing the fouling (34). The exoPG, RG-rhamnoglycuronohydrolase, and RG-galacturonohydrolase are less important in this respect. It has also been suggested that RG-degrading enzymes are useful for the production of cloudy apple juices and carrot macerates (35).

For the near future, it is anticipated that RG-degrading enzymes will become more important. A potential application may be the production of tailor-made bioactive RG fragments. Japanese studies suggest that pectic fragments, RG in particular, have an array of health-promoting effects (36). At this moment, efforts are directed toward unraveling the carbohydrate epitopes, which are important for certain health claims. With the various endo-type enzymes, specific structures may be generated which might be modified with appropriate glycosidases. Undoubtedly, the heterogalacturonan-specific exoenzymes will be more important in this application than in juice manufacturing. Further, it is interesting to note that soy pectin is different from that of other plants (37). Soy pectin does not seem to contain homogalacturonan, but instead consists exclusively of RG and XGA. Soy is an extremely important raw material for human and animal nutrition. We know that application of the enzymes described in this chapter is insufficient to open up the cell wall

structure of this plant material. Novel auxiliary enzymes remain to be discovered for improving the recovery of valuable nutrients from soy.

## Enzymic Hydrolysis of Cereal (1 → 3,1 → 4)- $\beta$ -Glucans

Maria Hrmova and Geoffrey Fincher

*University of Adelaide, Glen Osmond, South Australia, Australia*

### I. INTRODUCTION

The (1 → 3, 1 → 4)- $\beta$ -glucans are important components of cell walls in members of the Poaceae family of higher plants (1). The (1 → 3, 1 → 4)- $\beta$ -glucans consist predominantly of long, linear chains of glucosyl residues that are linked via (1 → 3)- and (1 → 4)- $\beta$ -glucosidic linkages; small amounts of protein may be associated with the polysaccharide (2). Although their distribution in higher plants is restricted to cell walls of the Poaceae, the (1 → 3, 1 → 4)- $\beta$ -glucans are constituents of most human diets and many animal feed formulations, because the Poaceae include key cereal species, such as wheat, rice, maize, barley, rye, sorghum, and millet. As cell wall components, the (1 → 3, 1 → 4)- $\beta$ -glucans usually make a relatively minor contribution to the total weight of cereal grains, but they can have a disproportionately large impact on grain technology, utilization, and nutrition. This impact is largely attributable to the propensity of these polysaccharides to be extracted from walls with aqueous solvents and thereafter to form solutions of high viscosity. Thus, in baking with cereal flours, the (1 → 3, 1 → 4)- $\beta$ -glucans and other wall polysaccharides will influence dough rheology, and in malting and brewing they can adversely affect the efficiency of malt extraction, filtration processes, and the quality of the final beer. Similarly, (1 → 3, 1 → 4)- $\beta$ -glucans can have undesirable effects on the digestibility of cereal-based stockfeeds by monogastric animals such as pigs and poultry. In contrast, they are important constitu-

ents of the “dietary fiber” component of human foods, which is considered to be of salutary importance in several areas of human digestion and health (3).

Against this background, we will describe in this chapter the enzymes that are responsible for the complete depolymerization of cereal (1 → 3, 1 → 4)- $\beta$ -glucans to glucose. This description will be focused on well-characterized enzymes from germinated grain and young seedlings of barley and maize and is likely to be equally relevant to the hydrolysis of (1 → 3, 1 → 4)- $\beta$ -glucans from wheat, rice, and other cereals. Finally, we will present selected examples that illustrate how a detailed understanding of enzyme structures and substrate specificities can provide opportunities for the manipulation of commercially important enzymes via newly emerging technologies, which can be used to enhance performance of these enzymes in the food industry.

### II. STRUCTURE AND PROPERTIES OF CEREAL (1 → 3,1 → 4)- $\beta$ -GLUCANS

Before embarking on a description of (1 → 3, 1 → 4)- $\beta$ -glucan endo- and exohydrolases, it is necessary to provide a little more information on the structure and properties of the polysaccharide itself. This information will be important in subsequent discussions on substrate specificity and substrate binding of individual enzymes that are involved in (1 → 3, 1 → 4)- $\beta$ -glucan depolymerization.

## A. Cell Walls of the Poaceae

In the primary cell walls of higher plants, a network of cellulosic microfibrils is embedded in a matrix which consists mainly of polysaccharides, but may also contain a secondary network of structural proteins (1, 4, 5). Matrix-phase polysaccharides include xyloglucans, heteroxylans, and pectic polysaccharides. Cell walls of the Poaceae are characterized by a matrix phase which consists predominantly of (1 → 3, 1 → 4)- $\beta$ -glucans and arabinoxylans; xyloglucans and pectic polysaccharides are relatively less abundant than they are in walls of many dicotyledonous plants (1, 4). The major wall polysaccharides found in the starchy endosperm of various cereal grains are compared in Table 1, where it can be seen that (1 → 3, 1 → 4)- $\beta$ -glucan content generally ranges from trace amounts to 75% of the wall, and from 0.1% to 8% of total grain weight.

## B. Chemical Properties of Cereal (1 → 3, 1 → 4)- $\beta$ -Glucans

In considering the chemical structures of cereal (1 → 3, 1 → 4)- $\beta$ -glucans it must be remembered that these polysaccharides occur as a heterogeneous family with varying molecular sizes and fine structural features. However, several (1 → 3, 1 → 4)- $\beta$ -glucan fractions have been characterized in detail, and their overall structures are similar, if not identical. The (1 → 3, 1 → 4)- $\beta$ -glucans from oats, wheat, and barley generally contain ~70% (1 → 4)- $\beta$ -glucosyl residues and 30% (1 → 3)- $\beta$ -glucosyl residues (7, 8). Adjacent (1 → 3)- $\beta$ -glucosyl residues are seldom if ever detected in these polysaccharides, but the single (1 → 3)- $\beta$ -glu-

cosyl residues are separated by variable numbers of adjacent (1 → 4)- $\beta$ -glucosyl residues.

In 90% of cases, the single (1 → 3)- $\beta$ -glucosyl residues are separated by two or three adjacent (1 → 4)- $\beta$ -glucosyl residues, as shown in Figure 1, but up to 10% of the water-soluble (1 → 3, 1 → 4)- $\beta$ -glucan from barley consists of blocks containing four to 14 contiguous (1 → 4)-glucosyl residues (9). Similar "cellulosic" blocks of adjacent (1 → 4)- $\beta$ -glucosyl residues are detected in (1 → 3, 1 → 4)- $\beta$ -glucans from oats (11). The linkage sequence in barley (1 → 3, 1 → 4)- $\beta$ -glucans has been studied at two levels. At the first level, the absence of adjacent (1 → 3)- $\beta$ -glucosyl residues indicates that (1 → 3)- and (1 → 4)-linkages are arranged nonrandomly, because if 30% of  $\beta$ -glucosyl residues are (1 → 3)-linked, one would expect to find frequent blocks of two or more advance (1 → 3)- $\beta$ -glucosyl residues. At the second level, however, mathematical analyses of the arrangement of the blocks of two or three adjacent (1 → 4)- $\beta$ -glucosyl residues, which together account for ~90% by weight of the polysaccharide, shows that these "cellotriosyl" and "cellotetraosyl" blocks (Fig. 1) are randomly distributed (10).

## C. Physical Properties of Cereal (1 → 3, 1 → 4)- $\beta$ -Glucans

Estimates of molecular masses of cereal (1 → 3, 1 → 4)- $\beta$ -glucans vary widely, mainly because of the different polysaccharide fractions that have been examined and because of the different methods used to determine molecular mass values. Sedimentation equilibrium ultracentrifugation indicates that water-soluble

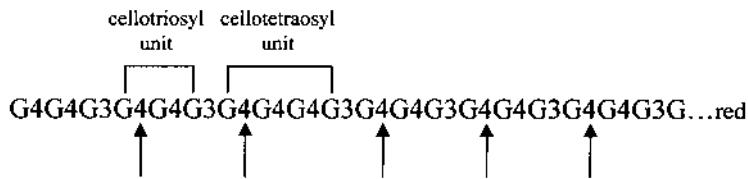

**Table 1** Relative Abundance of (1 → 3, 1 → 4)- $\beta$ -Glucans in Cereal Grains and in Cell Walls from the Starchy Endosperm

Cereal species	Overall (1 → 3, 1 → 4)- $\beta$ -glucan content <sup>a</sup> (% grain weight)	Approximate cell wall composition					
		(1 → 3, 1 → 4)- $\beta$ -Glucan	Arabinoxylan	Pectin	Glucomannan	Xyloglucan	Cellulose

Source: Ref. 6.

**Figure 1** Distribution of linkages in barley ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucans. G =  $\beta$ -glucosyl residues; 3 = ( $1 \rightarrow 3$ )-linkages; 4 = ( $1 \rightarrow 4$ )-linkages; red = reducing end; arrows = sites of hydrolysis by ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan endohydrolases (EC 3.2.1.73). (From Ref. 10.)

barley ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucans have weight average molecular weights in the range 200,000–300,000 (12, 13). These values correspond to polysaccharides containing 1200–1800 glucosyl residues.

The high viscosities of cereal ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan solutions can be attributed not only to the high molecular masses of the polysaccharides, but also to their high degree of molecular asymmetry (Fig. 2). Woodward et al. (9) showed that the water-soluble barley ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan has an axial ratio (average length:average width) of  $\sim 100$ . It might be anticipated that such long, extended molecules would aggregate and precipitate from aqueous solution. However, the irregular spacing of the ( $1 \rightarrow 3$ )-linkages along the polysaccharide chain introduces irregularly spaced links that preclude extensive intermolecular associations and prevent precipitation from solution. Thus, the arrangement of the ( $1 \rightarrow 3$ )- and ( $1 \rightarrow 4$ )- $\beta$ -glucosyl residues along the polysaccharide chain accounts for the solubility of large ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan molecules in water, their extended flexible chain conformations, and their tendency to form aqueous solutions of high viscosity (6). It is precisely these properties that enable relatively low abundance ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucans to exert such a large influence on cereal grain utilization in food and related industries.

### III. OVERVIEW OF ENZYMIC HYDROLYSIS OF ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -GLUCANS

Enzymes that mediate the depolymerization of wall-bound ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucans and their degradation products have been mostly extracted from germinated barley grain, young barley seedlings, or maize or barley coleoptiles. Several different types of enzymes would be required to completely depolymerize ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucans to glucose. Candidate enzymes and their action patterns are summarized in Figure 3. In germinated

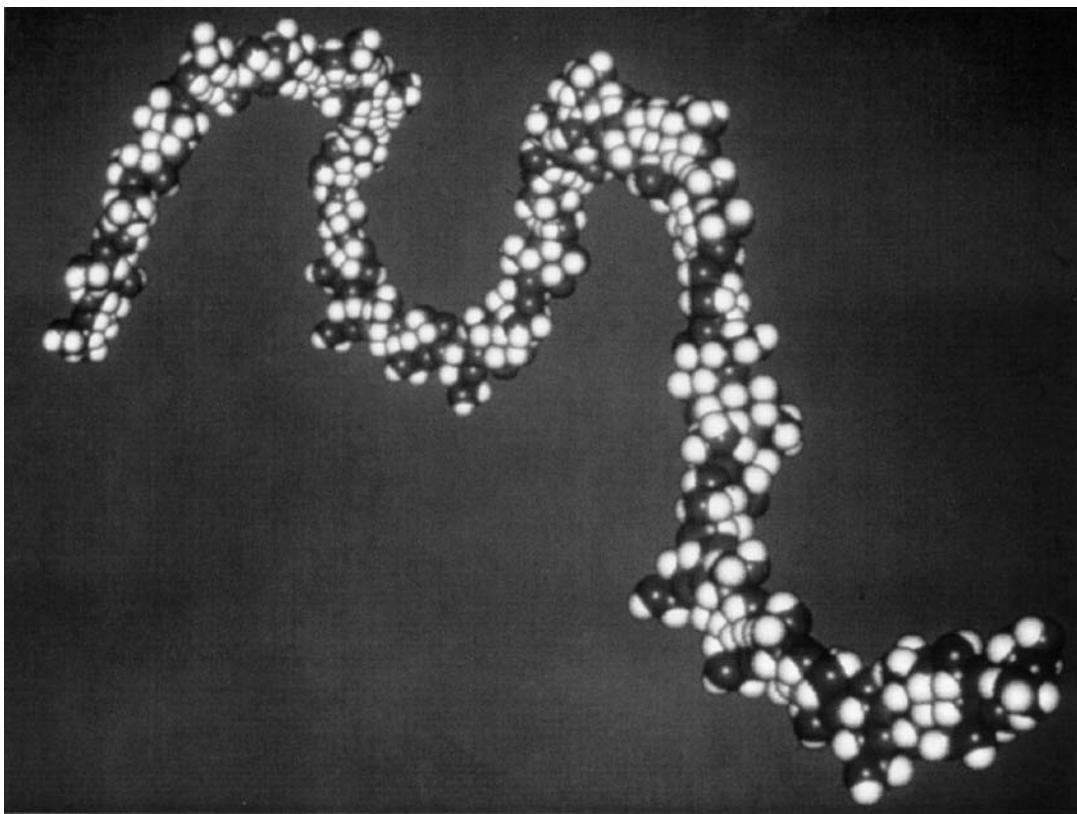

grain, where a significant proportion of total endosperm glucosyl residues are embodied in cell wall ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan (15), it might be expected that a battery of enzymes would catalyze the complete conversion of the polysaccharide to glucose, which could be translocated as an energy source to the developing seedling. In elongating coleoptiles, only partial hydrolysis of the ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan might be required to “loosen” crosslinking polysaccharides in the wall during turgor-driven cell expansion.

#### A. Enzymes That Release Large Fragments of ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -Glucans

The first step involves a hypothetical endoacting enzyme (designated Endo-X in Fig. 3) that releases polymeric wall ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan into solution, without hydrolyzing it to low-molecular-mass oligosaccharides. An enzyme with this action pattern in germinated barley grain has been the subject of persistent reports in the malting and brewing literature, and has been given the name  $\beta$ -glucan solubilase (16). The enzyme has not yet been purified for detailed characterization, and in one report it was suggested that the enzyme originated from microorganisms that reside on the surface of the barley grain (17). However, another ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan endohydrolase extracted from maize coleoptiles also releases relatively high-molecular-mass ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan from cell walls (18). It is unlikely that the maize coleoptiles would be heavily contaminated with microorganisms. Furthermore, the NH<sub>2</sub>-terminal sequence of the maize endohydrolase (19) matches the sequences of numerous cDNAs in the rice and maize EST databases, and is clearly of plant origin.

#### B. ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -Glucan Endohydrolases

Much more precise information is available for the ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan endohydrolases of the EC

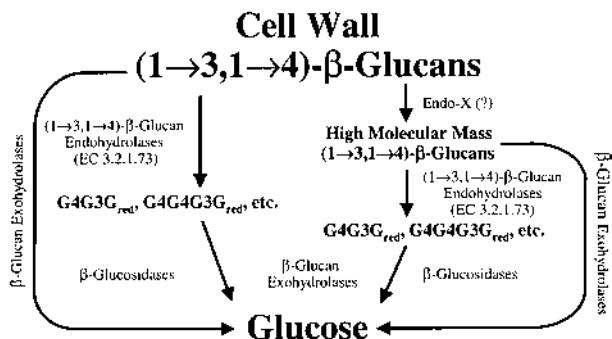

**Figure 2** Computer-generated instantaneous conformation of barley (1 → 3, 1 → 4)- $\beta$ -glucan. (From Ref. 14.)

3.2.1.73 group. These enzymes catalyze the hydrolysis of (1 → 4)- $\beta$ -glucosyl linkages but only where these linkages are immediately adjacent, on the reducing terminal side, to (1 → 3)- $\beta$ -glucosyl residues (Fig. 1). Thus, the (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases of this group have a strict requirement for adjacent (1 → 3)- and (1 → 4)- $\beta$ -glucosyl residues (Fig. 1), and the enzymes release a series of oligosaccharides that contain (1 → 4)- $\beta$ -glucosyl residues and a single (1 → 3)- $\beta$ -glucosyl residue at the reducing terminus (Figs. 1, 3). Tri- and tetrasaccharides are the most abundant products of hydrolysis, but higher oligosaccharides of up to 10 or more (1 → 4)- $\beta$ -glucosyl residues, again with a single reducing terminal (1 → 3)- $\beta$ -glucosyl residue, are released from the cellulosic regions of cereal (1 → 3, 1 → 4)- $\beta$ -glucans (20, 21). The (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases are abundant in germinated cereal grains (20, 22), where they are clearly key enzymes in the degradation of cell walls of the starchy endosperm. They are also detected in young leaves and roots, but are not detected in elongating barley coleoptiles (23).

### C. Hydrolysis of Oligosaccharides

The (1 → 3, 1 → 4)- $\beta$ -oligoglucosides released by (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases can be further hydrolyzed to glucose (Fig. 3). This process will be particularly important in the germinated grain. The enzymes responsible for the hydrolysis of the (1 → 3, 1 → 4)- $\beta$ -oligoglucosides have not been identified unequivocally, although  $\beta$ -glucosidases (EC 3.2.1.21) and a group of broad-specificity  $\beta$ -glucan exohydrolases are likely to be involved (Fig. 3). The latter enzymes can hydrolyze not only the (1 → 3, 1 → 4)- $\beta$ -oligoglucosides but also polymeric (1 → 3, 1 → 4)- $\beta$ -glucans and other polysaccharides (18, 24, 25).

Because the substrate specificities, action patterns, and three-dimensional structures of the (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases, the  $\beta$ -glucosidases, and the  $\beta$ -glucan exohydrolases are now well defined, these will be discussed individually and in detail in the sections below. However, the definition of these enzymic properties depends on the availability

**Figure 3** Enzymic hydrolysis of cell wall  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucans. For explanation see text in Section III. Symbols are as described in legend to Figure 1.

of highly purified enzyme preparations and a range of additional analytical techniques. Some methodological strategies for the purification and characterization of  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan hydrolases are outlined in the next section.

#### IV. EXPERIMENTAL APPROACHES TO ENZYME CHARACTERIZATION

##### A. Enzyme Purification and Assay Procedures

The development of a protocol for the preparation of highly purified enzyme is considered of paramount importance for studies on the enzymic hydrolysis of cereal  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucans. Enzymes extracted from germinated barley grain and elongating coleoptiles are generally amenable to purification by fractional precipitation with ammonium sulfate, cation and/or anion exchange chromatography, and size exclusion chromatography (18, 24, 26, 27), but additional steps involving hydrophobic interaction chromatography, chromatofocusing, or affinity chromatography are usually required to achieve high levels of purity.

Enzyme purity can be rigorously demonstrated through gel electrophoresis, provided sufficient enzyme is loaded onto the gel. A single protein band on an overloaded gel, and NH<sub>2</sub>-terminal amino acid sequence that shows a single sequence at the expected yields, are sound complementary procedures through which enzyme purity can be confidently assessed.

Another potential complication during the purification of cereal  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan hydrolases is that assay systems may not be specific for a particular enzyme type. Thus, the cereal  $\beta$ -glucan exohydro-

lases hydrolyze polymeric  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucans,  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -oligoglucosides, 4'-nitrophenyl  $\beta$ -glucoside (4NPG), and a range of other oligo- and polysaccharides (25). The  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolases are absolutely specific for  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucans. Putative  $\beta$ -glucosidases hydrolyze not only 4NPG, but also  $(1 \rightarrow 4)$ - $\beta$ -oligoglucosides (27). During the early stages of purification, it may therefore be necessary to assay column fractions with a number of substrates in order to monitor the activity of a particular glucan endo- and/or exohydrolase. Huber and Nevins (28) specifically measured the maize coleoptile  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase by adding HgCl<sub>2</sub> to the cereal  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan substrate; HgCl<sub>2</sub> inhibits the  $\beta$ -glucan exohydrolases, but not the endohydrolases.

##### B. Problems with Enzyme Classification

The broad specificity of certain cereal  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan hydrolases not only presents problems for the selection of a diagnostic substrate during purification and characterization, as described above, but also creates problems for the classification of the enzyme into existing Enzyme Commission categories (29). Thus, the cereal  $\beta$ -glucan exohydrolases have such a broad specificity that they do not fit any EC classification.

Similarly, cereal  $\beta$ -glucosidases are difficult to place in existing EC categories (27), because they hydrolyze cello-oligosaccharides at significantly higher rates than synthetic aryl  $\beta$ -glucosidic substrates such as 4NPG. Partly because of these difficulties, a new method for the classification of glycoside hydrolases has gained considerable support in recent years. This method is based on sequence alignments and hydrophobic cluster analysis (HCA) (30), and has been used to group the glycoside hydrolases into ~90 families (<http://afmb.cnrs-mrs.fr/CAZY>) (31). It is becoming clear that HCA is particularly useful for identifying similarities in enzymes for which amino acid sequence similarities are relatively low, and that members of each family have similar three-dimensional conformation (32). Thus, the “structural” classification provided by HCA usefully complements the EC “substrate specificity” classification. For example, the HCA method shows that  $\beta$ -glucosidases can be classified into families 1 and 3, and this further emphasizes the inadequacies of designating an enzyme as a  $\beta$ -glucosidase simply because it hydrolyzes the synthetic substrate of convenience, 4NPG (27).

### C. Primary Structures of Enzymes

Preliminary amino acid sequence information can be obtained by direct NH<sub>2</sub>-terminal sequencing of the purified enzyme or by sequencing peptides generated from the purified enzyme by peptidase digestion. To define the complete primary structure of the enzyme it is usually necessary to isolate and sequence a corresponding cDNA. If the amino acid sequence deduced from the nucleotide sequence of the cDNA exactly matches the NH<sub>2</sub>-terminal and peptide amino acid sequences determined directly from the purified enzyme, then the primary structure of the enzyme can be considered solved. However, it is often at this stage that we discover that multiple isoforms of an enzyme exist. Indeed, most enzymes involved in cereal (1 → 3, 1 → 4)- $\beta$ -glucan hydrolysis are encoded by multigene families, and care must be taken to define exactly which isoenzyme is under examination.

### D. Specificity and Action Pattern

Once the purity of an enzyme is clearly established, its activity on a broad range of alkyl and aryl  $\beta$ -glucosidic substrates, oligosaccharides, and polysaccharides can be checked quickly and easily. Analysis of the products released during hydrolysis by thin-layer chromatography or other simple procedures will reveal whether the enzyme exhibits an endo- or an exohydrolytic pattern. Proton NMR can be used to measure the anomeric configuration of released reducing-end monosaccharide residues, and hence to classify the particular enzyme into “retaining” or “inverting” groups (27, 33).

### E. Three-Dimensional Structures

Perhaps the ultimate data that allow catalytic mechanisms, substrate specificity, and substrate binding to be defined in precise molecular terms are provided by detailed knowledge of the 3D structure of the enzyme of interest. Furthermore, 3D structural information can quickly reveal rational design opportunities that can be used to engineer enhanced performance into a commercially important enzyme. Increased temperature or pH stability, and altered substrate specificity are but a few examples of how 3D structural information can be applied for the manipulation of enzyme utilization in food industries. These possibilities are explored further in later sections of this chapter.

To solve the 3D structures of enzymes that participate in cereal (1 → 3, 1 → 4)- $\beta$ -glucan hydrolysis, x-ray crystallography remains the method of choice; indeed, the structures of a barley (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolase and a barley  $\beta$ -glucan exohydrolase have now been solved by x-ray crystallography (34, 35). The major bottleneck in the technology is probably associated with difficulties in obtaining high-quality crystals. Crystals can take up to several months to grow to the 0.2–1 mm size required by most x-ray crystallographers (36). If a good-quality native data set can be collected from the x-ray diffraction patterns, together with data sets for heavy-metal derivatives of the enzymes, crystallographers can generally solve the structure of the enzyme.

A final point to be made here is that protein modeling is finding an increasing important place in defining “likely” 3D structures of enzymes for which no crystallographical data are available. If the complete primary structure of an enzyme can be deduced from a cDNA, and if the 3D structure of a closely related enzyme from the same family of glycoside hydrolases has been solved, it is possible to use modeling software programs to generate a likely 3D structure for the enzyme. The limitations and constraints of modeling must be acknowledged, but there are several techniques that can be used to evaluate the reliability of the model (37).

## V. CEREAL (1 → 3, 1 → 4)- $\beta$ -GLUCAN ENDOHYDROLASES

### A. Substrate Specificity and Action Pattern

Two (1 → 3, 1 → 4)- $\beta$ -glucan 4-glucanohydrolases (EC 3.2.1.73) from barley have been purified from extracts of germinated grain and characterized (20, 21). Both are members of the family 17 group of glycoside hydrolases (31). Similar enzymes are found in germinated wheat (22, 38), rye (39), sorghum (40), and other cereals (41). The properties of the two barley isoforms are compared in **Table 2**. Unlike other glucoside hydrolases that hydrolyze cereal (1 → 3, 1 → 4)- $\beta$ -glucans, the substrate specificity of the EC 3.2.1.73 enzymes from barley is absolute; the enzymes will only hydrolyze (1 → 4)- $\beta$ -glucosyl linkages where these are immediately adjacent, toward the reducing end of the polysaccharide, to a (1 → 3)- $\beta$ -glucosyl residue, as shown in **Figure 1**. Reaction products are (1 → 3, 1 → 4)- $\beta$ -oligoglucosides which have a single (1 → 3)- $\beta$ -linkage at their reducing termini (Figs. 1, 3). This indicates that the enzymes are endohydrolases,

**Table 2** Properties of Barley ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -Glucan Endohydrolases

Property	Isoenzyme EI	Isoenzyme EII
Apparent molecular mass	30,000	32,000
Amino acids	306	306

as does their ability to very rapidly reduce the viscosity of ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan solutions (20). Chen et al. (33) used proton NMR to show that the anomeric configuration of released products is retained during hydrolysis.

### B. Three-Dimensional Structure

The 3D structure of barley ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan endohydrolase isoenzyme EII has been determined at  $\sim 2.2\text{--}2.3$  Å resolution by x-ray crystallography (34). The enzyme adopts a ( $\alpha/\beta$ )<sub>8</sub> TIM barrel fold. The most striking feature of the enzyme is a deep substrate-binding cleft that extends across its surface (Fig. 4). The open cleft is consistent with the enzyme's endohydrolytic pattern, because it would allow the enzyme to bind its substrate at essentially any position along the polysaccharide backbone for the hydrolysis of internal glycosidic linkages.

### C. Substrate Binding

The precise details of substrate binding and the identity of amino acid residues involved have not been defined. When relatively long ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -oligo-glucoside substrates are allowed to diffuse into crystals, they clearly bind to the enzyme. However, they are subsequently hydrolyzed and products diffuse away, even at low temperatures and suboptimal pHs, and it has therefore not been possible to generate diffraction data for the enzyme-substrate complex (M Hrmova, JN Varghese, GB Fincher, unpublished). We are now attempting to define

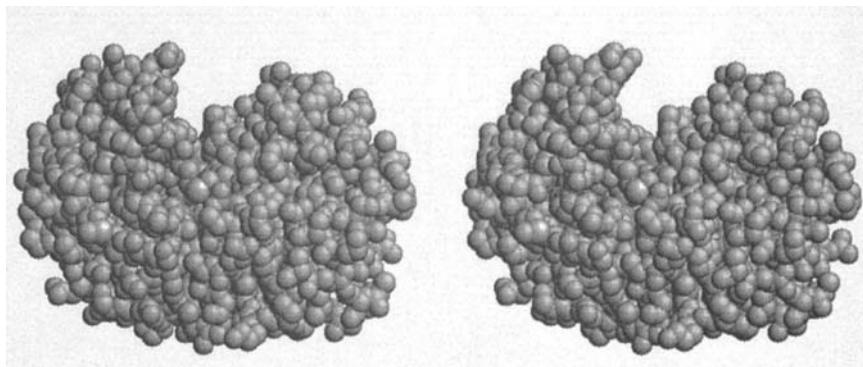

enzyme-substrate interactions by diffusing nonhydrolyzable S-glycoside substrate analogs (44) into barley ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan endohydrolase crystals, in the expectation that the substrate analogs will be bound but that their S-glycosidic linkages will not be cleaved by the enzyme. Thus, the substrate analogs should remain associated with the enzyme during the generation of x-ray diffraction data.

Measurements of the substrate binding cleft that runs across the surface of the barley ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan endohydrolase indicate that it is long enough to accommodate up to eight glucosyl residues of the ( $1 \rightarrow 3, 1 \rightarrow 4$ )- $\beta$ -glucan substrate (34).

## VI. CEREAL $\beta$ -GLUCOSIDASES

### A. Substrate Specificity and Action Pattern

Two  $\beta$ -glucosidases purified from extracts of germinated barley grain have been designated isoenzymes  $\beta$ I and  $\beta$ II (26, 27, 45), and their properties are shown in Table 3. The enzymes are members of the family 1 group of glycoside hydrolases (31), although it is difficult to classify them into existing Enzyme Commission groups. The enzymes hydrolyze 4NPG and are therefore referred to as  $\beta$ -glucosidases of the EC 3.2.1.21 group (26, 27, 37). However, more detailed studies on their substrate specificities show that the enzymes hydrolyse a range of di- and oligosaccharides. Highest activity is observed for celldextrin substrates, for which the rate of hydrolysis increases as the length of the substrate increases from cellobiose to cellohexose (Fig. 5) (26, 27). In all cases, the barley enzymes

**Figure 4** Three-dimensional structure of the barley (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolase. Stereoview space-filling representation of an  $(\alpha/\beta)_8$  TIM barrel fold. The drawing was generated using RasMol (43). (From Ref. 34.)

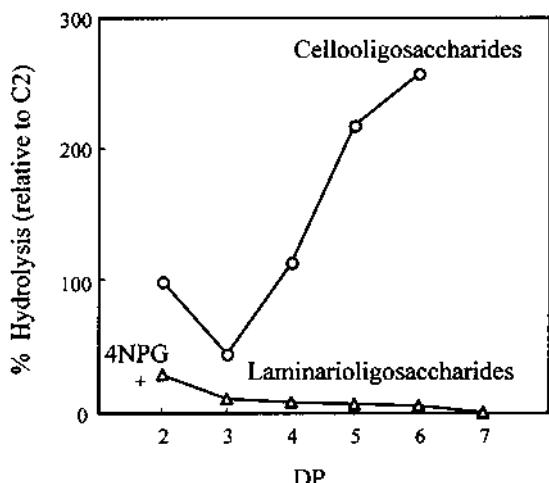

remove single glucose units from the nonreducing ends of the substrates, and anomeric configuration is retained during hydrolysis (27). The barley  $\beta$ -glucosidases also catalyze glycosyl transfer reactions, through which higher oligosaccharides containing (1 → 3)-, (1 → 4)-, and (1 → 6)- $\beta$ -linkages are generated during hydrolysis of 4NPG (37). The increased activity of the enzymes as chain length of cello-oligosaccharides increase (Fig. 5) is suggestive of a polysaccharide exohydrolase rather than an enzyme that is specific for low-molecular-mass  $\beta$ -oligoglucosides (27). Indeed, the action patterns and specificities of the barley  $\beta$ -

glucosidases are more typical of polysaccharide exohydrolases of the (1 → 4)- $\beta$ -glucan glucohydrolase group (EC 3.2.1.74). The uncertainties associated with the classification of the barley enzymes are acknowledged by Hrmova et al. (37), who propose that the enzyme be referred to as a  $\beta$ -glucosidase/ $\beta$ -glucan exohydrolase until its native substrate in germinated barley grains has been identified unequivocally. The preference of barley grain  $\beta$ -glucosidases for (1 → 4)- $\beta$ -oligoglucosides of increasing chain length suggests that it might have an extended substrate-binding region.

**Table 3** Properties of Barley  $\beta$ -Glucosidases

Property	Isoenzyme BI	Isoenzyme BII

## B. Three-Dimensional Structure

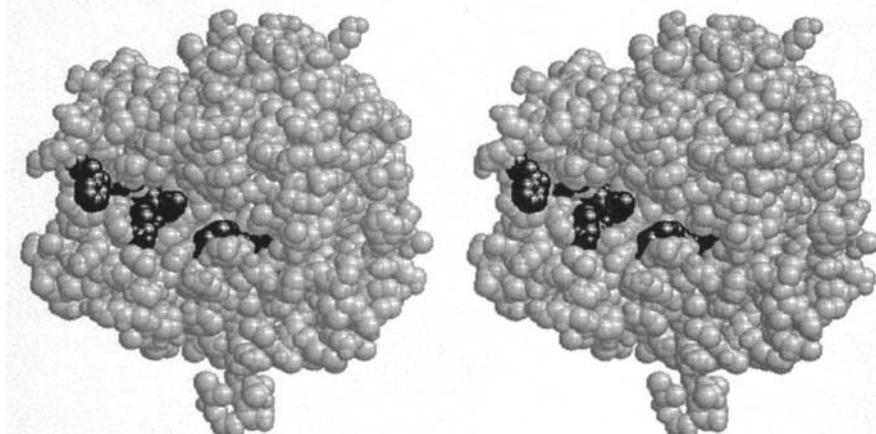

There are no reports of 3D structures for cereal  $\beta$ -glucosidases. When the primary structure of the barley  $\beta$ -glucosidase isoenzyme  $\beta$ II deduced from a cDNA sequence (26) was analyzed using molecular modeling software programs (37), 3D models with very high reliability scores were built using as a template the crystal structure of a cyanogenic  $\beta$ -glucosidase from white clover (46) (Fig. 6). A deep, funnel-shaped pocket, or dead-end tunnel, in the barley  $\beta$ -glucosidase

is revealed in these modeling experiments, and this can be reconciled with the substrate specificity. When  $(1 \rightarrow 4)$ - $\beta$ -oligoglucosides were used as molecular rules in the active-site pocket, it became clear that at least six glucosyl residues would be closely associated with the enzyme surface (37). This suggests that the enzyme has five or six glucosyl-binding subsites. Furthermore, catalytic amino acid residues are located near the bottom of the pocket, and the inside surface of the pocket is lined with aromatic amino acid residues (Fig. 6) that could be involved with substrate binding, through stacking interactions with nonpolar surfaces of glucosyl residues (47). In contrast to the cleft observed on endoacting polysaccharide hydrolases (Fig. 4), the dead-end tunnel geometry (Figure 6) is consistent with an exo-action pattern, through which single glucosyl residues are released from one end of the polysaccharide.

## VII. THE BROAD-SPECIFICITY $\beta$ -GLUCAN EXOHYDROLASES

### A. Substrate Specificity and Action Pattern

Two barley  $\beta$ -glucan exohydrolases, designated isoenzymes ExoI and ExoII, have been characterized in detail (24, 25, 27). Similar enzymes are found in elongating maize coleoptiles (18) and in dicotyledonous plants (48–50). Although two  $\beta$ -glucan exohydrolase isoenzymes have been purified from barley seedlings, Southern hybridization analyses suggest that the

**Figure 6** Three-dimensional modeled structure of the barley  $\beta$ -glucosidase. Stereoview space-filling representation of  $(\alpha/\beta)_8$  TIM barrel fold. The aromatic amino acid residues lining the surface of the active site pocket are colored in black. The drawing was generated using RasMol (43). (From Ref. 37.)

enzymes are encoded by a family of five to six genes (AJ Harvey, M Hrmova, GB Fincher, unpublished). The properties of barley  $\beta$ -glucan exohydrolase isoenzymes ExoI and ExoII are shown in Table 4.

The barley  $\beta$ -glucan exohydrolases are exoacting enzymes that hydrolyze the nonreducing terminal glycosidic linkage in a broad range of aryl  $\beta$ -glycosides,  $\beta$ -oligoglucosides, and polymeric  $\beta$ -glucans. The anomeric configuration of the released glucose unit is retained, and, at high substrate concentrations, the enzymes catalyze a range of glycosyl transfer reactions (25, 27). The enzymes can be confidently classed as polysaccharide exohydrolases rather than  $\beta$ -glucosidases because of their ability to rapidly release glucose from a number of polysaccharide substrates, including laminarin and cereal (1  $\rightarrow$  3, 1  $\rightarrow$  4)- $\beta$ -glucans (25). The barley  $\beta$ -glucan exohydrolases can be classified into the family 3 group of glycoside hydrolases (31), but again their broad substrate specificities make it difficult to assign them to existing EC groups.

The barley  $\beta$ -glucan exohydrolases also catalyze the hydrolysis of (1  $\rightarrow$  3)- $\beta$ -glucosidic linkages at higher rates than other linkage types (Fig. 7) (25, 27). However, hydrolytic rates are relatively independent of the length of substrates, especially at degrees of polymerization of 3 and above (Fig. 7), and the

enzymes have no difficulty hydrolyzing mixed linkage (1  $\rightarrow$  3, 1  $\rightarrow$  4)- $\beta$ -oligoglucosides (25, 27). This is in marked contrast to the barley  $\beta$ -glucosidase, for which rates of hydrolysis increase with the chain length of cello-oligosaccharides (Fig. 5), but (1  $\rightarrow$  3)- $\beta$ -oligosaccharides, (1  $\rightarrow$  3)- $\beta$ -glucans, and (1  $\rightarrow$  3, 1  $\rightarrow$  4)- $\beta$ -glucans are hydrolyzed very slowly, if at all. The small effect of substrate chain length on hydrolytic rate would suggest that the enzyme has a relatively short substrate-binding region, and indeed, subsite mapping experiments indicate that only two or three glucosyl-binding subsites are present (M Hrmova, GB Fincher, unpublished). Once these subsites are fully occupied, reaction rates would be maximal and would be expected to be unaffected by any increases in length of substrates.

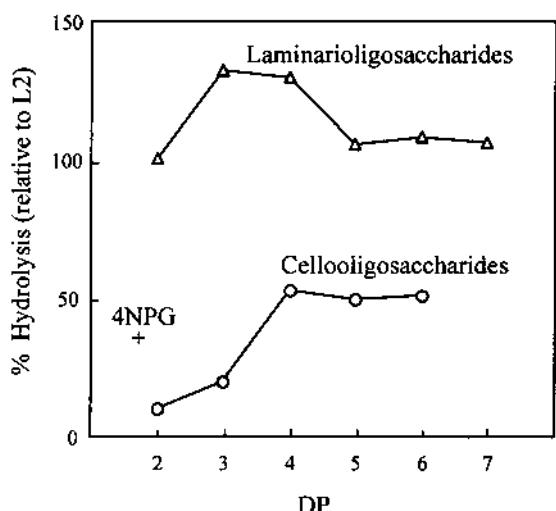

## B. Three-Dimensional Structure

The barley  $\beta$ -glucan exohydrolase isoenzyme ExoI was recently crystallized by vapor diffusion in the presence of ammonium sulfate and polyethylene glycol (36). Platinum and mercury derivatives of the crystals were subsequently obtained, and this allowed the 3D structure of the enzyme to be solved by x-ray crystallography at 1.8–2.2 Å resolution (35).

**Table 4** Properties of Barley  $\beta$ -Glucan Exohydrolases

Property	Isoenzyme ExoI	Isoenzyme ExoII

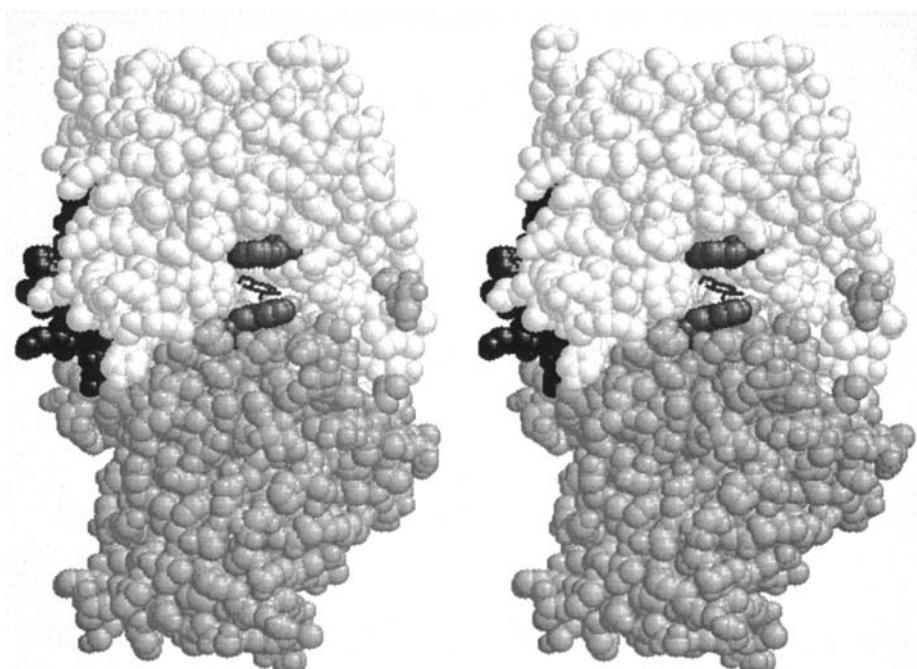

**Figure 7** Relative rates of hydrolysis of  $\beta$ -oligoglucosides by the barley  $\beta$ -glucan exohydrolase. (From Ref. 27.)

The enzyme is globular in shape but has two distinct domains. The first consists of 357 amino acid residues that fold into a  $(\alpha/\beta)_8$  TIM barrel. A 16 amino acid linker joins the first domain to the second domain,

which consists of residues 374–599 arranged in an  $(\alpha/\beta)_6$  sandwich. The  $(\alpha/\beta)_6$  sandwich has a six-stranded  $\beta$ -sheet, with three  $\alpha$ -helices on either side of the sheet (Fig. 8) (35). At the COOH-terminal region of the enzyme (residues 500–605) is a long, antiparallel loop. Carbohydrate can be detected on each of three potential *N*-glycosylation sites at Asn221, Asn498, Asn600 (35). Of particular interest in the crystal structure is the presence of a glucose molecule at the bottom of a surface pocket on the enzyme. The entrance to the pocket is shaped like a coin slot in a vending machine and is located near the interface of domains 1 and 2. The glucose is tightly bound to the enzyme and is likely to be the product of the enzyme-catalyzed reaction that has not been released after hydrolysis is complete (Fig. 8). It follows, therefore that the pocket occupied by the glucose represents the substrate-binding region of the enzyme.

As already noted for the barley  $\beta$ -glucosidase (Sec. VI.B), the 3D structure of the barley  $\beta$ -glucan exohydrolase (Fig. 8) and the positioning of catalytic residues in its substrate-biding pocket can be reconciled with its substrate specificity (Table 4). At 13 Å in depth, the catalytic pocket could accommodate two

**Figure 8** Three-dimensional structure of the barley  $\beta$ -glucan exohydrolase. Stereoview space-filling representation of the overall structure. The  $(\alpha/\beta)_8$  TIM barrel (colored in white) and the  $(\alpha/\beta)_6$  sandwich (colored in light gray) represent domains 1 and 2, respectively. The linker region connecting the two domains is on the left and is marked in black. Active-site region of the enzyme, which is bounded by Trp286 and Trp434 (colored in dark gray), contains a trapped glucose moiety (in a dark gray wireframe representation). The drawing was generated using RasMol (43). (From Ref. 35.)

to three glucosyl residues, given that the distance between glycosidic oxygen atoms of two adjacent residues in (1 → 3)- or (1 → 4)- $\beta$ -glucans is ~ 5–6 Å (51). Furthermore, the length of the substrate-binding region estimated by subsite mapping is also two to three glucosyl residues (M Hrmova and GB Fincher, unpublished). In addition, if the pocket is deep enough for only two glycosyl residues, the remainder of the oligomeric or polymeric substrate would project out of the pocket and away from the enzyme surface. Thus, substrate binding would be relatively independent of the overall substrate shape for the  $\beta$ -glucan exohydrolases, in contrast to the  $\beta$ -glucosidases, where the substrate has to have the correct shape to fit into the much longer substrate-binding tunnel (Fig. 6). Because substrate shape is determined in large part by the type of glycosidic linkage, the lack of strict shape requirements for substrates of the  $\beta$ -glucan exohydrolases could explain why substrates with many different linkage types can be hydrolyzed by this broad-specificity  $\beta$ -glucan exohydrolase.

### VIII. BIOLOGICAL ROLES OF THE DIFFERENT ENZYMES IN CEREAL (1 → 3, 1 → 4)- $\beta$ -GLUCAN HYDROLYSIS

The availability of precise information on the specificity, action pattern, and kinetics of key  $\beta$ -glucan exo- and endohydrolases from higher plants provides important clues on the biological roles of individual enzymes during the hydrolysis of cereal (1 → 3, 1 → 4)- $\beta$ -glucans. The potential roles of the enzymes in germinated grain, where cell walls of the starchy endosperm are completely degraded, are compared in the sections below with their potential roles in elongating vegetative tissues, where partial hydrolysis of cell wall polysaccharides is believed to “loosen” the wall structure sufficiently to allow turgor-driven cell expansion during normal growth and development.

#### A. (1 → 3, 1 → 4)- $\beta$ -Glucan Endohydrolases

It can be confidently concluded that the primary function of the EC 3.2.1.73 group of (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases in germinated grain is in the hydrolysis of cell wall (1 → 3, 1 → 4)- $\beta$ -glucans. Both the (1 → 3, 1 → 4)- $\beta$ -glucan substrate and the (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases are restricted in their distribution to the Poaceae. The enzymes are expressed in germinated grain in response to the phy-

tohormone gibberellic acid (GA). Expression occurs in the scutellar epithelium and in the aleurone layers, where it is under tight spatial and temporal control (52, 53). Isoenzyme EI is the predominant isoform found in the scutellum, while isoenzyme EII is secreted only from the aleurone layer. The genes encoding both barley isoenzymes have been isolated, and various sequence motifs that might be related to GA induction and tissue specificity of expression have been identified (54–56).

While the (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases are clearly involved in depolymerization of wall (1 → 3, 1 → 4)- $\beta$ -glucans in germinated grain, it is not so clear whether or not another endohydrolase might be responsible for the initial release of relatively high-molecular-mass (1 → 3, 1 → 4)- $\beta$ -glucan from the walls (Fig. 3). As noted in Figure 3, the final products of hydrolysis of the endohydrolases will be a family of (1 → 3, 1 → 4)- $\beta$ -oligoglucosides. These still contain a significant proportion of total grain glucose (15), but their complete hydrolysis to glucose requires the activity of other enzymes.

In barley, (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolase isoenzyme EI is also expressed in young leaves and roots, where transcription of the gene is mediated by auxins (23, 53). The enzyme is also found in young roots of rice (57). Auxins participate in several physiological processes that are related to wall metabolism in plants, including cell elongation, vascular differentiation, phototropic responses, and geotropism. Because (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolases of the EC 3.2.1.73 group appear to be completely absent from elongating barley coleoptiles (23), a role in cell elongation seems unlikely.

#### B. $\beta$ -Glucosidases

The functional role of  $\beta$ -glucosidases in cereals is more difficult to define. In barley, the genes encoding the enzyme are expressed only in the maturing endosperm of the grain (26). The enzyme itself is also detected in the late stages of grain development and in ungerminated grain; activity does not increase after germination (26, 45). Possible functions of the  $\beta$ -glucosidases in developing and germinated grain have been reviewed by Leah et al. (26), and some of these are related to cell wall metabolism. The  $\beta$ -glucosidases are expressed at a time when (1 → 3, 1 → 4)- $\beta$ -glucan is being deposited in the walls of starchy endosperm cells (26), and might be involved in trimming or turnover of wall (1 → 3, 1 → 4)- $\beta$ -glucans during their synthesis.

Finally, the  $\beta$ -glucosidases could be responsible for salvaging glucose units from the (1 → 3, 1 → 4)- $\beta$ -oligoglucosides released from wall (1 → 3, 1 → 4)- $\beta$ -glucans by endohydrolases. The  $\beta$ -glucosidases are able to hydrolyze not only the more abundant tri- and tetrasaccharides released by the endohydrolases, but also the longer-chain “cellulosic”  $\beta$ -oligoglucosides that have single (1 → 3)- $\beta$ -glucosyl residues at their reducing termini (Figs. 1, 3) (27). The detection of the  $\beta$ -glucosidases in germinated grain is consistent with such a role in the complete depolymerization of wall (1 → 3, 1 → 4)- $\beta$ -glucans to glucose, and, based on current evidence, we believe that this might be a likely function of the barley  $\beta$ -glucosidases.

### C. $\beta$ -Glucan Exohydrolases

The  $\beta$ -glucan exohydrolases from barley hydrolyze polysaccharides such as laminarin and cereal (1 → 3, 1 → 4)- $\beta$ -glucans, as well as a range of  $\beta$ -oligoglucosides, including (1 → 3, 1 → 4)- $\beta$ -oligoglucosides (Table 4). This broad specificity, together with a distribution that includes not only the Poaceae but also many dicotyledons, makes it difficult to assign a single, unequivocal function to the enzyme.

Because the  $\beta$ -glucan exohydrolases hydrolyze (1 → 4)- $\beta$ -glucosidic linkages more slowly than (1 → 3)- $\beta$ -glucosidic linkages (Fig. 7), it might be argued that these enzymes are less likely to play a role in hydrolysis of (1 → 3, 1 → 4)- $\beta$ -oligoglucosides in germinated grain than are the  $\beta$ -glucosidases. The genes encoding the  $\beta$ -glucan exohydrolases are transcribed in the scutellum of germinated grain, but their mRNAs are most abundant in the elongating coleoptile (AJ Harvey, M Hrmova, GB Fincher, unpublished). This latter observation has led to the suggestion that  $\beta$ -glucan exohydrolases function in auxin-mediated cell elongation in growing coleoptiles (24, 58; AJ Harvey, M Hrmova, GB Fincher, unpublished), where the amount of (1 → 3, 1 → 4)- $\beta$ -glucan in walls decreases markedly during coleoptile growth (59) in a process that has been linked to the wall “loosening” believed to be necessary for cell elongation (60).

In concluding that the broad-specificity  $\beta$ -glucan exohydrolases are likely to play a role in cell elongation during normal growth and development of plants, it must be acknowledged that the actual enzymic mechanism of wall loosening cannot be precisely explained. Once can visualize wall loosening as a partial endohydrolysis of polysaccharides that noncovalently crosslink cellulosic microfibrils in the wall; turgor pressure-driven forces would allow the cellulose

microfibrils to slip past each other if the strength of the crosslinking or matrix phase between the microfibrils were weakening (5). It is not easy to visualize how an exoacting hydrolase of the  $\beta$ -glucan exohydrolase type would be able to cleave crosslinking polysaccharides between cellulosic microfibrils. It might also be argued that this fundamental concept as to how cell wall components might behave during cell expansion is simplistic, and that our inability to describe the enzymology of the process reflects our generally inadequate understanding of the role of walls in cell expansion as a whole.

Another possible function of the  $\beta$ -glucan exohydrolases could be linked to defense strategies developed by plants to counter pathogen attack. The enzymes can hydrolyze (1 → 3)- $\beta$ - and (1 → 3, 1 → 6)- $\beta$ -glucans of the type commonly found in fungal cell walls (61), and could act in synergy with the better-known pathogenesis-related (PR) proteins, (1 → 3)- $\beta$ -glucan endohydrolases (EC 3.2.1.39), to degrade walls of invading fungi and thus to arrest their growth (25).

## IX. APPLICATIONS IN THE FOOD INDUSTRY

Cell wall (1 → 3, 1 → 4)- $\beta$ -glucans are widely recognized for their effects on extract viscosity during the commercial utilization of cereals. Although the (1 → 3, 1 → 4)- $\beta$ -glucans and their highly viscous solutions are considered beneficial in human diets (3), in most commercial applications the high viscosity of (1 → 3, 1 → 4)- $\beta$ -glucan solutions is undesirable.

### A. Malting and Brewing Industries

Attempts by the food and beverage industries to address these problems through the application of modern technologies have been concentrated so far in the malting and brewing industries. Specifications for barley quality are tailored predominantly for these industries, and emphasis has been placed on parameters such as grain size, dormancy, malt extract, grain protein content, development of starch-degrading enzymes (diastatic power), and removal of (1 → 3, 1 → 4)- $\beta$ -glucans. High levels of (1 → 3, 1 → 4)- $\beta$ -glucans in barley malt are considered undesirable because they are often indicative of incomplete cell wall breakdown in the starchy endosperm and are therefore correlated with low values for malt extract (41). Further, undegraded (1 → 3, 1 → 4)- $\beta$ -glucans can cause filtration difficulties in the brewery,

again because of their propensity to form solutions of high viscosity, and can contribute to the formation of undesirable hazes in the final product (62).

The quality specification relating to the removal of  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucans can clearly be tackled on two fronts. Firstly, breeders can select for barley with inherently low  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan contents (3), or for barleys with the potential to produce high levels of  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan hydrolases after germination. The importance of these two parameters in barley-breeding programs is underscored by the efforts to place on detailed genetic maps the quantitative trait loci (QTLs) that control  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan content and  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase activity (64, 65).

The second approach to the  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan problem in the malting and brewing industries is to produce an improved barley through genetic engineering technologies. The genes encoding  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan synthases have not yet been isolated, and manipulation of initial  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan levels by downregulating this gene is therefore not possible at this stage. However, the two genes encoding barley  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolases have been cloned (54–56), as have  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase genes from various *Bacillus* spp. (66, 67). Thus, genetic manipulation of genes encoding these endohydrolases could result in elevated levels of the enzyme in malt, and this in turn could result in the rapid removal of residual, high-molecular-mass  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan molecules in malt extracts.

## B. Increased Levels of $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -Glucan Endohydrolases

There are several approaches to increasing  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucanase activity via genetic engineering. One would be to attach a more powerful promoter to the native barley  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase genes. The promoter would need to be activated in the appropriate tissue at the appropriate time, so powerful constitutive promoters that were active in many tissues throughout growth and development would be of little value in this approach. However, if a barley  $\alpha$ -amylase promoter were attached to a barley  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase gene, it might be anticipated that high levels of the enzyme would be expressed in aleurone cells after germination, because the expression patterns of  $\alpha$ -amylases and  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucanases in barley are similar (68). The major disadvantage of using more

powerful promoters on the barley  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase genes, even if these promoters direct appropriate tissue-specific and temporal expression patterns, is the potential to upset the metabolic balance in the germinated grain. Given that the grain has a finite energy potential and well-evolved regulatory mechanisms to ensure that the correct balance of individual hydrolytic enzymes is obtained, higher levels of  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolases might be achieved at the expense of other enzymes, which might then become rate limiting and cause unpredicted metabolic imbalances and associated difficulties in the malting and brewing processes.

## C. Increased Stability of $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -Glucan Endohydrolases

A second approach to increasing  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase activity for the malting and brewing industries could be to increase the stability of the existing enzyme, without trying to increase expression levels at the gene level. In this approach the enzyme itself would be engineered for increased stability, but the native  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucanase gene promoter would be retained so that the metabolic balance of the germinated grain would not be perturbed. The amount of  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase in germinated barley grains will clearly meet the normal physiological requirements for starchy endosperm mobilization and successful germination of the grain. However, these enzymes are irreversibly denatured and almost completely inactivated at the temperatures used during kilning (up to 85°C) or during mashing (usually ~65°C) (21, 69). Thus, if the stability of the enzymes could be increased at these temperatures so that more of the enzyme survived the kilning and mashing steps, the higher levels of surviving enzyme could hydrolyze residual high-molecular-mass  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucans after mashing.

How then, could the loss of  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase activity at elevated temperatures be addressed? Firstly, heat-stable  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucanases occur naturally in various microbial species. An extremely thermostable  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucanase has been engineered by intragenic recombination of gene segments from *Bacillus macerans* and *B. amyloli-quefaciens* (67). The gene encoding this hybrid, thermostable  $(1 \rightarrow 3, 1 \rightarrow 4)$ - $\beta$ -glucan endohydrolase, has been expressed in barley protoplasts (70 and in transgenic barley (71).

Another approach to preventing the loss of (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolase activity at the temperatures encountered during malting and brewing would be to engineer enhanced thermostability into the barley enzyme itself. Random mutagenesis of the cDNA or gene encoding the barley enzyme could be used to generate thermostable mutants. Alternatively, the detailed three-dimensional structure of barley (1 → 3, 1 → 4)- $\beta$ -glucan endohydrolase isoenzyme EII (34) could be used to rationally redesign the enzyme (72). In related work, a small improvement in heat stability has been engineered into the barley (1 → 3, 1 → 4)- $\beta$ -glucanase isoenzyme EI through the addition of an N-glycosylation site to the protein (73).

#### D. Genetic Engineering

Perhaps the major technological bottleneck in the application of genetic engineering to improve cereal performance in the commercial arena has been the difficulty associated with transformation. Transformation procedures for wheat and barley have been developed in recent years (74, 75) but have often been plagued by very low transformation frequencies, inconsistent results, and an inability to transform the elite breeder lines. The foreign or manipulated DNA has generally been introduced into immature embryo or microspore cultures using microparticle bombardment (74) or, more recently, using methods based on *Agrobacterium tumefaciens* transformation (75).

At this stage it is important to acknowledge that genetic engineering and genetically manipulated organisms (GMOs) are not universally accepted by consumers. Indeed, considerable resistance to these new technologies has been experienced, especially where human food is derived from GMOs (76, 77). In considering whether to engineer barley with an altered barley (1 → 3, 1 → 4)- $\beta$ -glucanase gene or with a naturally thermostable bacterial gene, as discussed in Section IX.C, consumer attitudes to foods derived from genetically engineered plants remain of central importance. Whether or not barley engineered with an altered barley gene would be more acceptable than a barley engineered with a bacterial gene remains to be seen.

#### ACKNOWLEDGMENTS

This work was supported by grants from the Australian Research Council and the Grains Research and Development Corporation. We thank

Mr. Andrew Harvey and Mr. Richard Stewart for their contributions to various aspects of the work, and Dr. Jose Varghese for his patience in teaching us the principles of x-ray crystallography.

## Enzymology of Endo-1,4- $\beta$ -Mannanases

**Henrik Stålbrand**

*Lund University, Lund, Sweden*

### I. INTRODUCTION

Mannan-based polysaccharides are abundant in nature; galactoglucomannan is the major softwood hemicellulose, and galactomannans are common storage polysaccharides in certain plant seeds. The major depolymerizing enzyme of these and similar polysaccharides is endo-1,4- $\beta$ -mannanase ( $\beta$ -mannanase, EC 3.2.1.78), which hydrolyzes randomly internal 1,4- $\beta$ -D-mannosidic linkages within the backbone of the polysaccharide (see Secs. VI and VII). Further hydrolysis into monomeric sugars is accomplished by the exohydrolases  $\alpha$ -galactosidase (EC 3.2.1.22) and  $\beta$ -mannosidase (EC 3.2.1.25). Heteromannan degradation is important in exogenous and endogenous conversion of plant polysaccharides.

Several  $\beta$ -mannanase-encoding genes from bacteria, fungi, and plants have been isolated. Generally,  $\beta$ -mannanase catalytic modules have molecular masses of 30–45 kDa. Like many glycoside hydrolases,  $\beta$ -mannanases may be modular proteins with molecular masses up to or even above 100 kDa.  $\beta$ -Mannanases (i.e., their catalytic modules) are retaining enzymes classified in family 5 and family 26 of glycoside hydrolases (see Sec. IX).

### II. THE SUBSTRATES

Hemicellulose is a collective term for a group of diverse plant cell wall polysaccharides, consisting of several

different monomeric sugar units linked with *O*-glycosidic linkages (1, 2). The two major groups of hemicellulose, heteroxylans and heteromannans, have, respectively, predominantly xylose units or mannose units in the main chain. The major softwood hemicellulose is acetylated galactoglucomannan which comprises up to ~20% of the softwood content (2). It has  $\beta$ -1,4-linked mannose and glucose residues in the main chain and is substituted with  $\alpha$ -1,6-linked galactosyl sidegroups. Two major types of acetyl galactoglucomannans occur in softwoods, one which can be solubilized in water and one which is alkali soluble (mannosyl:glucosyl:galactosyl ratio of 3:1:1 and 3:1:0.1, respectively) (1). Hardwoods contain 3–5% unsubstituted glucomannan (2). The degree of polymerization (DP) of galactoglucomannan and glucomannan hemicellulose is ~100–200 (1, 2).

Certain plants contain other types of mannan and heteromannans present especially in seeds as storage polysaccharides (3). Leguminous seeds from several species contain galactomannan, which has a backbone of  $\beta$ -1,4-linked mannose residues with  $\alpha$ -1,6-galactosyl side groups. Carob (*Ceratonia siliqua*) seed galactomannan (contained in locust bean gum) and guar galactomannan have a DP of ~1500 and 900, respectively (4). The mannosyl to galactosyl ratio is ~5/1 for locust bean gum and 2/1 for guar gum (4). The galactomannans can be extracted from the milled seeds (5). These polysaccharides can form highly viscous solutions and are important owing to their use as thickeners in the food industry and other industrial sectors.

They are also used in combination with xanthan gum to form strong gels and in combination with kappa carrageenan to form stronger and more elastic gels (6–8). Ivory nut (*Phytelephas macrocarpa*) mannan is a linear  $\beta$ -1,4-linked insoluble mannan (9).

### III. OCCURRENCE OF $\beta$ -MANNANASES

Both aerobic and anaerobic microorganisms produce plant cell wall polysaccharide-degrading enzymes, reviewed in Warren (10). Some of these microorganisms are present in decaying plant material, in soil, or in the rumen; others are plant pathogens, reviewed in Warren (10) and Klein and Eveleigh (11).

$\beta$ -Mannanases are produced by species of bacteria, fungi, and plants, and several  $\beta$ -mannanase genes from these organisms have been cloned (12–21). Furthermore,  $\beta$ -mannanase activity has been purified from a gut preparation of the snail *Helix pomatia* (22). Also, some extremophiles produce  $\beta$ -mannanase; the genes have been cloned from thermophilic bacteria (23–25).

$\beta$ -Mannanase activity has also been detected in several plant seeds, which is correlated to their germination (26, 27). For example,  $\beta$ -mannanase activity has been detected in seeds of tomato (28–30), *Coffea arabica* (31) carob, and fenugreek (32). Low levels of  $\beta$ -mannanase activity were detected in banana fruits during ripening (33). The  $\beta$ -mannanase encoding gene from tomato (*Lycopersicon esculentum*) has been isolated (17). Several tomato  $\beta$ -mannanase isoforms have been observed during germination (29).

### IV. PRODUCTION OF MICROBIAL $\beta$ -MANNANASES

Expression of hemicellulases and cellulases among fungi like *Trichoderma* and *Aspergillus* spp. is commonly glucose repressed (34–37). However, variations even within a species have been observed, partly due to the development of mutant strains, reviewed by Kubicek and Penttilä (37).  $\beta$ -Mannanases are extracellular proteins, but may be cell associated as indicated for anaerobes.

The most commonly used carbon sources for microbial  $\beta$ -mannanase production are galactomannan and other mannans. Fungal  $\beta$ -mannanases have been produced in submerged cultures on locust bean gum by, for example, *Aspergillus niger* (38), *Trichoderma harzianum* (39), and *Aspergillus awamori* for which also wheat bran was used (40). Reese and

Shibata (9) screened for and detected  $\beta$ -mannanase activity in cultures of several fungi using ivory nut mannan or carob galactomannan as carbon source. In this study, two fungi produced moderate  $\beta$ -mannanase activity when grown on cellulose. Media containing cellulose have also been used for  $\beta$ -mannanase production by *Trichoderma reesei* (41). Higher levels of  $\beta$ -mannanase were produced on cellulose when compared to locust bean gum (42). *Trichoderma reesei*  $\beta$ -mannanase production appears to increase when glucose is depleted (36). The plant-pathogenic fungi *Sclerotium rolfsii* produced  $\beta$ -mannanase when grown on several carbon sources, including sorbose, cellulose, mannan, and heteromannans (43).  $\beta$ -Mannanase was produced by the yeast *Aureobasidium pullulans* in media containing either galactomannan, galactoglucomannan,  $\beta$ -1,4-manno-oligosaccharides, or a synthetic nonmetabolized glycoside: methyl  $\beta$ -D-mannopyranoside (44).

### V. $\beta$ -MANNANASE MULTIPLICITY

Frequently, polysaccharidases are produced in multiple forms, which at least in some cases, is a reflection of the composition and complexity of naturally occurring substrates. As an example, usually several genetically distinct endoglucanases and cellobiohydrolases are secreted by cellulolytic organisms (10, 45).  $\beta$ -Mannanases are commonly extracellularly produced in multiple forms as observed for some bacteria (20, 46), several plant seeds (26, 29), and several fungi, including *Scelortium rolfsii* (47) and *Trichoderma* spp. (39, 41).  $\beta$ -Mannanase isoforms may be post-translationally modified products of the same gene (16) or products of separate genes (21).

### VI. CATALYTIC MECHANISM AND MANNAN HYDROLYSIS

$\beta$ -Mannanases hydrolyze randomly internal 1,4- $\beta$ -D-mannosidic linkages in mannan and heteromannan polysaccharides. The *A. niger* and the *T. reesei*  $\beta$ -mannanases can efficiently hydrolyze manno-oligosaccharides with a DP of 4 or higher; the major hydrolysis products of ivory nut mannan after extensive incubation are mannobiose and mannotriose (38, 41). Mannotriose can only be slowly hydrolyzed and, owing to secondary hydrolysis of mannotriose (38, 48, 49) mannose may also be produced from ivory nut mannan hydrolysis (50).

Glycoside hydrolases acting on polymeric substrates often have several substrate binding subsites. Each subsite binds one backbone monosaccharide unit. The kinetics of oligosaccharide hydrolysis suggest at least four subsites for the *T. reesei* (48) and the *A. niger* (49)  $\beta$ -mannanases.

Each glycoside hydrolase family comprises enzymes that hydrolyze the glycosidic bond by either of two catalytic mechanisms—one that yields a net retention of the anomeric configuration, and one that yields a net inversion (51, 52). Two catalytic residues participate in the mechanism: a nucleophile and an acid/base catalyst. The retaining mechanism is a two-step process. A covalent glycosyl enzyme intermediate is formed, which is hydrolyzed in the second step (51, 52). Retaining glycoside hydrolases may perform transglycosylation (53). Hitherto  $\beta$ -mannanases have been classified in glycoside hydrolase families 5 and 26 (see Sec. IX), which have the retaining mechanism. Accordingly, transglycosylation has been observed for several  $\beta$ -mannanases including those from *T. reesei* and *A. niger* (38, 48, 49).

## VII. HETEROMANNAN HYDROLYSIS

$\beta$ -Mannanases also hydrolyze heteromannans. However, their activity is generally restricted by the galactosyl sidegroups and the main-chain glucose residues of the substrate (22). The subsite-binding properties may vary among enzymes of different origin. The major hydrolysis products from incubation of fungal as well as bacterial  $\beta$ -mannanase with heteromannans are mixed oligosaccharides, mannotriose, and manno-biose, sometimes with the production also of mannose (49, 54, 55), as reviewed by Viikari et al. (56). These products are hydrolyzed further by exohydrolases, also secreted by the microorganisms. Thus, the cooperation of several enzymatic activities is needed for the degradation of heteromannans. In addition to  $\beta$ -mannanase (EC 3.2.1.78),  $\alpha$ -galactosidase (EC 3.2.1.22) and  $\beta$ -mannosidase (EC 3.2.1.25) are also needed for the complete hydrolysis of galactoglucomannan into monomeric sugars (57, 58).  $\beta$ -Mannosidases hydrolyze terminal nonreducing mannose residues, and  $\alpha$ -galactosidases hydrolyze  $\alpha$ -1,6-linked galactosyl side groups from oligomeric and sometimes polymeric substrate (59–62).  $\beta$ -Glucosidase (EC 3.2.1.21) may be needed for the hydrolysis of non-reducing-end glucose residues. For the complete hydrolysis of acetylated galactoglucomannan, acetyl esterase is also needed (63, 64).

The pattern of galactomann hydrolysis and the apparent subsite-binding requirements have been interpreted from structural analysis by NMR of isolated hydrolysis products from the galactomannan and glucomannan incubated with *A. niger*  $\beta$ -mannanase (49). It is suggested that the enzyme has five substrate binding subsites— $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ , and  $\epsilon$ —which is equivalent to  $-3$ ,  $-2$ ,  $-1$ ,  $+1$ , and  $+2$ , according to the nomenclature given by Davies et al. (52). Binding to at least four subsites is required for efficient hydrolysis. Substitution of the substrate monomers at two of the subsite positions (but not at the other) restricted hydrolysis, most likely by preventing binding (49). The hydrolysis of pine kraft pulp galactoglucomannan by the *T. reesei*  $\beta$ -mannanase was also studied by NMR analysis of the produced mixed oligosaccharides (55). Judging from this study, the *T. reesei* enzyme also appears to be restricted by galactosyl sidegroups in a similar way to the *A. niger* enzyme. Also, the restriction by the substrate main-chain glucose residues has been studied for some  $\beta$ -mannanases (49, 55).

## VIII. MODULAR STRUCTURE OF $\beta$ -MANNANASES

Glycoside hydrolases like cellulases and hemicellulases commonly have a modular structure. The catalytic modules may be attached to other module(s), such as carbohydrate-binding modules (10). The modules are often connected by linker peptides. Furthermore, as reviewed (10, 45), anaerobic cellulolytic organisms like *Clostridium* spp. frequently form large cell-associated multienzyme complexes. Although several  $\beta$ -mannanases are sole catalytic modules of  $\sim 30$ –45 kDa (13, 15, 18), some  $\beta$ -mannanases are modular proteins with molecular masses from 50 kDa up to 100 kDa (12, 14, 16, 19, 20, 23, 25, 65). Examples of modular  $\beta$ -mannanases from anaerobes are enzymes which carry an additional endoglucanase catalytic module and cellulose binding modules (12) or putative protein binding modules which may be involved in the formation of multienzyme complexes (19, 65).

Also, some aerobic organisms produce modular  $\beta$ -mannanases (14, 16, 20). The *T. reesei* family 5  $\beta$ -mannanase has a C-terminal cellulose-binding module (16, 38, 66). Biely and Tenkanen (58) discussed the possibility that the presence of a cellulose-binding module on the *T. reesei*  $\beta$ -mannanase is part of the reason for the superior performance in bleaching experiments for this enzyme (67). The *Cellulomonas fimi* enzyme is the

first  $\beta$ -mannanase reported to contain a mannan-binding module (68). It interacts with galactomannan.

## IX. CATALYTIC MODULES OF $\beta$ -MANNANASES

On the basis of sequence and, where available, structural similarities, the catalytic modules of glycoside hydrolases has been classified into different families by Henrissat et al. (69) (see also <http://afmnb.cnrs-mrs.fr/~pedro/CAZY/ghf.html>). Enzymes in a particular family have a conserved overall fold, conserved catalytic mechanism and conserved catalytic and other residues. Known  $\beta$ -mannanases belong to family 5 or family 26 of glycoside hydrolases; both contain enzymes which have the retaining mechanism. Family 5 and family 26 enzymes belong to the clan GH-A (4/7  $\beta/\alpha$ -barrel superfamily) of glycoside hydrolases (70).

### A. Glycoside Hydrolase Family 5

Family 5 includes several enzymatic activities for which the corresponding genes have been cloned. These are, for example, several endo-1,4- $\beta$ -glucanases and cellobiohydrolases in addition to  $\beta$ -mannanases. The genes of family 5  $\beta$ -mannanase have been isolated both from prokaryotes (12–14, 24) and eukaryotes, i.e., from fungi (15, 16) and from a plant—tomato (17). The three-dimensional structure of two  $\beta$ -mannanases of family 5 has been determined (Sec. X) (71, 72). Structures of family 5 enzymes are  $(\beta/\alpha)_8$ -barrels. Eight residues are conserved, including two catalytic glutamates (73, 74).

### B. Glycoside Hydrolase Family 26

Family 26 contains several  $\beta$ -mannanases from bacteria (18–20) and from one species of anaerobic fungi (21) for which the genes have been isolated. Two glutamates have been identified as the putative catalytic residues (75). At least two additional residues are conserved. Crystallization and preliminary x-ray diffraction studies have been reported for a  $\beta$ -mannanase of *Pseudomonas fluorescence* subsp. *cellulosa* (76). Family 26 enzymes have been predicted to belong to the clan GH-A and thus to have the  $(\beta/\alpha)_8$ -barrel structure (75).

## X. STRUCTURES OF $\beta$ -MANNANASE CATALYTIC MODULES

Generally, endoacting cellulases and hemicellulases are expected to have an active site which is present in a quite open cleft, as is the case for structurally determined family 5 endoglucanases. Judging from the three  $\beta$ -mannanase structures available (71, 72, 76), these enzymes also have roughly this general architecture. These catalytic modules form the *Thermomonospora fusca* and *Trichoderma reesei*  $\beta$ -mannanases belong to family 5 of glycoside hydrolases, and thus both structures are  $(\beta/\alpha)_8$ -barrels and share the same overall fold. In both  $\beta$ -mannanase structures the two catalytic glutamates are situated in a groove across the surface of the enzymes. As expected, the conserved tryptophan in family 5, probably forming the -1 subsite, is present in both structures. It is unclear if the other subsites also are conserved or similar for the two  $\beta$ -mannanases. For the *T. fusca* enzyme complex structures with mannotriose enabled the identification of subsites -3 and -2 (71). The +1 and +2 subsites were identified for the *T. reesei*  $\beta$ -mannanase (72).

## XI. $\beta$ -MANNANASE ASSAYS

### A. Conditions for Catalysis

As previously reviewed (22, 56), generally, compared to bacterial mannanases, fungal  $\beta$ -mannanases have lower pH optima, between  $\sim 3.0$  and 5.5. Among the highest yet reported pH optima for a  $\beta$ -mannanase is pH 9, for the enzyme from an alkalophilic *Bacillus* sp. (46). In many cases,  $\beta$ -mannanases are stable for hours at their optimal pH up to a temperature of at least 50°C. The  $K_m$  values reported for *Trichoderma* and *Aspergillus*  $\beta$ -mannanases on locust bean gum varies between 0.0015 to 0.7 g/L (15, 22, 42).

### B. Assays Based on Detection of Reducing Sugars Produced by Hydrolysis

The following assay procedure is used for the *Trichoderma reesei*  $\beta$ -mannanase (41), and can be used generally (adjustments of buffer and pH may be needed depending on the enzyme).  $\beta$ -Mannanase activity is assayed using 0.5% (w/v) locust bean gum (SIGMA G-0753). The substrate is suspended in 50 mM citrate or acetate buffer, pH 5.3, by homogenizing at 80°C and heating to the boiling point, cooled, and stored overnight with continuous stirring, then centrifuged and the pellet discarded. The enzyme sample (0.2

mL) is incubated with 1.8 mL substrate solution at 5 °C for 5–30 min. The reducing sugars liberated in the enzymatic reaction are assayed by the addition of 3 mL DNS-reagent, boiling for 5 min, cooling, and measuring the absorbance at 540 nm. Recipe for the DNS reagent can be found in Meth Enzymol, Vol 160 (1988), pp 87–112. A standard curve is prepared with D-mannose. The enzymatic activity is given in nanokatals (nkat). An assay based on the quantification of the released reducing sugars using the Somogyi-Nelson copper agent has also been described (22).

#### C. Assay Based on Detection of Dyed Oligosaccharides Produced by Hydrolysis

Carob galactomannan dyed with Remazol Brilliant Blue R (AZO-carob galactomannan, Megazyme, Wicklow, Ireland) is used as the substrate. After enzyme substrate incubation for 10 min, ethanol is added to stop the reaction and to precipitate high-molecular-weight galactomannan. Low-molecular-weight fragments stay soluble and can be spectrophotometrically quantified at 590 nm, due to the attached dye (22). This assay is relative. To relate to enzyme activity units, a standard curve (supplied by Megazyme for each batch of substrate) with known enzyme amounts should be prepared.

#### D. Zymogram

After running a protein sample with isoelectric focusing (IEF), bands with  $\beta$ -mannanase activity can be identified by the use of 2% agar overlay gel (2 mm thick) containing 0.5% locust bean gum (41). When the IEF is done the overlay gel is incubated with the separation gel at 50 °C for 45 min; then the overlay gel is stained with 0.1% Congo Red solution and destained with 1 M NaCl.  $\beta$ -Mannanase activity appears as clearing zones. The overlay gel should be made in a 50-mM buffer with a pH suitable for enzyme activity and stability (50 mM citrate, pH 5.3, for the *T. reesei* and *A. niger*  $\beta$ -mannanases). The method also works with native polyacrylamide gel electrophoresis. Zymograms can also conveniently be made with AZO-carob galactomannan (20).

#### E. Plate Assays

$\beta$ -Mannanase activity secreted from bacterial or yeast colonies can be detected by growing the microorganisms on agar plates containing 0.5% locust bean gum (16). After making replicas, the microorganism is care-

fully washed off and the plate is incubated with 0.1% Congo Red solution, then destained with 1 M NaCl.  $\beta$ -Mannanase activity is detected as clear halos. Locust bean gum dyed with Remazol Brilliant Blue R can also be used for detection of clones with  $\beta$ -mannanase (24).  $\beta$ -Mannanase activity in single plant seeds can be detected by the plate assay using locust bean gum and Congo Red staining (77).

#### F. Assays of Other Enzymes Active on Heteromannans

The exoglucosidases  $\alpha$ -galactosidase,  $\beta$ -mannosidase, and  $\beta$ -glucosidase can be assayed using colorimetric detection using nitrophenylglycosides as the substrate, as described for example by Rättö and Poutanen (40).

### XII. APPLICATIONS OF $\beta$ -MANNANASES

$\beta$ -Mannanases have several potential and existing applications in particular in the food and feed, pulp, and paper industries. The industrial applications have been reviewed by several authors (56, 78, 79).  $\beta$ -Mannanase can solubilize softwood pulp mannan (80, 81) and can be used as an aid in pulp bleaching (67, 80, 82). Improvement of animal feed with  $\beta$ -mannanase has been reported (83). Coffee beans contain heteromannan which is extractable with hot water from the roasted bean (84). Extracted green coffee bean mannan has been hydrolyzed with  $\beta$ -mannanase (85). A potential application for  $\beta$ -mannanase is to reduce the viscosity of the extract during production of instant coffee (78).  $\beta$ -Mannanase and other hemicellulases may also be used to reduce the viscosity of pineapple juice during processing (86). Over the past few years, attention has been directed toward endogenous  $\beta$ -mannanase in plant seed germination (27). Furthermore,  $\beta$ -mannanases may be used in the conversion of biomass and for the hydrolysis and modification of polysaccharides. The potential application of  $\beta$ -mannanase in the hydrolysis of galactomannan-based fluids used in oil and gas well stimulation has been shown (87).

Other hemicellulases, endo-1,4- $\beta$ -xylanases, have after a relatively short time of research and development, reached major applications especially in pulp bleaching (88) and in cereal processing (89). Increased attention for  $\beta$ -mannanases will likely open up new applications for these enzymes.

## Lysozyme

**Akio Kato**

*Yamaguchi University, Yamaguchi, Japan*

### I. INTRODUCTION

Fleming found the lytic action of human nasal mucus and tear on *Micrococcus* cells in 1922 and he reported the similar lytic action of egg white constituent on Gram-positive bacteria. He proposed the name lysozyme for the enzyme and *Micrococcus lysodeikticus* for the organism serving as the substrate (1). Lysozyme cleaves the  $\beta$ -(1,4)-glycoside linkages between N-acetylglucosamine and muramic acid in bacterial cell wall and chitin or other oligomers. In addition to glycosidase activity, this enzyme has transglycosylation activity (2) and esterase activity (3). Thus, numerous names have been proposed for this enzyme. The Commission on Enzyme Nomenclature in 1964 recommended "E.C. 3.2.1.17. Systematic name: mucopeptide N-acetylmuramyl hydrolase; trivial name: mucopeptide glucohydrolase, lysozyme." Lysozyme is easily crystallized from chicken egg white, and a large amount of the enzyme can be obtained. Therefore, lysozyme has been one of the most intensively investigated and characterized enzymes.

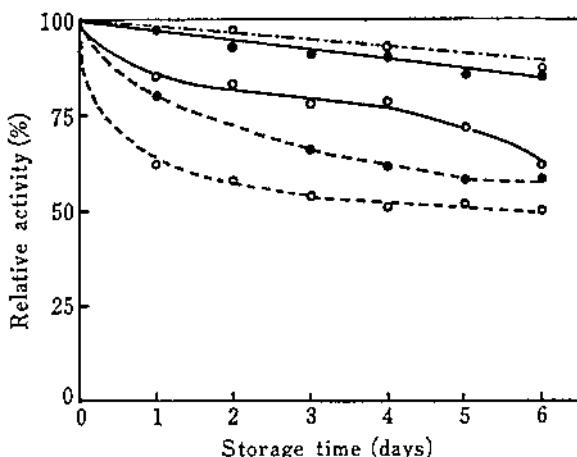

### II. LYSOZYME IN FOODS

Lysozyme exists abundantly in chicken egg white and constitutes 3.5% of the total egg white proteins when calculated on the basis of lytic activity. Since lysozyme interacts with ovomucin gel in egg white, the content may be  $> 3.5\%$ . The lysozyme activity in hen egg white decreases during storage of egg dependent on the tem-

perature, as shown in Figure 1. The activity is retained  $> 80\%$  during storage at low temperature for 1 week, while it is decreased  $< 60\%$  during storage at room temperature for 1 week (4). The loss of lysozyme activity results from the increases in pH during storage of egg. The pH increases up to 9.3 within several days' storage at room temperature. On the other hand, lysozyme is stable in acidic pH in the presence of CO<sub>2</sub> gas, as shown in Figure 1. Lysozyme interacts with ovomucin in thick egg white. It is well known that the interaction is responsible for the gel structure of thick egg white (5). The ovomucin-lysozyme interaction decreases with egg white thinning.

### III. UTILIZATION OF LYSOZYME IN FOODS

Hen egg white lysozyme is utilized as a food preservative with antimicrobial effects without any food toxicities. The bactericidal action of lysozyme is intensive on Gram-positive bacteria but much weaker on Gram-negative bacteria, because the former expose the cell wall consisting of peptidoglycan, while the latter has a unique cell envelope, which consists of the outer membrane, inner membrane, and peptidoglycan layer. Therefore, the perturbation of the outer membrane structure is needed to enhance the susceptibility to lysozyme of the peptidoglycan layer in Gram-negative bacteria. Despite this disadvantage, lysozyme is generally used as a food antiseptic. The antimicrobial action may be efficient on Gram-positive bacteria but ineffi-

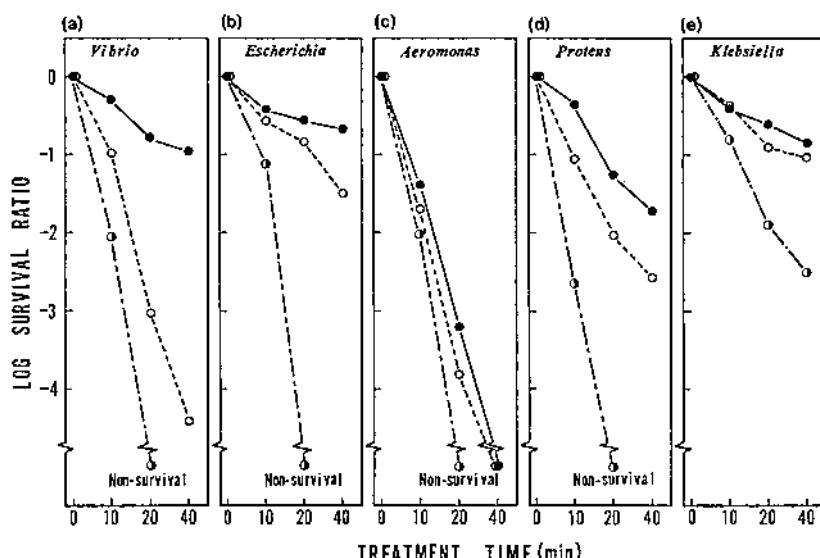

**Figure 1** Effects of the temperature and pH on the relative activity of lysozyme in egg white during storage. ●—●, 5°C (final pH 9.0); ○—○, 20°C (final pH 9.3); ●---●, 30°C (final pH 9.4); ○---○, 40°C (final pH 9.5); ○—-○, stored in an atmosphere of CO<sub>2</sub> at 30°C (final pH 6.5). (From Ref. 4.)

cient on Gram-negative bacteria. Some attempts to enhance the antimicrobial action for Gram-negative bacteria have been done by our colleagues. Ibrahim et al. in 1991 found that the covalent attachment of palmitic acid residues to the lysyl residues of lysozyme

greatly enhanced the bactericidal action on *E. coli* (6). Nakamura et al. in 1991 reported that the Maillard-type lysozyme-polysaccharide conjugate also enhanced the bactericidal action on various Gram-negative bacteria (7). The antimicrobial action of lysozyme-dextran conjugate is shown in Figure 2. The bactericidal action is enhanced by heating at 50°C. The polysaccharide attachment seems to stabilize lysozyme and to have stronger affinity to the outer membrane of Gram-negative bacteria. These modified lysozymes can be used as food antiseptics effective on various bacteria.

#### IV. PROPERTIES AS PROTEIN

Lysozyme consists of 129 amino acids and the molecular weight is 14,307 daltons. The protein contains many more basic amino acids (11 arginines and six lysines) than acidic amino acids (six aspartic acids and two glutamic acids), and the isoelectric point is 11.2. The amino acid and nucleotide sequences of prelysozyme are shown in Figure 3. The sequence -1 to -18 is the signal peptide, and the N-terminus of mature lysozyme is the position 1 (lysine). Lysozyme has four disulfide bonds: Cys6-127, Cys30-115, Cys64-80, and Cys76-94. Human lysozyme, which consists of 130 amino acids, is very similar to hen egg white lysozyme in its primary and tertiary structures and the positions of

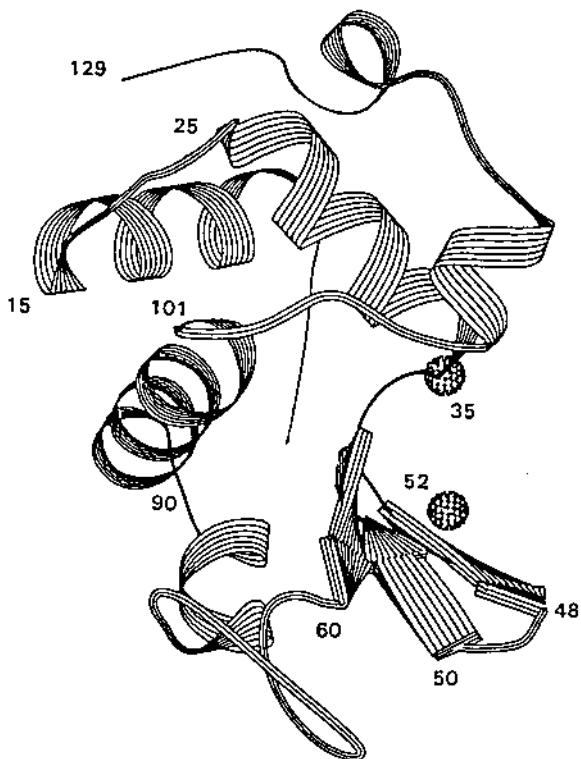

**Figure 2** Antimicrobial activity of lysozyme-dextran conjugate for five Gram-negative bacteria. (a) *V. parahaemolyticus* IFO 12713; (b) *E. coli* IFO 12713; (c) *A. hydrophila* IFO 13286; (d) *P. mirabilis* IFO 12668; (e) *K. pneumoniae* IFO 14438. ●, Control (medium without lysozyme or conjugate); ○, addition of 0.05% lysozyme; ●, addition of 0.05% lysozyme-dextran conjugate. The abscissa is the heating time at 50°C. (From Ref. 7.)

**Figure 3** Amino acid and nucleotide sequences of hen egg white pre-lysozyme. The cDNA is inserted between *Kpn*1 and *Bam*H1 in pUC18. Numbering of the nucleotide sequence starts at the most likely position for the 5' end of mRNA derived from the sequence of the genomic clone. The Met (-18) to Gly (-1) is the signal peptide and correctly processed in eukaryote cell, resulting in the N-terminal lysine.

disulfide bonds.  $\alpha$ -Lactalbumin, which consists of 123 amino acids, is also homologous to lysozyme in its primary and tertiary structure and in the position of disulfide bonds. The x-ray analysis of hen egg white lysozyme was carried out by Blake et al. in 1965 as the first enzyme to have its tertiary structure deter-

mined by x-ray crystallography (8). The ribbon drawing model is shown in Figure 4. As shown in Figure 4, it divides the molecule into two parts—a predominantly helical core, and an irregular  $\beta$ -strand core. The helical core consists of four  $\alpha$ -helices (5–15, 25–35, 88–99, and 108–115), and the  $\beta$ -strand core consists of three  $\beta$ -

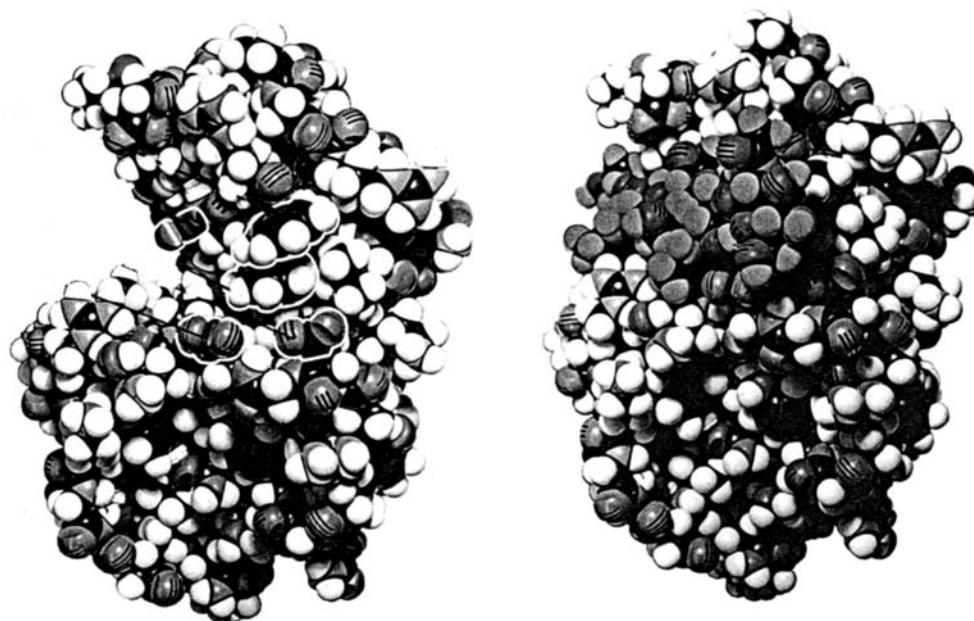

**Figure 4** Ribbon drawing model of hen egg white lysozyme. The two catalytic residues, glutamic acid 35 and aspartic acid 52, are represented as small spheres.

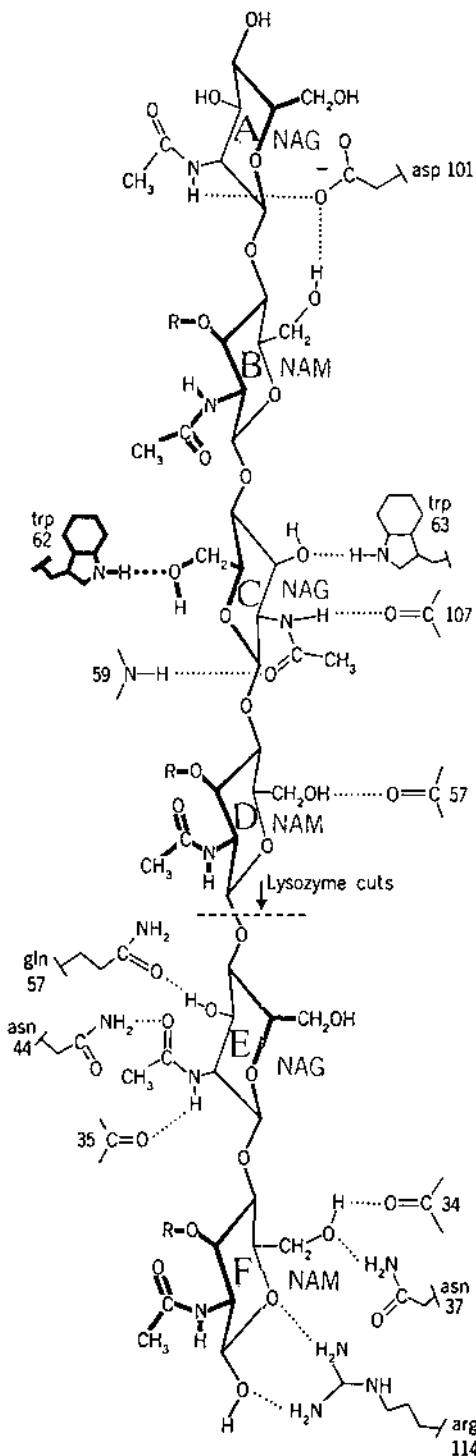

strand regions (38–46, 50–54, and 57–60). The two structural domains ( $\alpha$  and  $\beta$ ) of lysozyme appears to be formed prior to docking of the domains to generate the native closed-packed structure (9). The  $\alpha$  domain forms persistent structure during folding more rapidly than the  $\beta$  domain. In addition to a  $\alpha$ -helical domain, lysozyme contains two  $3^{10}$  helices (79–84 and 119–124).

## V. PROPERTIES AS ENZYME

The most striking feature of the molecule is the crevice running across the waist of the egg-shaped molecule. The crevice is the active site of lysozyme which has the binding area for the substrate of hexasaccharide (N-acetylglucosamine/N-acetylmuramic acid)<sub>3</sub>. The space-filling CPK model of lysozyme (left) and its interaction with substrate are shown in Figure 5 (10). The substrate is compactly bound to the crevice of the lysozyme molecule. A schematic view of the substrate hexamer, NAG-NAM-NAG-NAM-NAG-NAM, and its interactions with the enzyme are shown in Figure 6 (10). The view is nearly straight into the crevice, with the heavy edges of the sugar rings on the exterior. The site of catalysis was identified to be between D and E rings. When a search was made in the vicinity of the D/E ring for possible cat-

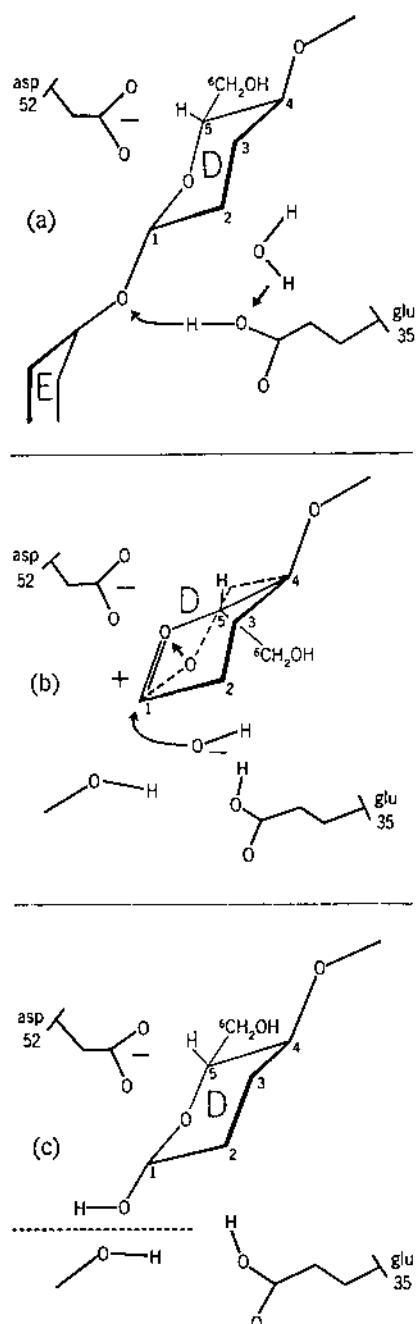

**Figure 5** Space-filling CPK model of hen egg white lysozyme. Left: Enzyme without substrate, showing active site crevice. Right: Enzyme-substrate complex, with hexamer NAG substrate. (From Ref. 10.)

**Figure 6** Substrate interactions with the active crevice in lysozyme. The dark edges of the carbohydrate rings are exposed to the outside, and the lighter ones are buried at the crevice bottom. (From Ref. 10.)

alytic groups, two candidates came to light: Asp52, in a polar environment where it will be ionized, and Glu35, in largely hydrophobic surroundings where it might easily remain protonated. The mechanism of cleavage of the polysaccharide bond in lysozyme is suggested as shown in Figure 7 (10). The proton of Glu35 first attacks the linkage oxygen and weakens the C<sub>1</sub>-O bond (a). If the bond is cleaved, ring D forms a carbonium ion. The nearby charged Asp52 helps to stabilize the carbonium ion (b). The Glu35 proton is replaced by another from an ionizing water molecule, and the resultant hydroxyl ion then attacks the carbonium ion and completes the reaction (c). This proposal of Phillips and coworkers (11–13) has been supported by a number of chemical and kinetic experiments.

The enzyme activity of lysozyme can be easily measured by the lytic action on *M. lysodeikticus* (*M. luteus*). However, the change in the turbidity of *M. luteus* does not necessarily reflect the real enzyme activity, because the lysis is a rupture of the bacterial cell wall and is not equal to the cleavage of glycosidic bonds. Nevertheless, the lytic action is generally used for the measurement of lysozyme activity because of the ease of the assay. The decrease in the turbidity of the suspension of *M. luteus* cell wall is followed by the absorbance at OD<sub>450</sub> and the enzyme activity can be represented as the initial rate. In order to get a linear curve for the decrease, a small amount of lysozyme (4 µg) should be added into the cell suspension (OD<sub>450</sub> = 0.7). When the enzyme reaction is done at room temperature for 1 min, a linear decrease curve is obtained and used to determine the initial rate. The optimal pH is ~ 7.0 using lytic activity. On the other hand, when the activity is measured using synthetic substrates, *p*-nitrophenyl N-acetylglucosamine oligomer (14) and glycol chitin (15), the optimal pH is 5 and 5.3, respectively. Therefore, the optimal pH of lytic activity is different from that of the glycosidic activity. The glycosidic activity is determined by measuring the reducing power produced by the glycolysis of ethylene glycol chitin (15). One milliliter of 0.5% ethylene glycol chitin is added to 0.5 mL lysozyme solution in sodium acetate buffer (pH 4.5). The mixture is incubated at 40°C for 30 min. After the reaction, 2 mL of the color reagent (prepared by dissolving 0.5 g potassium ferricyanide in 1 L of 0.5 M sodium carbonate) is added and the mixture is immediately boiled for 15 min to estimate the reducing power resulting from the hydrolysis of ethylene glycol chitin.

**Figure 7** Mechanism of cleavage of the polysaccharide bond in lysozyme. (From Ref. 10.)

## VI. PURIFICATION OF LYSOZYME

Lysozyme is easily crystallized from fresh chicken egg white. A 5% sodium chloride (w/w) is added to the homogenized egg white adjusted to pH 9.5–9.8. The

egg white is stirred for 48 h at 4°C. The resulting crystals are collected and solubilized in a half-volume of acetate buffer (pH 4.5). The solution is recrystallized at least five times. Thus, the purified lysozyme is obtained and the purity is 100%. On the other hand, lysozyme can be purified by cation exchange chromatography, because the enzyme is a basic protein. For example, when the recombinant lysozyme is expressed in *S. cerevisiae*, the yeast medium is applied to CM-toyopearl equilibrated with a buffer of low ionic strength, and the adsorbed basic proteins are eluted in a gradient manner.

## VII. RECENT BREAKTHROUGH STUDIES ON LYSOZYME

Since lysozyme is easily obtained in a purified form, it has been studied comprehensively as a model protein for structure, dynamics, and folding. The recent development of recombinant techniques has enabled elucidation of the molecular mechanism of structural and functional properties of lysozyme. In early studies, recombinant lysozyme was investigated in the *E. coli* expression system. However, since the prokaryotic cells have a different secretion system from eukaryotic for correct foldings cells, the correctly folded lysozyme could not be expressed. It seems likely that the folding of disulfide-rich protein such as lysozyme is difficult in *E. coli* because of the absence of endoplasmic reticulum (ER) in which proteins are posttranslationally folded. Although the enzyme is obtained as an inclusion body, the yield of refolding is at a very low level. The N-terminus of recombinant lysozyme is methionine, while that of native lysozyme is lysine. Since the N-terminus lysine is essential for correct folding, the substitution of N-terminus lysine with another amino acid results in a significant decrease in the stability of lysozyme. Kumagai et al. in 1987 found that hen egg white lysozyme was correctly processed and folded in *S. cerevisiae* (16). The N-terminus of recombinant lysozyme is lysine and the stability is the same as the native lysozyme. Since *S. cerevisiae* is a typical eukaryotic cell with an ER system, lysozyme is correctly processed and folded in the yeast. Taniyama et al. in 1992 reported the folding mechanism of disulfide bond-deficient human lysozyme C77/95A mutant secreted in *S. cerevisiae* (17). Although the deficient mutants of other disulfide bonds could not be secreted, only C77/95A mutant secreted by eight-fold greater than wild-type in yeast. The stability of

C77/95A mutant greatly decreased despite the correct folding. These observations show that the disulfide bond Cys77–95 contributes to the stabilization of the folded form of human lysozyme.

Recently, the identification of human lysozyme as an amyloidogenic protein which causes serious diseases is of particular interest. The two unknown natural mutations (Ile56Thr and Asp67His) in the human lysozyme gene both cause autosomal-dominant hereditary amyloidosis (18). It has been suggested that the lysozyme amyloid fibril may be formed by the intermolecular  $\beta$ -sheet association due to  $\beta$ -strand exposed to the molecular surface by a single amino acid substitution.

We have developed new approaches for industrial application using genetic modifications of lysozyme. Nakamura et al. (19) reported that the large molecular size of N-glycosylated lysozyme with a poly-mannose chain was predominantly expressed in yeast carrying the lysozyme gene modified to have N-linked signal sequence Asn-X-Thr/Ser at the position of the molecular surface. The polymannosyl lysozyme showed remarkable heat stability in that no coagulation was observed by heating at 100°C. In addition to heat stability, the lysozyme revealed excellent emulsifying properties, superior to the commercial emulsifiers (20).

On the basis of the idea that the covalent attachment of palmitic acid residues to the lysyl residues of lysozyme stabilizes it and makes it more active (6), Ibrahim et al. (21) attempted the genetic fusion of a hydrophobic pentapeptide (Phe-Phe-Val-Ala-Pro), which forms a  $\beta$ -strand conformation with the same length as a palmitic acid residue, to its C-terminus. As expected, the hydrophobic peptide fusion greatly enhanced the bactericidal action to *E. coli*. These modified lysozymes having antimicrobial action against both Gram-positive and Gram-negative bacteria and can be used for industrial applications in future.

## Ribonucleases

**Jaap J. Beintema and Wei Zhao**

*University of Groningen, Groningen, The Netherlands*

### I. INTRODUCTION

#### A. Chemical Reactions Catalyzed

Ribonucleases depolymerize ribonucleic acids by cleavage of phosphoric diester bonds between nucleotide residues. This means that they are specialized phosphotransferases or phosphoric diester hydrolases. A further specification is that they are endonucleases, as exonucleases degrade nucleic acids from one of the two termini, which results in little depolymerization. Cleavage may occur between phosphate and the 3'-oxygen of the ribose, producing 5'-phosphomonoesters (EC 3.1.26) or between phosphate and the 5'-oxygen of the ribose, producing 3'-phosphomonoesters (EC 3.1.27). Enzymes with the latter cleavage specificity often are transferases producing 2',3'-cyclic phosphate as intermediates, which generally are hydrolyzed in a second reaction catalyzed by the same enzyme. Figure 1 shows as an example the two successive reactions catalyzed by bovine pancreatic ribonuclease.

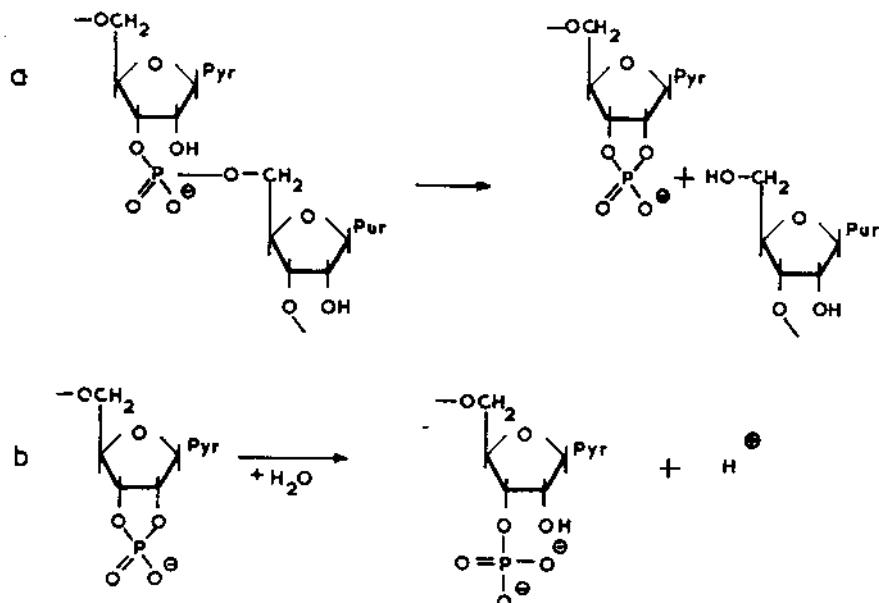

#### B. Chemical Structure of Substrates

Generally, nucleases are specific for either deoxyribonucleic acids (deoxyribonucleases) or ribonucleic acids (ribonucleases), although nucleases also occur which cleave both substrates producing either 5'-phosphomonoesters (EC 3.1.30) or 3'-phosphomonoesters [micrococcal nuclease (1); EC 3.1.31.1].

#### C. Classification According to Enzyme Commission Nomenclature

Section II of this handbook is organized according to the classification of enzymes as presented in Enzyme Nomenclature (2). In this classification “hydrolases (EC group 3)” are listed separately from “transferases (EC group 2).” However, for several enzymes this distinction is not correct as they are transferases reacting with compounds with general formula R-OH in which R may also be H, (H-OH) as will be discussed below.

The best-characterized ribonucleases belong to the endoribonucleases producing 3'-phosphomonoesters, with 2', 3'-cyclic phosphate as intermediates. This feature indicates that they will not be active on deoxyribonucleic acids. These ribonucleases have been classified earlier also as nucleotidyl transferases (EC 2.7.7) or phosphoric diester hydrolases (EC 3.1.4). Three superfamilies with this cleavage pattern are those of ribonucleases A (3-11), T<sub>1</sub> (12, 13), and T<sub>2</sub> (12), respectively. Mammalian pancreatic ribonucleases belong to the ribonuclease A superfamily and the two successive catalyzed reactions are shown in Figure 1. Enzymes belonging to this family have a strict specificity for a pyrimidine base at the 3'-side of the cleaved phosphoric diester bond and a general preference for a purine base at the 5'-side. Taking into account the reversibility of chemical reactions, the second reaction with H-OH as reacting molecule can be considered as the reverse of the first reaction with R-OH as leaving group. Generally the second (hydroly-

**Figure 1** The two successive reactions catalyzed by bovine pancreatic ribonuclease. This ribonuclease belongs to the ribonuclease A superfamily, which has a strict specificity for a pyrimidine base at the 3'-side of the cleaved phosphoric diester bond. Within the superfamily this ribonuclease belongs to the family of pancreatic-type, secretory ribonucleases 1, which have a higher preference for cytosine than uracil as pyrimidine. These enzymes have a general preference for a purine base at the 5'-side of the diester bond, with highest activities with an adenine at that side. The pyrimidine-binding site includes a disulfide-linked loop structure in the molecule, which is absent in mammalian angiogenins and in non-mammalian members of the superfamily. These enzymes do not have a strong adenine preference and in several cases even prefer guanine over adenine.

sis) reaction is much slower than the first (transferase), and several members of the ribonuclease A superfamily do not even hydrolyze the intermediate cyclic phosphates (6). This example shows that the classification of these ribonucleases as hydrolases (EC 3.1.27) is less correct and that the previous classification as transferases (EC 2.7.7) is more appropriate.

## II. IMPORTANCE OF RIBONUCLEASES TO QUALITY OF FOOD AND IN FOOD DIGESTION

Enzymes to be included as topics in a Handbook of Food Enzymology should have either a role (or potential role) in food production or processing, or be important in digestion of food components in the human species, in its domesticated animals, or in biotechnology. In this respect the history of ribonuclease research is a disappointing one. One of the first enzymes to be isolated and purified in crystalline form has been ribonuclease, a digestive enzyme which

could be isolated in relatively large amounts from bovine pancreas, a major product of the beef industry (14). This enzyme has played a key role in the development of the study of proteins, with four Nobel Prizes in chemistry (in 1972 and 1984) awarded for research on it. However, it was later found that ribonuclease is only present in high amount in the pancreas of ruminants and species that have a ruminantlike digestion, and in a number of species with cecal digestion (15, 16). For instance, the ribonuclease content in human pancreas is < 1% of that in bovine pancreas, and in the 1970s ribonuclease disappeared again as an important digestive pancreatic enzyme in textbooks for medical students.

Ribonuclease was considered around 1980 as a dull enzyme, without a relevant biological function and not very interesting for chemical investigations. However, since then the enzyme underwent a renaissance by the discovery of proteins with novel biological actions, which after structural studies proved to be homologs of ribonucleases with their ribonuclease activities being a condition of these special actions (17, 18).

### **III. RIBONUCLEASES ARE PROTEINS OR CATALYTICALLY ACTIVE NUCLEIC ACIDS**

Not all ribonucleases are proteins. Catalytically active nucleic acids include predominantly ribonucleases, among which ribonucleases P are very well characterized ones. Ribonucleases P (EC 3.1.26.5) consist of a protein and a ribonucleic acid component, of which the latter is the catalytically active part, requiring a metal ion for its activity, and producing 5'-phosphomonoesters (19).

### **IV. OCCURRENCE OF RIBONUCLEASES**

#### **A. Digestion of Extracellular RNA**

The three best-characterized superfamilies of ribonucleases are those of the already-mentioned ribonuclease A, T<sub>1</sub>, and T<sub>2</sub>. All members of these superfamilies are extracellular ones, have sequences coding for signal peptides at the DNA level, and are primarily digestive enzymes for foreign RNA, originating from dead cell material.

The ribonuclease A superfamily has a strong specificity for endonucleolytic cleavage with a pyrimidine at the 3'-side of the cleaved phosphodiester bond (EC 3.1.27.5) and includes homologous enzymes isolated from many mammalian, avian, reptilian, and amphibian sources. No representatives have yet been found in fishes or nonvertebrate taxa. Other enzymes mentioned under EC 3.1.27.5 in Enzyme Nomenclature (2) are not well characterized and probably are not homologous. Several representatives have specific functions and have a very low or no apparent activity with more conventional ribonuclease substrates (10).

Nine separate families with sequences that are > 50% identical in each family can be distinguished in the ribonuclease A superfamily:

1. Mammalian (pancreatic-type or secretory) ribonucleases 1. This family, with a rather high preference for cytidine relative to uridine, includes digestive pancreatic enzymes (4), but also paralogous ribonucleases isolated from bovine semen (20) and brain (21).

2. Mammalian (nonsecretory or neurotoxin-type) ribonucleases 2 (7, 22). This family includes both enzymes isolated from tissues such as liver and kidney, and more specialized ones, isolated from eosinophil cells, such as the enzymatically active human eosinophil derived neurotoxin (EDN), which has also been isolated from other human sources, and the enzymatically inactive human eosinophil cationic protein (ECP;

also called ribonuclease 3). EDN and ECP are the products of a gene duplication which occurred in an ancestor of Old World monkeys and apes after their divergence from the ancestor of New World monkeys. Recently, another human enzyme (ribonuclease 6) belonging to this family with low enzymatic activity has been discovered and characterized.

3. Mammalian ribonucleases 4 (8). These are basic uridyl-preferential enzymes, isolated from the liver of several mammalian species.

4. Mammalian angiogenins (or ribonucleases 5) (9, 23). These proteins stimulate blood vessel formation. They are virtually inactive toward RNA. However, their biological activity requires intact enzymic active sites and involves very specific cleavage of RNA molecules.

5 and 6. Ribonucleases from chicken liver (24) and chicken transformed bone marrow cells (25, 26).

7 and 8. Pancreatic ribonucleases from the pancreas of reptiles [turtle (27) and iguana (28)].

9. Several amphibian ribonucleases (5, 29).

Ribonucleases T<sub>1</sub> and T<sub>2</sub> were discovered originally in the commercial digestive Taka-Diastase from *Aspergillus oryzae* (30). Enzymes homologous with RNase T<sub>1</sub> with a preference for guanine have been isolated from several fungi (EC 3.1.27.3; EC 3.1.27.4) (12), but this superfamily also includes homologous prokaryotic representatives such as enzymes from several *Bacillus* spp. [EC 3.1.27.2; barnase and binase (13)], which have a less strict preference for guanine. A specialized fungal member of this superfamily isolated from *Aspergillus* spp. is  $\alpha$ -sarcin (EC 3.1.27.10), which has cytotoxic properties resulting from a very specific cleavage pattern of ribosomal RNA (31).

The ribonuclease T<sub>2</sub> superfamily is the most ubiquitous one in living nature. Members of this superfamily (EC 3.1.27.1) with a preference for purines (A or G) have been isolated, sequenced, and characterized from a large number of fungi, plants, and animals (including mammals) (12). The active site of members of this superfamily consists of two very diagnostic cassettes with primary structures: I/L-H-G-L-W-P and W-X-H-E-W/Y-X-K/T-H-G, respectively. Similar cassettes can be recognized even in the sequences of prokaryote and virus ribonucleases, which show no recognizable homology to the eukaryote enzymes in the remainder of the sequences. These prokaryote and virus ribonucleases, but also several animal members of the RNase T<sub>2</sub> superfamily, are not purine preferential anymore (12).

Pancreatic enzymes in the ribonuclease A superfamily and microbial (especially fungal) representatives in

the other two may be classified as digestive enzymes, depolymerizing foreign RNA. Also an extracellular T<sub>2</sub> ribonuclease from tomato (RNase Le) has a digestive role, as its expression and excretion from cells are stimulated by shortage of inorganic phosphate in the extracellular environment, necessitating digestion of organic phosphate sources (32).

However, even pancreatic ribonucleases do not have only a digestive function as they have been identified in other tissues and body fluids as well, often in comparable quantities as observed in the pancreas (see Sec. IV.B). Other ribonucleases are synthesized exclusively in tissues which have no digestive function. Highly interesting are proteins which were isolated and characterized at first because of specific biological properties (18). Surprisingly, sequence analyses showed them to be members of one of the three extracellular ribonuclease superfamilies, which was confirmed by demonstrating ribonuclease activity, often at a low level or only with very specific cleavage patterns. Generally these ribonuclease activities were found to be a condition of the specific biological actions. Ribonucleases endowed with these special bioactions [RISBases (18)] are angiogenins (9, 23), the cytotoxic and aspermatozoic bovine seminal ribonuclease (20), amphibian members of the ribonuclease A superfamily such as onconase (33) and lectins from frog oocytes (5), self-incompatibility proteins in plants, which belong to the ribonuclease T<sub>2</sub> superfamily (12), and the already-mentioned  $\alpha$ -sarcin, which is a ribonuclease T<sub>1</sub> superfamily member (31).

A general feature of these ribonucleases endowed with special bioactions is that available evidence indicates that they exert their cytotoxic actions by cleavage of intracellular RNA in their target cells. This means that in some way these extracellular enzymes are internalized again, for which several specific receptor-mediated processes have been proposed and also experimentally demonstrated (23, 33). Members of the ribonuclease A superfamily bind cytoplasmic protein ribonuclease inhibitors (RI) with very high affinities (34). In a previous review we pointed to the paradox that these cytoplasmic inhibitors bind to non-cytoplasmic ribonucleases (35), but recent studies about uptake in foreign cells point to a biological function of these inhibitors. Within mammals there is little specificity in ribonuclease inhibitor interactions, also not with respect to the different ribonuclease families occurring in this vertebrate class. But ribonucleases from one vertebrate class (mammals, birds, amphibians) and inhibitors from another one do not bind to each other (5, 36).

## B. Role of Pancreatic Ribonucleases as Digestive Enzymes in Mammals

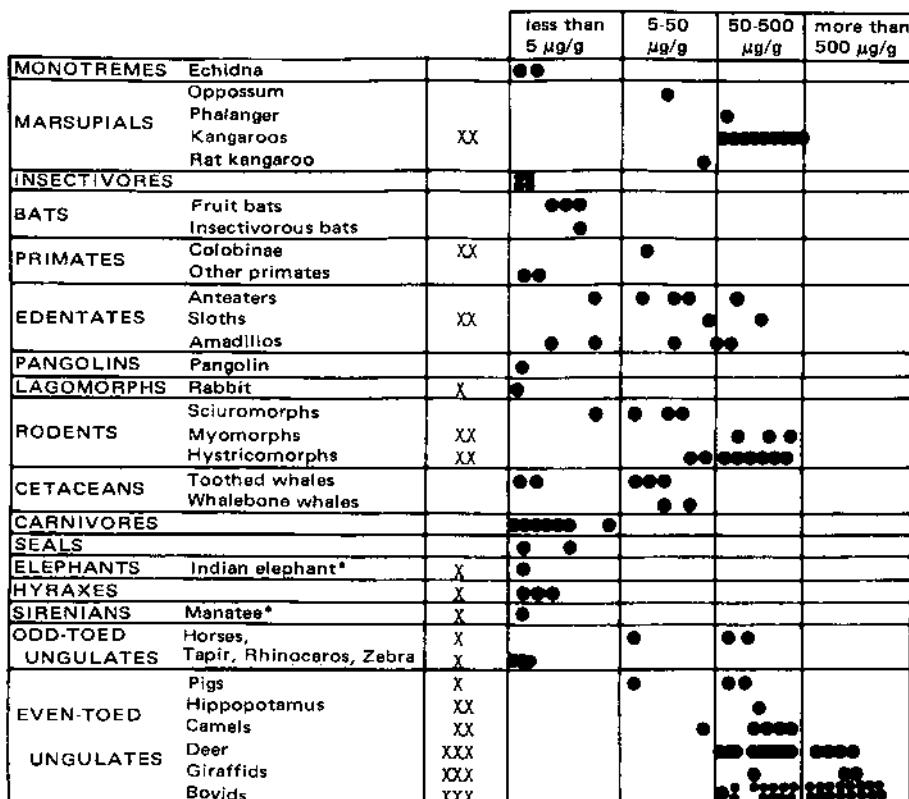

In Section II of this chapter it has already been mentioned that pancreatic ribonuclease is only present in high amounts in the pancreas of a limited number of mammalian taxa. Large quantities of this enzyme are found in ruminants and species that have a ruminant-like digestion, and in a number of species with cecal digestion (Fig. 2). However, there are also herbivores with cecal digestion with extremely low ribonuclease contents in the pancreas, such as lagomorphs (rabbit), hyraxes, manatee, and elephant (16). Barnard (15) proposed that an elevated level of pancreatic ribonuclease is the response to the necessity of digesting large amounts of ribonucleic acid derived from the microflora of the stomach of ruminants. This explanation agrees with the elevated level of stomach lysozyme in several ruminants and species that have a ruminantlike digestion (37). As far as we know, however, these roles of ribonuclease and lysozyme have never been investigated by comparative physiologists studying digestive systems of mammals.

The most striking differences between pancreatic ribonucleases concern the presence or absence of covalently attached carbohydrate. These differences may be related to the digestive system and the diet of the species involved. A number of pancreatic ribonucleases have carbohydrate attached to asparagine residues at positions 21, 22, 34, 62, 76, and/or 88 (Fig. 3). These positions are part of highly variant sequences at the surface of the molecule, far from the active site.

Only asparagine residues in Asn-X-Ser/Thr sequences have been found to act as attachment sites, where X may be any residue except proline (Fig. 3). However, not all Asn-X-Ser/Thr sequences possess carbohydrate chains. Other features of the ribonuclease molecule and/or the effectiveness of the carbohydrate-attaching system apparently influence the glycosylation process.

Figure 4 summarizes the occurrences of an Asn-X-Ser/Thr sequence in several investigated mammalian ribonucleases and their glycosylation states. The sugar composition of the carbohydrate chains is also indicated schematically in this figure. Both simple-type chains containing only glucosamine and mannose, and complex-type chains also containing fucose, galactose, and sialic acid occur.

All six carbohydrate sites in ribonucleases are located at external bends of the folded chain. This localization ensures maximal exposure of the carbohydrate moieties to the external solvent. In Figure 5 a

**Figure 2** Pancreatic ribonuclease content in mammalian taxa. XXX, ruminants; XX, ruminantlike digestion; X, (mainly) herbivorous. \*Pancreas badly autolyzed.

space-filling model of carbohydrate-free bovine ribonuclease is compared with the same model with three biantennary complex-type oligosaccharide chains attached at positions 22, 34, and 62, representing the minor glycosylated component of horse ribonuclease. Probably the carbohydrate moieties do not occupy fixed positions because of the presence of a number of flexible bonds, but the latter model shows the increase in volume as a result of the addition of carbohydrate.

The glycosylation states of the ribonucleases investigated were correlated with the type of fermentation (stomach or cecal) used by the species involved (Fig. 4). It was found that species with cecal digestion, such as pig, horse, and the hystricognath rodents (guinea pig and relatives), produce ribonucleases with large carbohydrate chains attached to several positions at the surface. Therefore, it was suggested that the presence of carbohydrate protects ribonuclease from absorption in the gut, enabling it to be transported to the large intestine where it should hydrolyze the ribonucleic acid derived from the cecal microflora.

(40). This would be analogous to the function of ribonucleases in the digestion of ribonucleic acid from the stomach microflora in ruminants and herbivores with ruminantlike digestion postulated by Barnard (15).

Ruminants and species with ruminantlike digestion (camel, hippopotamus, sloth, kangaroo) have less carbohydrate attached to their ribonucleases. Therefore, it seems that glycosylation of pancreatic ribonuclease may not be advantageous for species with stomach fermentation. These species escaped glycosylation of their ribonucleases not only by amino acid replacements in the protein (camel, reindeer), but probably also by developing a much less effective carbohydrate-attaching enzyme system in the pancreas than encountered in other species. Hippopotamus ribonuclease is an example of the second solution. This enzyme has four carbohydrate attachment sites, with carbohydrate attached to only one of them in only a fraction of the molecules.

If glycosylation of a ribonuclease is avoided by amino acid replacements, the enzyme will also not be glycosylated if its gene is expressed at other sites of the

body, but other pancreatic enzymes may be glycosylated extensively in the species involved. However, a less effective carbohydrate-attaching enzyme system in the pancreas will result in a general scarcity of glycosylated secretory pancreatic proteins, but the same gene product may be extensively glycosylated at other sites of the body. An example is human ribonuclease, which has three carbohydrate attachment sites, one being completely and one partially glycosylated in the pancreatic enzyme (41). The urinary enzyme, which is not synthesized in the pancreas, is glycosylated completely at all three sites (42).

These examples show dramatic secondary effects of apparently neutral replacements. Strong positive or negative selection may influence the presence of Asn-X-Ser/Thr sequences in proteins. However, the presence of a short oligosaccharide chain in bovine ribo-

**Figure 4** Occurrence of Asn-X-Ser/Thr sequences at the six carbohydrate sites (residues 21–23 or 22–24, 34–36, 62–64, 76–78, and 88–90) in ribonuclease and compositions of carbohydrate moieties. ■, completely glycosylated Asn-X-Ser/Thr sequence; □, part of the molecules are glycosylated; □, Asn-X-Ser/Thr sequence without carbohydrate attached; —, no Asn-X-Ser/Thr sequence present. **Figure 5** Space-filling models of bovine ribonuclease (left) and of a glycosylated ribonuclease with three biantennary complex-type oligosaccharide chains attached to the surface (right). This figure is a collage of the figure on p. 81 in Ref. 38 (ribonuclease) and Fig. 11B in Ref. 39 (spatial conformation of a biantennary glycan of the N-acetyllactosamine type in the T-conformation).

nuclease B, the minor glycosylated component, may be a neutral property. The three-dimensional structure of this protein was found to be identical to that of bovine ribonuclease A, with the carbohydrate chain extending into the solvent. This chain is disordered for most part and exerts no influence on the structure of the protein (43, 44).

Evolutionary selection against the occurrence of Asn-X-Ser/Thr sequences should occur if glycosylation is disadvantageous for the stability or function of the protein. Evidence of this has been presented by Hunt and Dayhoff (45) and Sinohara and Maruyama (46), who observed that Asn-X-Ser/Thr sequences occur less frequently than expected by chance in extracellular proteins from eukaryotes.

Similar glycosylation requirements for ribonucleases from different taxa may explain convergences in functional and structural characteristics. The pancreatic ribonuclease of giraffe is positioned with that of pronghorn and not with those of deer in most parsimonious trees of the sequences (21) as a consequence of a number of rather rarely observed amino acid replacements. However, since these shared replacements occur at internal positions, the relationship does not come to clear expression in many of the properties of these enzymes. Thus, giraffe ribonuclease is very similar to that of moose (a deer species) in glycosylation and other properties. It may be significant that in a classification of ruminants based on feeding ecol-

ogy and stomach structure (47), moose and giraffe are grouped together as large “concentrate selectors” with a diet containing relatively little cellulose fiber and a simple (primitive) stomach.

Strongly positively charged ribonucleases are considerably more active on double-stranded RNA than ribonucleases with a smaller excess of positive charges on the surface (48). We do not know whether the activity of the ribonucleases on double-stranded RNA has any function. The ribonucleases with the larger excess of positive charges are the ribonucleases from human and whale pancreas, bovine semen, and ruminant brain. These enzymes have no function in the digestion of microfloral RNA from the stomach or cecum of herbivores. This suggests that there is a relationship between the excess of positive charges of ribonucleases and nondigestive functions.

Man and langur monkey are two species in the same mammalian order, of which the latter possesses all features of having ruminantlike digestion. The amino acid sequence of their ribonucleases differ at 14 (11%) of the positions (49). This leaves no doubt that they are located on the same branch in a most parsimonious tree. The hypothesis that species with ruminantlike digestion not only have a higher ribonuclease content in their pancreas, but also have less excess of positive charge and fewer attached carbohydrates, is in agreement with data presented in Table 1.

### C. Intracellular RNA Processing and Turnover

Many RNA species in living cells are continuously synthesized, processed and degraded, in which ribonucleases should play a major role. However, disappointingly much less is known about these ribonucleases than about those discussed in the previous sections.

Deutscher (50) and Nicholson (51) list endoribonucleases identified and characterized in the prokaryote *Escherichia coli*. These lists include the excreted periplasmic enzyme ribonuclease I (EC 3.1.27.6), which is a member of the ubiquitous ribonuclease T<sub>2</sub> superfamily (12) discussed in the previous section. Interestingly, there occurs a modified form of this ribonuclease, ribonuclease I\*, which has no signal peptide sequence on its coding DNA, is not secreted through the cytoplasmic membrane, and may exert its function intracellularly. Less well characterized enzymes are ribonucleases M and R, which are similar to ribonuclease I.

The major participant in mRNA decay in *E. coli* is ribonuclease E. This enzyme also plays a role in rRNA maturation. This is a divalent metal requiring enzyme, producing 5'-phosphomonoesters (EC 3.1.26). It has a

**Table 1** Several Characteristics of Human and Langur Pancreatic Ribonucleases

<sup>a</sup>Simple-type carbohydrate chains only contain glucosamine and mannose.

polypeptide sequence of 1061 amino acids, much longer than the extracellular enzymes discussed in the previous section. A similar activity is exhibited by the already mentioned ribonuclease P (EC 3.1.26.5), of which the ribonucleic acid component is the catalytically active one.

More specialized *E. coli* ribonucleases are ribonucleases III (EC 3.1.26.3) and H1 and H3 (EC 3.1.26.4), which cleave double-stranded (ds) RNA molecules and the RNA strand of RNA-DNA hybrids, respectively. Other, less well characterized ribonucleases in *E. coli* are ribonucleases IV and F (producing 3'-phosphate termini; EC 3.1.27.7), P2, O, PIV, PC and N.

Few intracellularly synthesized eukaryotic ribonucleases have been identified and characterized. Two of the few examples are the 2'-5'A (=oligoadenylate with  $2' \rightarrow 5'$  internucleotide linkages)-dependent human and murine ribonucleases L (52) which cleave RNA with the production of 3'-phosphoryl and 5'-hydroxyl groups. The polypeptide chains of these enzymes have chain lengths of  $\sim 750$  residues, and each includes a ribonuclease domain of  $\sim 200$  residues, with some sequence similarity with ribonuclease E. This suggested homology, however, is not in agreement with the different cleavage specificities of these mammalian and *E. coli* enzymes. Another ribonuclease E-related activity in mammalian cells is the product of the human ard-1 gene, which encodes a basic, proline-rich 13.3-kDa molecular-weight protein (53). Expression of this gene in *E. coli* can complement a mutant of the ribonuclease E gene, but there are no indications that this gene product represents a ribonuclease. Wennborg et al. (54) have isolated from human cell extracts a ribonuclease with the same specificity as ribonuclease E. Antibodies to ribonuclease E recognize this human protein, which has, however, not yet been structurally characterized.

Moiseyev et al. (55, 56) have isolated, characterized and sequenced two plant ribonucleases isolated from ginseng calluses. These enzymes, with polypeptide lengths of  $\sim 150$  residues, are homologous with cytotoxic intracellular pathogenesis-related proteins (IPR or PR-10) from several plants such as parsley (57) and bean (58), and with pollen allergens from tree species such as birch (59) and alder (60). This suggests that the cytotoxic properties of these latter proteins are caused by their ribonuclease activities. However, this hypothesis is still being met with skepticism. In addition, this protein family does not contain any conserved histidine residues, a universal active-site residue in all other investigated ribonuclease families so far investigated.

So, although much knowledge has already been collected about intracellular RNA processing and degrading activities in eukaryotes (61, 62), little is known about the responsible enzymes. Part of these enzymes will be proteins, but many others may be enzymatically active RNA molecules (ribozymes). Penny and coworkers recently published a model for the evolution of life from an RNA world to the emergence of eukaryotes and prokaryotes (63), and summarized the presence of RNAs in modern organisms that are relics from the ancient RNA world. Proteins have gradually replaced RNAs in catalysis by virtue of their superior catalytic properties. However, in the case of large substrates such as RNA the rate of diffusion is the slowest reaction step, and catalytic perfection will not help much in speeding up the reaction rate. Therefore, it is not surprising that in intracellular RNA metabolism still many catalytically active RNAs are used. These authors also propose that the prokaryote genome organization was derived from a "eukaryotelike" one, which is supported by the fact that prokaryotes use proteins for many activities in RNA processing, for

which eukaryotes use RNA-protein (RNP) complexes (64).

## V. DETERMINATION OF RIBONUCLEASE ACTIVITY

Methods for the determination of ribonuclease activities measure either the depolymerization of RNA or of homopolyribonucleotides (poly(C), poly(G), etc.), the cleavage of dinucleotides of defined structure, or the hydrolysis of cyclic nucleotides. Table XXIII on p. 751 in Richards and Wyckoff (65) summarizes methods used at that time, which have not changed much since then. As discussed before (Sec. I.C), the hydrolysis of cyclic nucleotides is the second reaction catalyzed by ribonucleases (Fig. 1); it generally is a rather slow one and in several cases even does not occur. Measurement of the depolymerization of RNA is the most sensitive method and can even be used for determination of the activity of family members discussed in Section IV.A with hardly any ribonuclease activity. However, these methods only give qualitative or relative quantitative data (e.g., relative to the activity of bovine pancreatic ribonuclease). Depolymerization of RNA is often measured by the formation of acid-soluble nucleotides, which, however, generally requires construction of nonlinear standard curves with known quantities of, e.g., pure bovine pancreatic ribonuclease.

Nevertheless, using one of the latter methods is most suitable for a first characterization of ribonuclease activity in biological samples and may be performed as follows (66): 0.01–0.05 mL sample solution

is incubated for 30 min at 37°C with 0.5 mL RNA (e.g., commercial purified yeast RNA) solution (0.4 mg/mL) in a buffer containing 100 mg gelatin, 0.1 mM EDTA, 0.1 M NaCl in 0.05 M Tris/HCl buffer, pH 7.5. The reaction is terminated by adding 0.5 mL precipitant which contains 0.1 g  $\text{UO}_2(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 3\text{H}_2\text{O}$  in 100 mL of 2.5% trichloroacetic acid. After keeping on ice for 30 min and centrifugation, the absorbance at 260 nm of the 10 times diluted supernatant is measured. The readings of the absorbance are not proportional to the enzymatic activity and produce an S-shaped curve, which requires the construction of a standard curve with a ribonuclease with similar specificity properties.

## VI. PROPERTIES AS ENZYMES

The extracellular representatives of the ribonuclease A, T<sub>1</sub>, and T<sub>2</sub> superfamilies are generally very stable enzymes, especially at low pH values. High temperatures are required for inactivation. They do not require cofactors or metal ions for activity. Pancreatic ribonucleases (ribonucleases 1) are inhibited by Zn<sup>2+</sup> and Cu<sup>2+</sup> ions. These latter enzymes depolymerize RNA with a pH optimum ~ 8.0 at ionic strength values of 0.1. However, the pH optimum for cleavage of dinucleotides or the hydrolysis of cyclic nucleotides is ~ 6.5–7.0.

In Table 2 several kinetic parameters of reactions catalyzed by bovine and turtle pancreatic ribonucleases are shown (67). The  $k_{\text{cat}}$  values for the cleavage of dinucleotide are several orders of magnitude higher than those for the hydrolysis of cyclic nucleotides.

**Table 2** Several Kinetic Parameters of Bovine and Turtle Pancreatic Ribonucleases

Substrate	Bovine ribonuclease		Turtle ribonuclease	
	$K_m$ (mM)	$k_{\text{cat}}$ (sec <sup>-1</sup> )	$K_m$ (mM)	$k_{\text{cat}}$ (sec <sup>-1</sup> )
cyclic 2', 3'-UMP	1.58	1.4	4.50	0.05
UpU	2.10	2.0	1.20	0.11
UpC	0.66	4.1	— <sup>a</sup>	— <sup>a</sup>
UpG	0.47	12.3	0.63	2.0
UpA	0.22	405	0.42	0.72
cyclic 2', 3'-CMP	0.43	1.5	0.82	0.45
CpU	1.05	8.7	0.52	0.97
CpC	0.58	10.8	0.28	0.38
CpG	0.42	43.3	0.28	15.2
CpA	0.18	675	0.34	6.3

<sup>a</sup>Too slowly hydrolyzed under the experimental conditions to obtain kinetic constants.

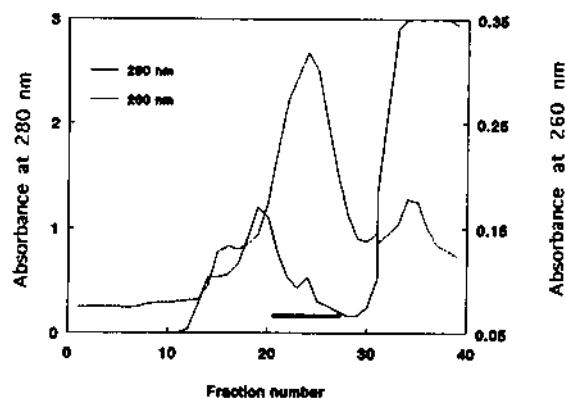

Source: From Ref. 67.

$k_{cat}/K_m$  values (relative to the activity of the bovine enzyme) observed for the hydrolysis of cyclic nucleotides by a large number of pancreatic ribonucleases from mammalian species vary from 0.2 (mouse; cyclic 2', 3'-CMP) to 2.9 (kangaroo; cyclic 2', 3'-UMP) (68).

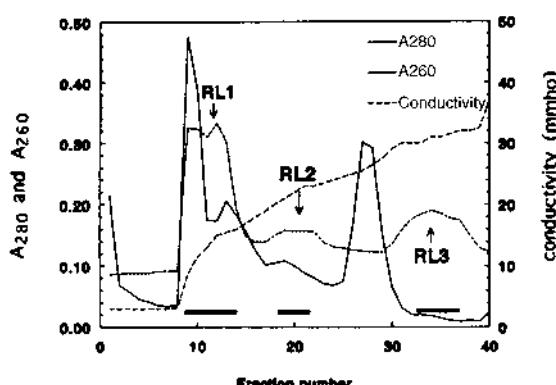

## VII. PURIFICATION OF A RIBONUCLEASE

As will be clear from the previous sections, there is no universal method for the isolation of a molecular entity with ribonuclease activity. Below, we shall summarize, as an example, our efforts to purify ribonucleases occurring in rat liver (66). As we intended to isolate members of the ribonuclease A superfamily, which are stable at low pH, while cytoplasmic inhibitors which bind to these ribonucleases are not stable at this pH, we have used homogenization of liver tissue with 0.125 M sulfuric acid as first step in the isolation procedure. After centrifugation, cold acetone ( $-20^{\circ}\text{C}$ ) was slowly added to the supernatant ( $4^{\circ}\text{C}$ ) to a concentration of 30% (v/v). After stirring for 4 h, the supernatant was obtained by centrifugation. More cold acetone was added to a concentration of 60% acetone (v/v). The suspension was kept overnight (at  $4^{\circ}\text{C}$ ). After centrifugation, the pellet was dissolved in 0.2 M sodium

acetate buffer, pH 5.0, for further purification by gel filtration on a Sephadex G-75 column ( $4^{\circ}\text{C}$ ). Ribonuclease activities were determined as described in Section V. One major peak with enzymatic activity was obtained (Fig. 6). A small shoulder of earlier eluting ribonuclease activity probably indicates the presence of a ribonuclease T<sub>2</sub> representative (12). Pooled fractions from the gel filtration on Sephadex G-75 were further fractionated on an SP-Trisacryl column as illustrated in Figure 7. Three fractions with enzymatic activity were obtained—RL1, RL2, and RL3—which were further purified by reversed-phase HPLC, using a C18 column and elution with a linear gradient of 0–60% acetonitrile (v/v) in 0.1% trifluoroacetic acid in 60 min. The flow rate was 1 mL/min. Pure ribonuclease 1 (the pancreatic enzyme) was obtained from RL1. Partial degradation at the N-terminus explains the shape of fraction RL1 in Figure 7. A homolog of human ribonucleases 2 and 6 was isolated from RL2, while RL3 contained ribonuclease 4, with some contamination of ribonuclease 5 (angiogenin). Approximately 20  $\mu\text{g}$  ribonuclease 1 (RL1), 5  $\mu\text{g}$  ribonuclease 2/6 (RL2), and 80  $\mu\text{g}$  ribonuclease 4 (RL3) were recovered from 1 kg rat liver. As these ribonucleases have very different specific activities (66), it is not possible to calculate enzyme recoveries during each step of the purification procedure.

**Figure 6** Sephadex G-75 gel filtration of a crude extract of rat liver. The column ( $2.5 \times 75$  cm) was equilibrated at  $4^{\circ}\text{C}$  with 0.05 M sodium acetate buffer, pH 5.0, and eluted with the same buffer. The flow rate was 1 mL/min. Fractions of 10 mL were collected. Ribonuclease activity was expressed as the reading of the absorbance at 260 nm (see Sec. V). Fractions indicated by a bar were pooled.

**Figure 7** SP-Trisacryl column chromatography of the active fractions of the Sephadex G-75 column. The column ( $1 \times 10$  cm) was equilibrated at  $4^{\circ}\text{C}$  with 0.05 M sodium acetate buffer, pH 5.0, and washed with 0.04 M KNa phosphate buffer, pH 7.0, and developed with a gradient of 0–1.0 M ammonium acetate in 0.05 M KNa phosphate buffer. Fractions of 2.0 mL were collected. Three active fractions indicated by bars are marked RL1, RL2, and RL3, respectively, and were collected separately.

## Proteolytic Enzymes

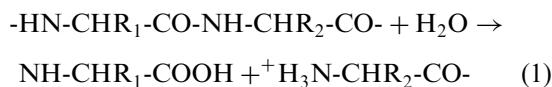

**John R. Whitaker**

*University of California, Davis, Davis, California, U.S.A.*

### I. INTRODUCTION

#### A. General Aspects, Including Importance for Food Science and Technology

Proteolytic enzymes hydrolyze peptide bonds in proteins and peptides [Eq. (1)]

They are found in all living organisms (animals, plants, and microorganisms). They are essential for digestion of food proteins to peptides and amino acids. The amino acids then are used for resynthesis of proteins unique for a specific organism. In the human gastrointestinal tract, the proteolytic enzyme pepsin (stomach) and a large group of small-intestinal proteolytic enzymes—trypsin, chymotrypsin, carboxypeptidases, leucine aminopeptidases, tripeptidases, and dipeptidases—convert the proteins of our ingested foods to amino acids. Humans have two internal digestive systems to hydrolyze proteins when they are no longer needed or are “worn out.” These involve the lysosomal organelles of the cell containing the catheptic enzymes and the general proteolytic enzymes of the blood system. The liver is also very active in hydrolysis and in biosynthesis of proteins for numerous cells.

Many proteins are produced as zymogens; i.e., they are inactive until limited specific proteolysis transforms them into active enzymes. Examples include propepsin,

protrypsin and prochymotrypsin, prolipases, proamylases, etc. In the blood-clotting mechanism, some nine pro-proteolytic enzymes need to be catalytically cleaved via a cascade process to form the active enzymes that permit blood clotting to occur (1). Proinsulin is initially synthesized in vivo and then converted to insulin by two proteolytic enzymes cleaving two different peptide bonds of pro-insulin (2). Several other examples are given in Table 1 and in Roberts and Herbert (3).

Proteins are synthesized in the endoplasmic reticulum on the m-DNA of the cell. Often, they are chemically modified following biosynthesis in numerous ways (4) and are transported outside the cell in to the blood system, where they are delivered to the host cells or other locations where they function. Transport out of the cell requires an N-terminal segment of amino acid residues (called the signal peptide), which is removed by highly specific proteolytic enzymes after the proprotein crosses the cell membrane (or wall in bacteria or plants). Proteins are continually synthesized and hydrolyzed at different rates, depending on the protein (Table 2) (5).

Some of the proproteins of glandular secretions are cleaved in the digestive tract to form specific peptides that have various physiological effects, such as the formation of adrenocorticotropic hormone (ACTH),  $\beta$ -lipotropic hormone ( $\beta$ -LP),  $\beta$ -melanocyte-stimulating hormone ( $\beta$ -MSH),  $\beta$ -endorphin, and enkephalin resulting from the specific proteolytic cleavage of a precursor protein of  $\sim 8000$  daltons (Fig. 1) (2, 3, 5).

**Table 1** Physiologically Important Proteolysis

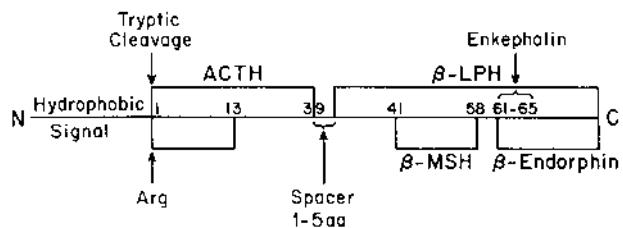

Conversion of food proteins to peptides and amino acids
Activation of zymogens to active enzymes
Blood coagulation
Collagen formation
Milk clotting in infant's stomach
Mammalian reproduction
Intracellular digestion of proteins
Protein translocation
Formation of hormones
Virus assembly
Immune response
Fibrinolysis
Blood pressure control
Sporulation of microorganisms
Germination of spores and plant seeds
Oncogenic transformation
Extracellular protein transport
Lysosomal protein degradation
Assembly of proteins, including tertiary and quaternary structures
Transfer of proteins across membranes
Inborn errors of amino acid metabolism and transport
Complement activation

Major physical property changes occur as the result of a single polypeptide bond cleavage by a highly specific protease. In the case of chymosin, hydrolysis of the -Phe105-Met106- bond of kappa-casein causes milk to clot (6). In the case of blood, sequential activation of the cascade of some ten pro-proteases leads to clotting of blood at the source of a wound in < 1 min (7). **Table 3** lists a number of food products in which proteolysis is important (8).

**Table 2** Rates of Intracellular Turnover of Some Selected Proteins

Protein	Half-life
Ornithine decarboxylase	10 min
$\delta$ -Amino levulinate synthetase	60 min
Catalase	1.4 d
LDH <sub>5</sub>	16 d
Mitochondria protein as whole	4–5 d
Rat protein (%)	4–5 d
Cultured cells	1–2% h

**Figure 1** Pituitary gland protein precursor proteolytically cleaved to produce the hormones ACTH (adrenocorticotrophic hormone),  $\beta$ -LPH ( $\beta$ -lipotropin hormone),  $\beta$ -MSH ( $\beta$ -melanocyte-stimulating hormone),  $\beta$ -endorphin, and enkephalin. (From Ref. 5.)

## B. Specificity

Each proteolytic enzyme is very specific for a few peptide bonds of proteins. First, a protein must be denatured (unfolded) in order to be hydrolyzed. The proteins in our food are denatured by cooking and/or processing. The proteins of foods consumed raw are generally denatured by the high acidity of the stomach (pH 1–2 due to hydrochloric acid). Some physiologically important proteins, such as zymogens, have small segments that do not fold and thereby are hydrolyzed at nonfolded locations (between domains) to give active enzymes, hormones, etc.

Proteolytic enzymes are also specific in terms of being endoproteases or exoproteases. The endoproteases, such as trypsin, chymotrypsin, and chymosin, hydrolyze peptide bonds in the interior of the polypeptide chains. The exo-proteases act on peptide bonds at the N-terminal (aminopeptidases) or the C-terminal (carboxypeptidases) of the protein. The di- and tripeptidases act on di- and tripeptides produced by endoproteases to convert them to amino acids. The various types of proteases of the small intestine can, working together, convert proteins to their constituent amino acids in 2–4 h at 37°C. The human body must receive the essential amino acids (lysine, tryptophan tyrosine + phenylalanine, valine, leucine, isoleucine, threonine, histidine, methionine + cysteine) from food, as they cannot be produced in the body.

Proteolytic enzymes are also absolutely specific for one or few of the amino acid residues at the scissile peptide bond. For example, trypsin hydrolyzes peptide bonds only at lysyl and arginyl residues that furnish the carbonyl moiety of the peptide bond. Chymotrypsin hydrolyzes peptide bonds only when tyrosine, phenylalanine, or tryptophan residues provide the carbonyl group of the peptide bond. The amino acid residue at the N-side of the peptide bond

**Table 3** Use of Proteolytic Enzymes in Food Processing

Food	Purpose of action
Baked goods	Softening action in doughs. Cut mixing time, increase extensibility of doughs. Improve texture, elasticity and loaf volume. Liberate $\beta$ -amylase.
Brewing	Body, flavor, and nutrient development during fermentation. Aid in filtration and clarification. Chill-proofing.
Cereals	Modify proteins to increase drying rate, improve product handling characteristics. Production of miso and tofu.
Cheese	Casein coagulation. Characteristic flavor development during aging.
Chocolate, cocoa	Action on beans during fermentation.
Egg, egg products	Improve drying properties
Feeds	Waste product conversion to feeds. Digestive aids, particularly for pigs.
Fish	Solubilization of fish protein concentrate. Recovery of oil and proteins from inedible parts.
Legumes	Hydrolyzed protein products. Removal of flavor. Plastein formation.
Meats	Tenderization. Recovery of protein from bones.
Milk	Coagulation in rennet puddings. Preparation of soybean milk.
Protein hydrolysates	Condiments such as soy sauce and tamar sauce. Bouillon. Dehydrated soups. Gravy powders. Processed meats. Special diets.
Antinutrient factor removal	Specific protein inhibitors of proteolytic enzymes and amylases. Phytate. Gossypol. Nucleic acid.
Wines	Clarification <sup>a</sup>
In vivo processing <sup>b</sup>	Conversion of zymogens to enzymes. Fibrinogen to fibrin. Collagen biosynthesis. Proinsulin to insulin. Macromolecular assembly.

<sup>a</sup>In large part caused by other than proteolytic enzymes

<sup>b</sup>Representative examples given.

determines the relative rate at which the peptide bond is hydrolyzed. Some other proteolytic enzymes are even more specific, as chymosin will hydrolyze only the Phe105-Met106 peptide bond of kappa-casein.

### C. Health Aspects Related to Metabolism of Proteins and Amino Acids

There are > 100 human diseases related to defects of protein and amino acid metabolism (9). These studies began as early as 1810, when Wollaston (10) discovered that defective cystine metabolism leads to cystine stones in the urinary tract due to high levels of cystine, lysine, ornithine, and arginine. The full extent and effect of these diseases are still not known.

One of the best known diseases is phenylketonuria due to the routine testing of newborns (10). This disease is caused by deficiency of the enzyme phenylalanine hydroxylase, which converts phenylalanine to tyrosine. To date, the only medical intervention available is to exclude phenylalanine from the diet by use of protein hydrolysates from which phenylalanine has been removed. When the conversion of phenylalanine to tyrosine is blocked, the urine is dark in color, pigmentation of the skin is reduced (albinism), and neurological disturbances may occur since the levels of

neurotransmitters dopamine and norepinephrine are reduced. At least eight diseases can result from failure in conversion of phenylalanine to formic acid and acetocetic acid (9).

In babies, chymosin is a key enzyme in the stomach (replacing pepsin). Chymosin clots milk, causing it to remain longer in the stomach, where it is digested. Lack of adequate chymosin activity leads to a number of abnormalities.

Some adult humans are unable to digest some of the proteins in foods, such as gluten in wheat. These can lead to allergic reactions. To date, the only remedy is to avoid such foods.

## II. TYPES OF PROTEOLYTIC ENZYMES

Given the large numbers of proteolytic enzymes (Sec. I), it is surprising that there are only four different types based on the active site. These are the serine proteases (EC 3.4.21), the cysteine proteases (EC 3.4.22), the aspartic proteases (EC 3.4.23), and the metalloproteases (EC 3.4.24), based on the catalytic group of the enzyme involved in the nucleophilic attack at the carbonyl carbon of the scissile peptide bond of the substrate.

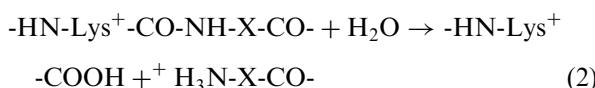

## A. Serine Proteases

The serine protease family includes trypsin, chymotrypsin, elastase, subtilisin, the nine proteases involved in blood coagulation (1), collagenase, and others.

### 1. Binding of Substrates and Inhibitors

Proteinwise, the serine proteases are a diverse group having different physical properties. However, at the active site they are essentially identical, except for the detail of the binding sites. The best-known binding sites are those for trypsin, chymotrypsin, elastase, and subtilisin. As shown in [Figure 2](#), the binding sites of trypsin, chymotrypsin, and elastase are very similar except for one amino acid difference. In trypsin, there is a lysine (Lys residue) at the bottom of the pocket. In chymotrypsin, there is a tyrosine (Tyr residue) at the bottom of the pocket in place of a Lys residue. In elastase, there is a valine (Val residue) on one side of the pocket, which blocks access of the substrate to most of the pocket.

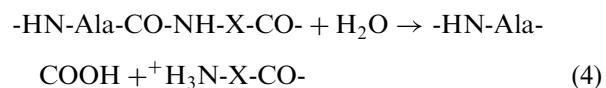

Because of these modifications in the pocket, only lysyl and argininyl amino acid residues of protein and peptide substrates can bind stereospecifically to the active site of trypsin so that the peptide bond is oriented properly for hydrolysis [Eq. (2)].

In chymotrypsin, the binding pocket is hydrophobic; therefore, the tyrosyl, phenylalanyl, and tryptophanyl amino acid residues of proteins and peptides can bind into the pocket stereospecifically so that hydrolysis occurs, as shown in Eq. (3) for tyrosine.

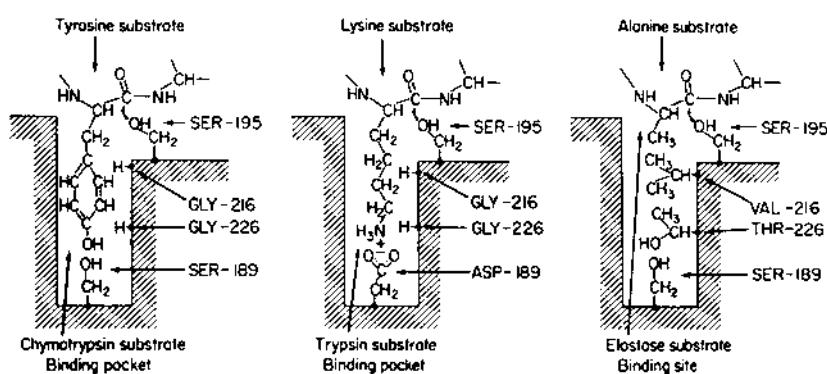

In elastase, the available binding pocket is small, such that only small hydrophobic side chain amino acid residues, such as alanyl, can be bound and hydrolyzed [Eq. (4)].

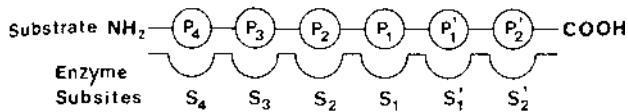

In 1967, Schechter and Berger (12) introduced the enzyme subsite concept to explain the binding of substrates into the active site of sulphydryl proteases ([Fig. 3](#)). This concept has been extended to include the other three types of proteases. For example, in subtilisin (a serine protease), similar in specificity to chymotrypsin, the binding site is at least six subsites in length – S<sub>4</sub>, S<sub>3</sub>, S<sub>2</sub>, S<sub>1</sub>, S'<sub>1</sub>, S'<sub>2</sub> (13, 14), and eight subsites are found with some substrates and competitive inhibitors. These enzyme subsites are not sequentially located but exist on several of the secondary structural  $\beta$ -strands (strands 1–8) ([Fig. 4](#)). The enzyme subsites interaction strengths with substrates are not equal. In subtilisin the subsite S<sub>1</sub> and S<sub>4</sub> are the strongest; the S'<sub>1</sub> and S'<sub>2</sub> subsites binding is relatively weak. In subtilisin BPN', S<sub>1</sub>, S<sub>2</sub>, and S<sub>3</sub> have been identified as Ser125-Leu126-Gly127 (16), while S'<sub>1</sub>, S'<sub>2</sub> and S'<sub>3</sub> are Gly102-Gln103-Tyr104 (17). In subtilisin produced by other strains, the subsites may show differences.

The native structures of subtilisin and trypsin are stabilized by calcium ions. However, the calcium ions do not participate in the binding and catalytic steps. They provide additional electrostatic binding with anionic bonds of the enzyme.

**Figure 2** Schematic substrate binding sites in chymotrypsin, trypsin, and elastase. (From Ref. 11.)

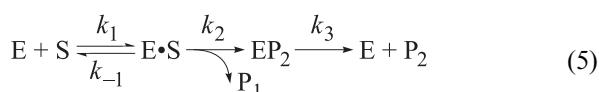

**Figure 3** Schematic representation of complex of enzyme-substrate binding at subsites. (From Ref. 12.)

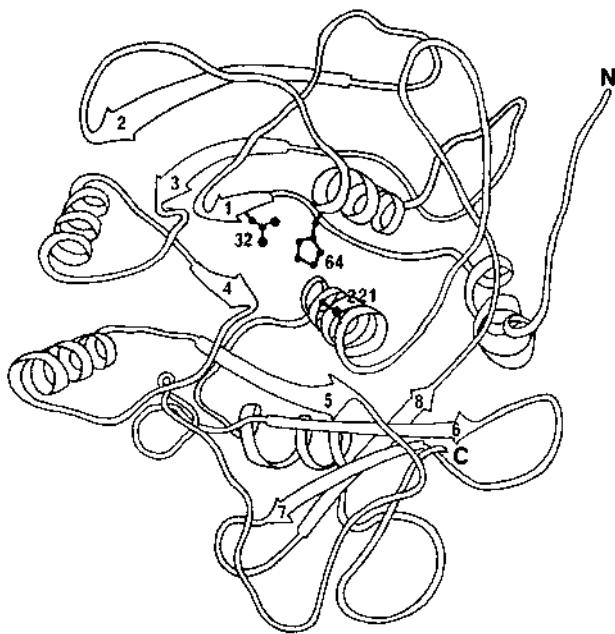

## 2. Catalytic Mechanism

The serine proteases generally hydrolyze both peptide and ester bonds of substrates, provided the enzyme substrate binding requirements are met as described above. Ester bonds of substrates are hydrolyzed much faster than peptide bonds since  $\Delta H^*$  is  $\sim 7$  kcal/mol for ester bonds vs. 20 kcal/mol for amide bonds. Therefore, small ester substrates, such as N-acetyl-L-tyrosine methyl (or ethyl) esters (for chymotrypsin and subtilisin) and N-benzoyl L-arginine methyl (or ethyl) esters (for trypsin) are used for mechanistic studies.

The serine proteases hydrolyze substrates by a two-step catalytic mechanism as shown by Eq. (5).

The first step, controlled by  $k_1$  and  $k_{-1}$  is the noncovalent binding of enzyme (E) and substrate (S) to form the Michaelis-Menten complex. Step 2, controlled by  $k_2$ , is the acylation step in which the acyl group (specificity side) of the substrate is transferred to the active site Ser oxygen of the enzyme active site (see Ser221 of Fig. 4) to form an ester bond [EP<sub>2</sub> in Eq. (5)]. Product P<sub>1</sub>, the HN side of the peptide bond (or OR side of ester bond), dissociates from the enzyme active site. This step is controlled by the pH-dependent ( $pK_a \sim 7$ ) protonated/deprotonated state of His64 of subtilisin (see Fig. 4). When the imidazole group of the catalytic site is protonated, the enzyme is inactive; when the imidazole group is unprotonated, the enzyme is active. The pH dependence of the acylation step can be sigmoidal (controlled by one  $pK_a$  for subtilisin) or bell shaped (controlled by two  $pK_a$ 's, the histidine residue, and the ionization of an N-terminal isoleucyl residue in trypsin and chymotrypsin). The N-terminal isoleucyl residue, in the  $^+H_3N$ -isoleucyl form, is essential for maintaining the native structure of the enzyme via an electrostatic bond. Therefore, for amide sub-

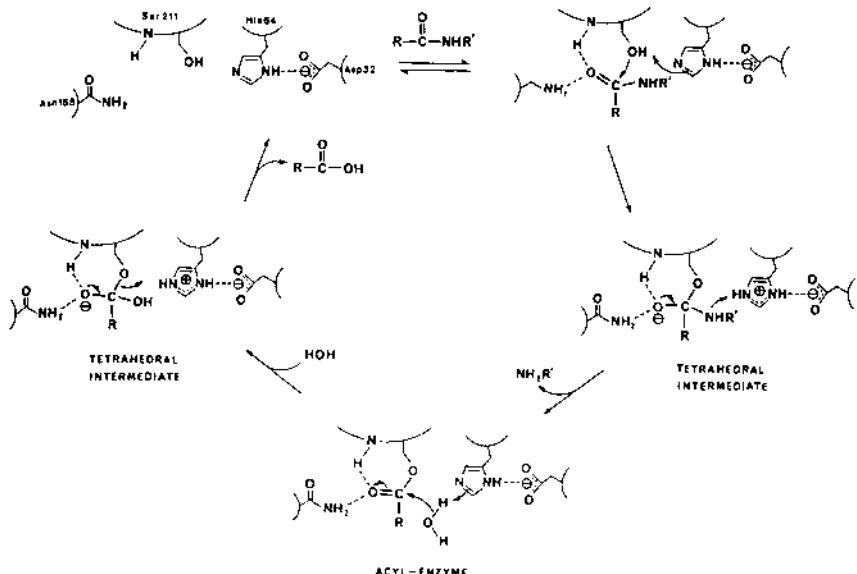

**Figure 4** Schematic diagram of the three-dimensional structure of subtilisin viewed down the central parallel  $\beta$ -sheet. The catalytic site is composed of Ser32, His64, and Asp221. The eight  $\beta$ -strands are number 1–8; the six  $\alpha$ -helices are coiled segments. (From Ref. 15.)

strates, the pH dependence of  $k_2$  is bell shaped while for ester substrates it is sigmoidal with a  $pK_a$  of  $\sim 7$  for trypsin and chymotrypsin.

The step controlled by  $k_3$  is due to deacylation (hydrolysis) in which the acyl group of the acyl-enzyme is removed by hydrolysis, eliminating the second product, P<sub>2</sub>, as an acid. A single ionizable group, that of the imidazole group of His64 (of subtilisin), controls the deacylation step, giving a sigmoidal curve with a  $pK_a$  of  $\sim 7$  for all serine proteases. The pH and temperature dependencies of the  $k_3$  step are identical for both amide and ester substrate hydrolyses.

Mechanistic details of the acylation and deacylation steps for subtilisin catalysis are shown in Figure 5. The acylation and deacylation half-reactions (Fig. 5) consist of the following steps: (a) formation of the Michaelis complex (ES) between the enzyme and substrate [ $k_1$  and  $k_{-1}$  of Eq. (5)] that is noncovalent and reversible; (b) formation of a covalent tetrahedral intermediate via nucleophilic attack by the reactive Ser221-O<sub>x</sub> on the carbonyl carbon of the scissile bond of the substrate (this step is facilitated by a general base catalysis by His64); (c) conversion of the tetrahedral intermediate to the covalent acyl enzyme via protonation of the leaving group R'NH<sub>2</sub>

**Figure 5** Reaction mechanism of subtilisin showing the catalytic pathway of acylation and deacylation via the formation of tetrahedral intermediates. (From Ref. 18.)

(P<sub>1</sub>) of the substrate by His64; (d) nucleophilic attack by a water molecule, assisted by general-base catalysis involving His64 (this leads to a second tetrahedral intermediate); and (e) breakdown of the tetrahedral intermediate via His64-catalyzed protonation of the Ser221-O<sub>γ</sub>, liberating the acyl group of the substrate as an acid (P<sub>2</sub>).

The steady-state reaction equations resulting from Eq. (5) are:

$$k_{\text{cat}} = k_2 k_3 / (k_2 + k_3) \quad (6)$$

$$K_m = K_s k_3 / (k_2 + k_3) \quad (7)$$

where  $K_s = k_{-1}/k_1$ .

For the reactive ester substrates, the rate of acylation is higher than deacylation ( $k_2 \gg k_3$ ) so that  $K_m$  is  $\sim K_s k_3/k_2$  and the rate-limiting step is that controlled by  $k_3$  (deacylation). For amide and peptide substrates,  $k_2 \ll k_3$ . Therefore,  $k_2$  approximates  $k_{\text{cat}}$  and  $K_m \sim K_s$ .

## B. The Cysteine (Sulphydryl) Proteases

Typical cysteine proteases include papain from the latex of unripe fruit of the *Carica papaya* tree, ficin from the fig tree (*Ficus carica*), actinin from kiwi fruit (*Actinidia chinensis*), and bromelain from the pineapple (*Ananas comosus*) as well as the mammalian

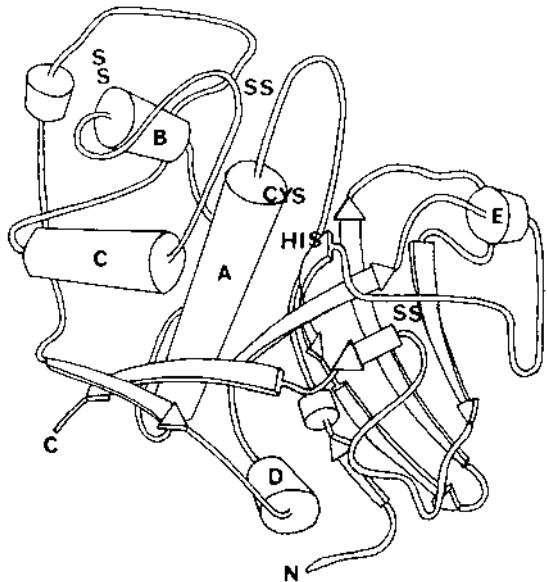

calpains ( $\text{Ca}^{2+}$  dependent) and some cathepsins (lysosomal).

The best-studied typical cysteine protease is papain, which will be discussed here because of its major uses in the food industry for chill proofing of beer and meat tenderization, as well as synthesis of peptides and other organic compounds. The lysosomal cathepsins are important because of their physiological roles in turnover of proteins in the body and their possible role in diseases, such as muscular dystrophy, osteoporosis, inflammatory heart diseases, and tumor invasion (19).

### 1. Protein Characteristics of Papain

Papain is a single polypeptide of 212 amino acids with a molecular weight of 23,350 daltons (20). It contains three disulfide bonds. Papain has exceptional stability to heat at neutral pH and to some organic solvents. It is the major protein in the aqueous phase of papaya latex, at  $\sim 5\%$  concentration. It can be spray dried at  $\sim 65^\circ\text{C}$  without loss of activity.

The primary sequence of amino acids in papain is known and the tertiary structure has been determined by x-ray crystallography (21). The molecule is folded into an ellipsoid with a dimension of  $50 \times 37 \times 37 \text{ \AA}$ . As shown in Figure 6, the polypeptide chain is folded into two domains, L and R. The L domain (N-terminal end of papain) includes amino acid residues 10–100, consisting of helices A, B, and C. The folding of the

**Figure 6** Schematic diagram showing the polypeptide folding in papain (actinidin folding is identical). The native molecule consists of two domains with a long cavity between the two. The left domain contains helices A, B, and C, while the right domain is formed from double  $\beta$ -sheet structures with helices D and E at opposite ends. The three SS's are disulfide bonds. The catalytic group Cys is on helix A while catalytic group His is on one of the  $\beta$ -strands. The third catalytic group is Asn (not shown). The substrate binds in the cavity formed by helix A and the pleated sheets to the right side (22).

three helices form a central core of high hydrophobicity. The R domain (C-terminal end) includes amino acid residues 113–207 and consists primarily of seven  $\beta$  strands which form a twisted antiparallel  $\beta$ -sheet producing a barrel with a large hydrophobic core. The two domains are covalently bound together only by three crossovers of the folded polypeptide chain. The interface of the two domains forms a groove (crevice) between the two domains which contains the active site of the enzyme.

## 2. Active Site of Papain

The active site, consisting of the binding and catalytic loci, is located in the groove formed by the two parallel R and L domains. The catalytic locus of papain consists of Cys25, (on the L domain), His159 (on R domain) [both shown at top of the groove (Fig. 6)], and Asn175 (not shown but located on the random chain within 5 Å of His159 on the R domain). The Cys25 lies adjacent to the N<sub>1</sub> of the His159 imidazole

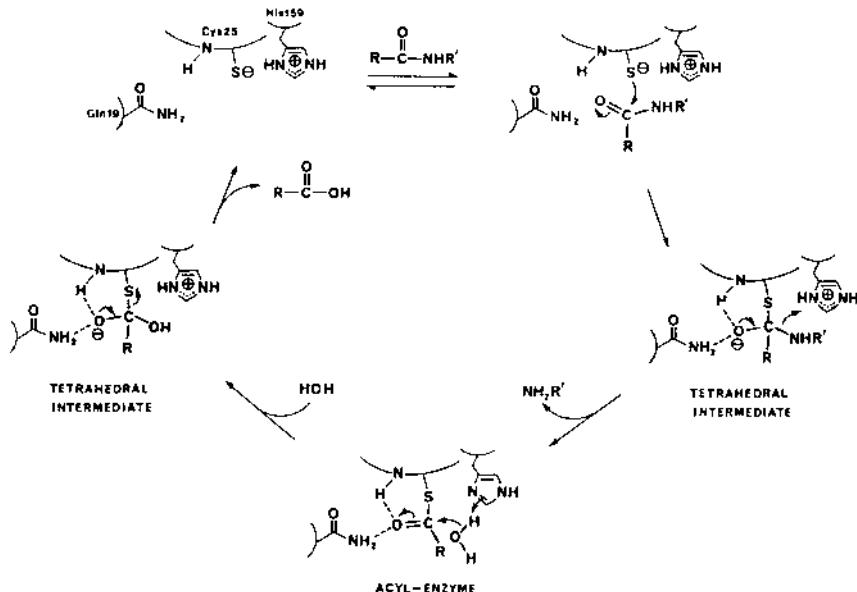

ring. The other His nitrogen, N<sub>2</sub>, is hydrogen bonded to the side chain oxygen (R-CO-NH<sub>2</sub>) of Asn175, which lies just above the His imidazole ring. During the covalent formation of the acyl enzyme, the imidazole rotates  $\sim 30^\circ$ , moving the His159-N<sub>1</sub> to a position coplanar with the leaving group nitrogen (23).

The binding locus of the active site of papain consists of seven subsites extending over 25 Å in the groove formed at the interface of the L and R domains. These subsites for binding are represented as -S<sub>4</sub>S<sub>3</sub>S<sub>2</sub>S<sub>1</sub>S'<sub>1</sub>S'<sub>2</sub>S'<sub>3</sub>- that interact with the peptide substrate amino acid side chains -H<sub>2</sub>N-P<sub>4</sub>, P<sub>3</sub>P<sub>2</sub>P'<sub>1</sub>P'<sub>2</sub>P'<sub>3</sub>- (12). Substrate specificity of the enzyme is largely determined by the acylating side (the -H<sub>2</sub>N-P<sub>4</sub>... side). The S<sub>1</sub> subsite of the enzyme is relatively nonselective, but it cannot accommodate P<sub>1</sub>-containing substrates with branched chains, such as valine. The S<sub>2</sub> subsite of the enzyme is primarily responsible for the selectivity of the substrate. It consists of contributions from the hydrophobic side chains of Tyr67, Pro68, Trp69, Phe207, Ala160, Val133, and Val157 (24). Thus, subsite S<sub>2</sub> has a strong preference for the hydrophobic amino acid side chains of Phe, Tyr, Val, and Leu of substrates (25). The S'<sub>1</sub> specificity is expressed in the deacylation step, similar to that for the serine proteases. The S'<sub>2</sub> subsite has a preference for the hydrophobic residues Leu and Trp. Therefore, the S'<sub>1</sub>-P'<sub>1</sub> interaction makes considerable contribution to binding and to the rate of hydrolysis (26, 27).

## 3. Catalytic Mechanism of Papain

The pathway of hydrolysis of substrates by papain, and other sulphydryl proteases, follows that of the serine proteases [Eq. (5)]. Following formation of the Michaelis complex, a covalent acyl enzyme intermediate is formed in the second step controlled by k<sub>2</sub>, releasing the first product. In the k<sub>3</sub>-controlled step, water is activated to hydrolyze the thionyl enzyme intermediate to give free enzyme and the acid product. Therefore, the rate-limiting steps are controlled by k<sub>2</sub> and k<sub>3</sub>, respectively, for amides and esters (24, 28). However, in contrast to the large differences found for ester vs. amide hydrolysis observed for subtilisin, trypsin, and chymotrypsin, the rates of ester and amide hydrolysis are similar for papain and the other cysteine proteases. This means that the cysteine proteases have a more efficient mechanism of lowering the activation energy, E<sub>a</sub>, for forming the acyl enzyme intermediate or the amide substrate.

Figure 7 summarizes the reaction mechanism for hydrolysis of substrates by papain and the other sulf-

**Figure 7** Reaction mechanism of papain showing the acylation and deacylation steps involving formation of tetrahedral intermediates. (From Ref. 18.)

hydrol proteases. The papain-catalyzed reaction pathways (Fig. 7) consists of the following steps: (a) the enzyme binds reversibly with the substrate to form a Michaelis complex, ES; (b) nucleophilic attack by the Cys25 thiolate anion on the carbonyl carbon of the scissile peptide bond of the substrate leads to the formation of a tetrahedral intermediate; (c) a collapse of the tetrahedral intermediate to an acyl enzyme is facilitated by protonation of the leaving group (amide nitrogen in the case of a peptide substrate) by the His159 imidazolium cation; (d) nucleophilic attack by a H<sub>2</sub>O molecule assisted by His159 acting as a base catalyst results in deacylation of the acyl enzyme (which is a thioester in the cysteine proteases). As shown, the pathway and mechanism are similar to those for the serine proteases.

### C. Aspartic Proteases

The aspartic proteases have two aspartic acid residues in the catalytic locus of the active site, thus the name of aspartic proteases.

Calf chymosin (older name “rennin”), porcine pepsin, cathepsin D, renin, penicillopepsin (*Penicillium* sp.), and the *Mucor pusillus* and *Mucor miehei* protease have been studied the most intensively. Calf chymosin and the *Mucor* proteases are very important in cheese making. The calf chymosin gene has been cloned and

expressed in *Escherichia coli* (29, 30), *Saccharomyces cerevisiae* (31), *Aspergillus nidulans* (32), and *A. awamori* (32). Recombinant calf chymosin produced in genetically modified *E. coli* (a bacterium; 33), *A. awamori* (a fungus; 32), and *Kluyveromyces lactis* (yeast; 34) are approved by FDA for use in cheese making. While the proteolytic pH optima for these enzymes are pH ~3–4, they are used at pH ~5.2 for coagulation of the caseins of milk for cheese manufacture. At pH 5.2, the major peptide bond hydrolyzed is the –Phe<sub>105</sub>Met<sub>106</sub> bond of kappa-casein.

### 1. Protein Structure of Chymosin

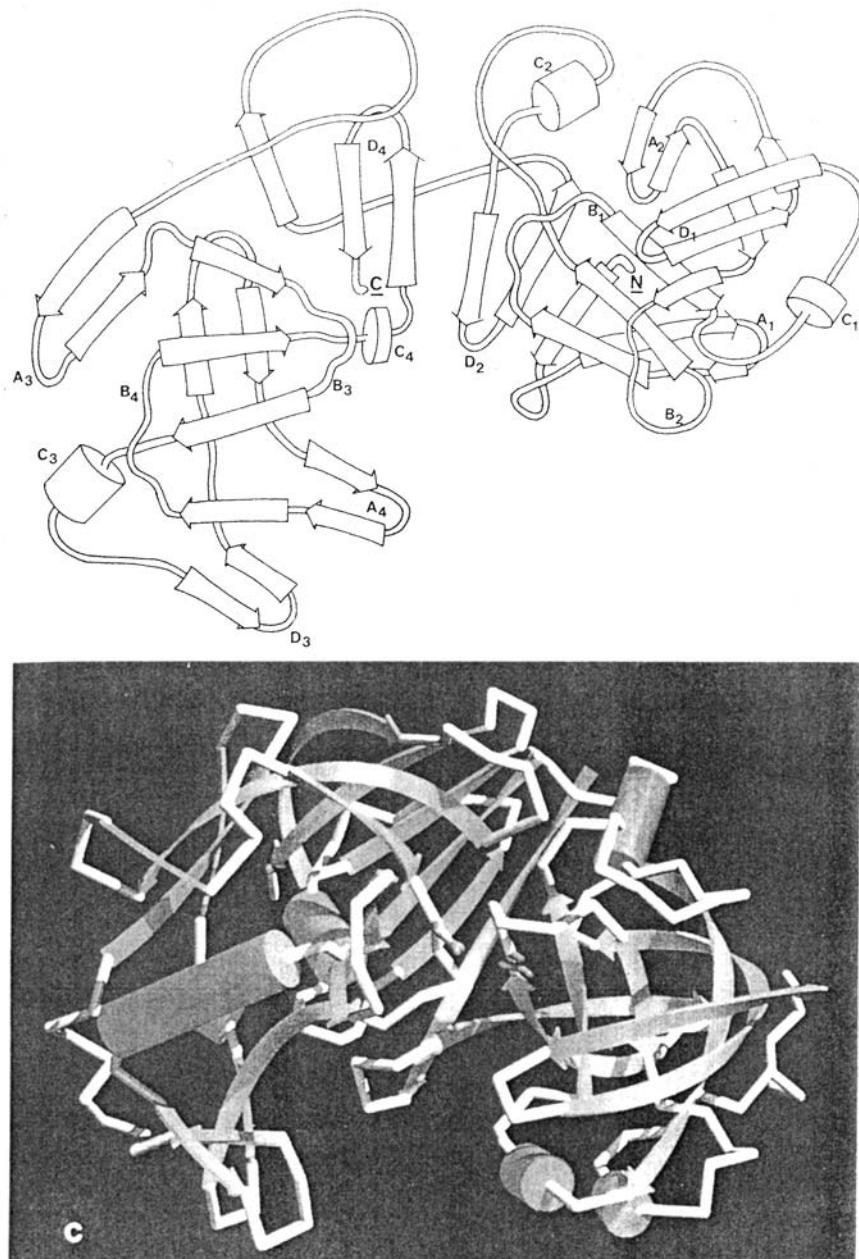

Calf chymosin, because of its commercial importance in cheese manufacture, is chosen for future detailed discussion in this chapter. Calf chymosin is produced as a prochymosin, without activity. Prochymosin is a single polypeptide chain of 365 amino acid residues. It is cleaved at the peptide bond between Phe42Gly43 by pepsin to give mature chymosin with 323 amino acid residues (35, 36). There are two chymosin isozymes. Chymosin A and B differ by a single amino acid residue, Asp or Gly difference at position 244, respectively (35, 36). The pH optimum of chymosin A is 4.2, while that of chymosin B is 3.7.

The single polypeptide chain of chymosin has an MW of 35 kDa, with three disulfide bonds. Its second-

ary structure is primarily a  $\beta$ -sheet protein with very little  $\alpha$ -helix structure (Fig. 8) (37b).

Chymosin, similar to other aspartic proteases, has two domains separated by a deep substrate binding cleft, with a pseudo-twofold symmetry (Fig. 8). The N-terminal (1–175 amino acid residue sequence) and C-terminal (176–323 amino acid resi-

due sequence) domains are topographically equivalent. Each of the domains is composed of two repeating motifs of four antiparallel  $\beta$ -strands and a helix. The two motifs pair to form two interlocked, four-stranded sheets that are packed orthogonally in each domain, giving a total of six antiparallel  $\beta$ -sheets (37b).

**Figure 8** (Top) The general secondary structures of acid proteases showing the location of the first  $\beta$  hairpin turn A<sub>1</sub>, wide loop B<sub>2</sub>, helix C<sub>1</sub>, and second hairpin turn D<sub>2</sub> in the right domain (37a). (Bottom) Recombinant bovine chymosin (37b). More details are in Ref. 37b.

## 2. Substrate Binding Locus of Chymosin

The extending binding locus is along the cleft between the two domains, containing up to seven subsites designated as  $S_4S_3S_2S_1S_1'S_2'S_3'$  with the catalytic site (see below) located between  $S_1$  and  $S_1'$ . The corresponding substrate units matching the binding site are  $\text{NH}_2\text{-P}_4\text{P}_3\text{P}_2\text{P}_1\text{P}_1'\text{P}_2'\text{P}_3'\text{-COOH}$ . Much research has been done on the effect of size and amino acid sequence of synthetic peptides as well as of bovine kappa-casein on  $K_m$  and  $k_{cat}$  for hydrolyzing the Phe105Met106 bond. A minimum of five amino acids including -SerPheMetAla- are required for hydrolysis of the PheMet bond. Addition of Leu to the N-terminal end and Ile to the C-terminal end to give substrate LeuSerPheMetAlaIle increases  $k_{cat}$  and decreases  $K_m$ . Addition of Pro further to either the N- or C-terminal end increased  $k_{cat}/K_m$  to  $22 \text{ mM}^{-1}\text{s}^{-1}$  (38). The 15-amino acid residue tryptic peptide from  $\kappa$ -casein (residues 98–112) with a sequence of HisProHisProHisLeu SerPheMetAlaIleProProLysLys used as a substrate for bovine chymosin gave  $k_{cat}/K_m$  of  $4715 \text{ mM}^{-1}\text{s}^{-1}$  at pH 5.3–5.5 and  $2123 \text{ mM}^{-1}\text{s}^{-1}$  at pH 6.6 (39). Kinetic studies using bovine  $\kappa$ -casein as substrate gave  $k_{cat}/K_m$  of  $1413 \text{ mM}^{-1}\text{s}^{-1}$  (pH 6.2, 30°C) with  $k_{cat}$  of  $68.5 \text{ s}^{-1}$  and  $K_m$  of  $0.048 \text{ mM}$  (40). Therefore, the results for the 15-amino acid residue tryptic peptide as substrate for bovine chymosin is considered to represent the maximal cleavage rate of the Phe105Met106 bond by chymosin.

## 3. Catalytic Locus of Chymosin

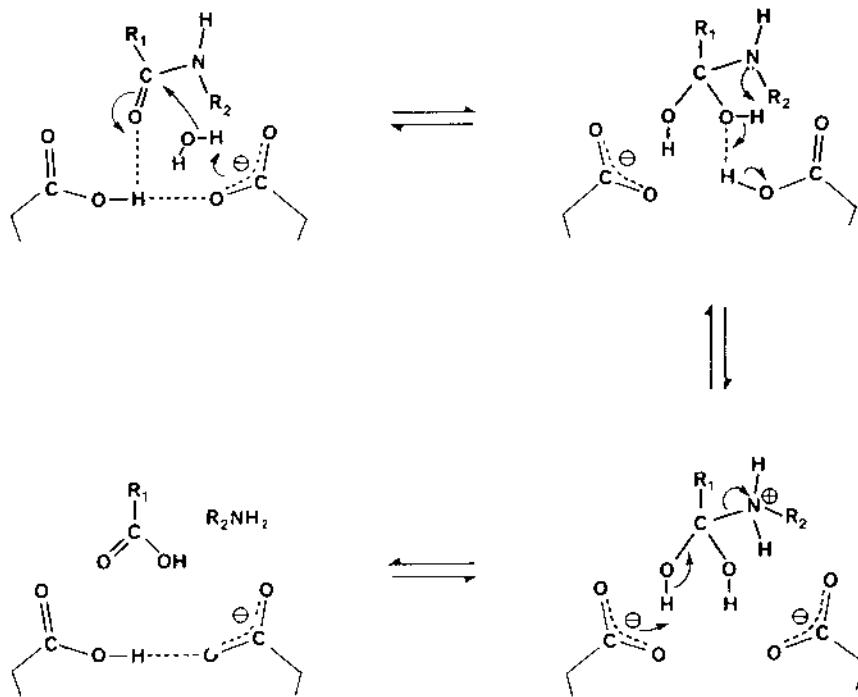

The catalytic locus is located at the base of the cleft between the N- and C-terminal domains (Fig. 8). It consists of the essential Asp34 and Asp216 amino acid residues, with the two carboxyl groups oriented toward the cleft. The distance between the carboxyl oxygens of the two aspartic acid residues is  $3.1 \text{ \AA}$ . The two essential aspartic acid residues are located at the ends of the  $B_1$  and  $B_2$  loops formed by two homologous segments, N-terminal Asp34Thr35Gly36Ser37Ser38 and C-terminal Asp216Thr217Gly218Thr219Ser220. These two loops overlap each other such that the O of the OH group of Thr35 of the N-terminal loop hydrogen bonds with the N of the peptide bond of Thr217G218. A  $\beta$ -loop of 12 sequential amino acid residues (residues 71–82: -Lys71 Pro72Leu73Ser74Ieu75His76Tyr77Gly78Thr79Gly80 Ser81Met82) forms a “flap” over the cleft, such that the substrate is enclosed in a hydrophobic environment especially at the scissile bond  $P_1P_1'$  (41).

Calf chymosin, like all the aspartic proteases, gives a bell-shaped pH- $V_{max}$  plot, with pKs of 3.2 and 4.7 for the synthetic substrate LysProA1aGluPhePhe(NO<sub>2</sub>) AlaLeu (42) and pKs of 2.3 and 4.7 if acid-denatured hemoglobin is the substrate (43). The pH optimum is 3.7, where one aspartic acid carboxyl group involved in catalysis is ionized and the second aspartic acid carboxyl group is protonated.

The proposed mechanism of hydrolysis by bovine chymosin is shown in Figure 9 (44, 45). It is a general acid/general base catalysis with no covalent intermediate. The peptide bond carbonyl oxygen of the substrate is protonated by the Asp diad proton. This protonation increases polarization of the carbonyl peptide bond ( $> \text{C} = \text{O} \cdots \text{H}^+$ ), resulting in a more positive carbon center for nucleophilic attack of a H<sub>2</sub>O molecule. The nucleophilic attack of H<sub>2</sub>O occurs at the peptide carbonyl carbon of the substrate by base catalysis ( $\text{-OH}$ ) assisted by the Asp carboxylate anion. This results in the formation of a noncovalent tetrahedral intermediate. The peptide bond nitrogen atom of the tetrahedral intermediate accepts a proton from a water molecule of the Asp diad. The N-protonation facilitates cleavage of the C-N bond of the tetrahedral intermediate.

## D. Metalloproteases

Most of the metalloproteases are exopeptidases. These include the carboxypeptidases A (peptidyl-L-amino acid hydrolase, EC 3.4.17.1) and B (peptidyl-L-lysine hydrolases, EC 3.4.17.2), glycyl-glycine dipeptidase (dipeptide hydrolase, EC 3.4.13.11), carnosinase (acts on  $\beta$ -alanyl-L-histidine and related compounds; amino-acyl-histidine hydrolase, EC 3.4.13.3), and cytosol aminopeptidase ( $\alpha$ -amino-acyl-peptide hydrolase, EC 3.4.11.1). All require Zn<sup>2+</sup> as cofactor. Prolidase (where proline or hydroxyproline is the carboxyl terminal residue; aminoacyl-L-proline hydrolase, EC 3.4.13.9) and iminodipeptidase (in which proline or hydroxyproline is the N-terminal residue; L-propyl-amino-acid hydrolase, EC 3.4.13.8-9) require Mn<sup>2+</sup>. These are just a few representatives of the many exopeptidases known. Thermolysin (EC 3.4.24.4) is a metalloendoprotease, with similar active site, specificity, and mechanism to carboxypeptidase A (see Chap. 79). Other metallopeptidases include the collagenases of microorganisms and the hemorrhagic proteinases of snake venoms.

**Figure 9** Proposed reaction mechanism of chymosin. (From Refs. 44, 45.)

### 1. Carboxypeptidase A

Bovine carboxypeptidase will be described as a prototype metalloproteolytic enzyme.

Most proteolytic enzymes are synthesized as proenzymes and are then activated by cleavage of one or more peptide bonds. This is a protective mechanism to prevent premature proteolysis. Bovine procarboxypeptidase A has a molecular weight of 87,000 and consists of three noncovalently linked polypeptide (subunits I, II, and III) (46).

Controlled trypsin treatment initially gives an enzymatically active product with one or a few peptide bonds hydrolyzed in subunit II and activity on N-acetyl-L-tyrosine ethyl ester similar to that of  $\alpha$ -chymotrypsin (a serine protease). Further treatment with trypsin hydrolyzes a peptide bond in subunit I, giving carboxypeptidase A-like activity on hippuryl-L- $\beta$ -phenyllactic acid (HPLA). The molecular weight is still  $\sim$  87,000 daltons, and both chymotrypsin and HPLA activities are present. More extensive treatment with trypsin destroys (inactivates and degrades) both subunits II and III, leaving only the 34,500-dalton subunit I with carboxypeptidaseslike activity on the synthetic substrates benzoyloxycarbonylglycyl-L-phenyl-

alanine (CGP) and benzoylglycyl- $\beta$ -L-phenyllactic acid (HPLA) as well as on the C-terminal ends of proteins and peptides containing any amino acid residue other than arginine or lysine (these C-terminal ends are susceptible to carboxypeptidase B hydrolysis).

During conversion of procarboxypeptidase A to carboxypeptidase A, several different peptide bonds at the N-terminal end of subunit I are hydrolyzed, giving at least four different active forms of carboxypeptidase A. These are  $A_\alpha$  (307 amino acid residues),  $A_\beta$  (305 residues),  $A_\chi$  (300 residues), and  $A_\delta$  (300 residues), but with different physical properties. The x-ray crystallographic structure of carboxypeptidase  $A_\alpha$ ,  $A_\beta$ , and  $A_\chi$  have been determined (Fig. 10). The N-terminal is an alanyl residue (No. 1), while the C-terminal is an asparagine residue (No. 307). Some 55 amino acid residues (18% of total) are involved in a twisted  $\beta$ -pleated sheet structure, made up of four pairs of parallel and three pairs of antiparallel strands that form one side of the pocket which extends into the molecule and forms the active site. The helical regions of the enzyme involve 92 amino acid residues (30% of total) and are primarily  $\alpha$ -helices. The remaining 160 amino acid residues (52%) are in random coils.

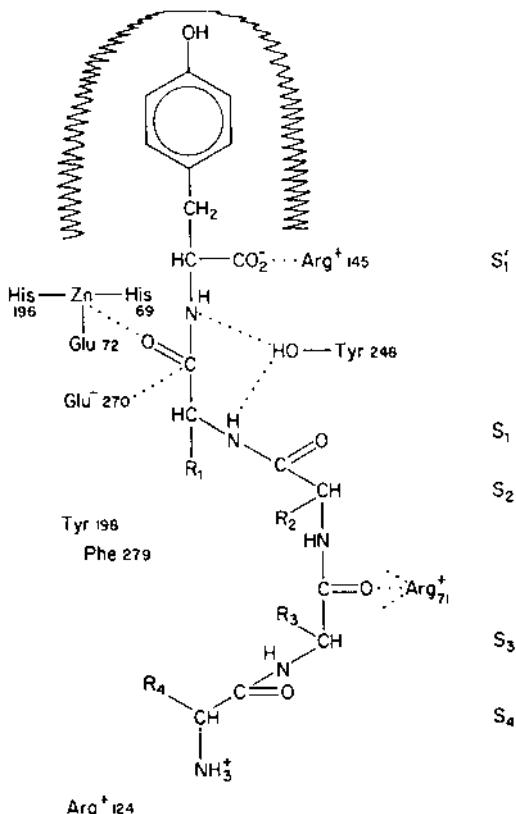

**Figure 10** Secondary and tertiary structures of carboxypeptidase A determined by x-ray crystallography. The small open circles along the protein chain represent the  $\alpha$ -carbon atoms of the 307 amino acid residues. The active site is indicated by the large circle in the center of the molecule. (From Ref. 47.)

The region around the active site is not a cleft, as described for subtilisin, papain, and chymosin earlier in this chapter, but rather is a hole in the enzyme. This is shown diagrammatically in Figure 11, where the hole is shown at the top of the figure in a zig-zag nature with the C-terminal tyrosine residue ( $S'_1$ ) of the substrate enclosed. The remainder of the substrate is vertically oriented with the other amino acid residues  $S_1$ ,  $S_2$ ,  $S_3$ , and  $S_4$  pointing downward. The peptide bond hydrolyzed is between  $S'_1$  and  $S_1$ . As the substrate is oriented, on the left side the  $Zn^{2+}$  (cofactor) of the enzyme is bound to His69, Glu72, and His196 residues of the enzyme and to the carbonyl O of the first peptide bond of the substrate; the Glu<sup>-</sup> 270 of the enzyme is coordinated with the C of the carbonyl group of the substrate; and on the right side Arg<sup>+145</sup> of the enzyme is electrostatically bound to the carboxylate group of residue 1 (phenylalanyl); the hydroxyl group of Tyr248 of the enzyme is coordinated to the N's of peptide bond one and peptide bond two of the substrate and Arg<sup>+71</sup> to the carbonyl O of peptide 3 of the substrate. Depending on the size and nature of the substrate, reactive groups of the substrate may also interact with Arg<sup>+124</sup>, Tyr198, and Phe279 of the enzyme.

Lipscomb et al. (47) proposed the following mechanism for the action of carboxypeptidase A. The most probable steps in the mechanisms that we slightly favor at present for polypeptide substrates, not necessarily in the order given, are as follows:

1. Water is displaced as the C-terminal side chain of the substrate moves into the (hydrophobic) pocket, the carboxylate group of the substrate saltlinks to Arg145, the carbonyl group of  $S_3$  and perhaps  $S_4$  bind to Arg71, and sidechains particularly of  $S_3$  but also of  $S_2$  and  $S_4$  associate with Tyr198 and Phe279. (Residues  $S_2$  and  $S_3$  and  $S_4$  are amino acid residues 1, 2, and 3 removed from the terminal amino acid residue of substrate.) The oxygen of the carbonyl group of the susceptible peptide (bond) probably coordinates to Zn, but the alternative in which this carbonyl is directed away from Zn has also been discussed. Large conformational changes associated with the binding step are the movement of the guanidinium group of Arg145 by  $\sim 2 \text{ \AA}$  to bind the terminal carboxyl group of the substrate, the coordinated movement of the OH of Tyr248 by  $12 \text{ \AA}$  to donate a hydrogen bond to the NH of the (strained) susceptible peptide bond and to receive a hydrogen bond from the penultimate peptide bond,

**Figure 11** Schematic drawing of a substrate bound in the active site of carboxypeptidase A. The NH and CO groups of the scissile peptide bond are in a plane perpendicular to that of the drawing. The substrate is arranged vertically and center of the diagram. The amino acid residues of the enzyme surround the substrate and are numbered. (From Ref. 47.)

and the movement of the carboxylate group of Glu270  $\sim 2 \text{ \AA}$  away from the region of the susceptible peptide bond in order to preserve normal Van der Waals contact in the binding step.

2. Tyr248 donates  $\text{H}^+$  to the NH of the peptide bond, forming a phenoxide ion (of Tyr248) which is stabilized by the hydrogen bond donated from the penultimate peptide bond, and in the case of the “Zn-carbonyl” mechanism, Glu270 forms an anhydride with the carbon of the polarized  $\text{C}^{\delta+} \cdots \text{O}^{\delta-} \cdots \text{Zn}$  carbonyl bond of the susceptible peptide (or Glu270 promotes the attack of water on this carbon atom).

3. After the peptide bond is split, a water molecule can cleave the anhydride (if formed) in a step which may be facilitated by the nearness of the phenoxide ion of Tyr248.

4. The remainder of the polypeptide chain moves away, the conformational changes are reversed, the C-

terminal residue leaves the pocket, and the water molecules reenter (47).

Whether or not the details of the mechanism are correct in all aspects, the complexity of the enzyme action is not likely to be any less complicated than described above. For the substrate, benzyloxy-carbonylglycyl-L-phenylalanine,  $k_{\text{cat}}$  is  $106 \text{ s}^{-1}$  at pH 7.50 and  $25.0^\circ\text{C}$ , which means that one molecule of enzyme converts 106 molecules substrate to product in 1 sec (9.4 msec per substrate molecule converted to product). Truly, an enzyme is a very efficient catalyst!

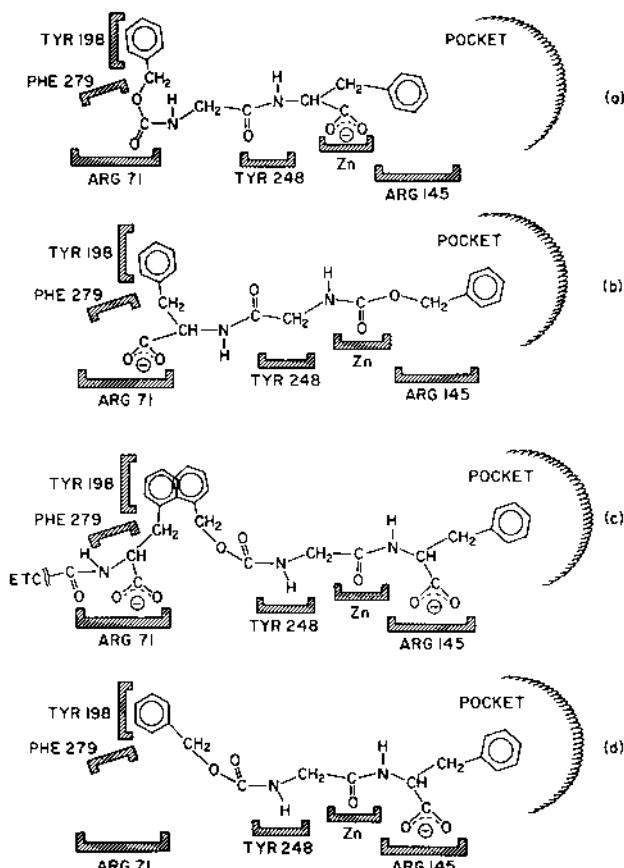

Subsequent research, including x-ray crystallography, showed that the substrate benzyloxycarbonylglycyl-L-phenylalanine (CGP) can bind into the active site of the enzyme in four different ways (Fig. 12). Binding in modes (a), (b), and (c) leads to inhibition of the enzyme, rather than catalysis as shown for mode (d).

### III. MEASUREMENT OF PROTEOLYTIC ACTIVITY

The activity of a protease is determined by whether it hydrolyzes peptide bonds in a protein. Its catalytic specificity is determined by which peptide bonds it hydrolyzes in the protein. Its catalytic efficiency is determined by how fast it hydrolyzes peptide bonds under standard conditions of pH, temperature, and enzyme concentration. Whether it is an endo- or exoprotease is determined by the products formed near the beginning of a reaction. Endoproteases hydrolyze the protein in the interior of the molecule, giving large polypeptide fragments. Exoproteases hydrolyze the N-terminal amino acid(s) from the protein (aminopeptidases) or from the C-terminal end (carboxypeptidases).

Proteases do not hydrolyze native protein molecules, i.e., those which are folded properly in the native state. An exception to this rule is that of a native protein folded into two or more independent domains. In this case the protease may hydrolyze peptide bonds in the random segment between the domains for which it has specificity. If a dissolved protein has both native and random structures in equilibrium ( $\text{N} \rightleftharpoons \text{R}$ ), a protease may hydrolyze the R form, thereby permitting all the protein to be hydrolyzed. Therefore, the rate of hydrolysis may be controlled by the rate at which N is converted to R in the reaction.

Two protein substrates are generally used to determine the presence of proteases in plant, animal, and

**Figure 12** Proposed modes of binding of the substrate benzoyloxycarbonylglycyl-L-phenylalanine into the active site of carboxypeptidase A. Only (d) is properly oriented to be converted to product. Substrate bound as shown in (a), (b), and (c) are competitive inhibitors. (From Ref. 47.)

microbial extracts. These proteins are bovine casein (generally mixture of  $\alpha_s$ ,  $\beta$ , and  $\kappa$ -caseins or purified  $\alpha_s$ -casein) and bovine hemoglobin. The caseins are flexible molecules and readily hydrolyzed by proteases without need for denaturation by urea, heat, or temperature treatment. On the other hand, hemoglobin must be denatured, usually with 6 M urea treatment, prior to use as substrate. One difficulty with casein is that it precipitates near its isoelectric point (pH 5.1), making it difficult to use in the pH range of  $5 \pm 1$ . Denatured hemoglobin is soluble in this acid pH range.

The protein assay methods generally depend on increase in trichloroacetic acid-soluble products from proteolysis or by milk-clotting activity (48).

### A. Casein Hydrolysis Method (49)

The Kunitz method is probably the most frequently used method to determine general proteolysis, applicable for all proteases (with modification of pH and presence of a sulphydryl compound for activation of cysteine proteases). The following procedure is a modification used for many years with great success (50).

A stock solution of casein is prepared by suspending 5 g casein (preferably made by the Hammarstein method (51) in 100 mL distilled water, adding 0.5 mL of 5 N NaOH with mixing and incubating at 90° C for 15 min. This solution can be stored in the refrigerator and can be used for up to a week. Just before use, the stock casein solution is adjusted to 1% concentration and to desired pH (depending on protease) and buffer concentration (usually 0.1 or 0.2 M). For cysteine proteases sufficient stock cysteine solution (prepared fresh each day) is added to give 25 mM cysteine concentration in the final reaction.

At the time of use, aliquots of the 1% casein solution (1–4 mL) are incubated for at least 5 min at the temperature of the experiment. Sufficient aqueous solution (used to prepare the enzyme) is added that the overall volume will be reached when the enzyme solution is added (any constant volume needed based on activity). A timer is started after mixing the enzyme with substrate for two or three inversions of the tube. Multiple tubes can be run by starting the reactions at 30-sec intervals. At the chosen time, 3 mL of 5% trichloroacetic acid (e.g., 3 mL for a 2.00-mL reaction of enzyme and substrate) is added and mixed immediately, to stop the reaction. The stopped reaction(s) are held for 1 h (this time can be shortened to 10–20 min by placing the tubes in a 40–50° C water bath). The holding time is to complete the precipitation of TCA-insoluble products (casein and large polypeptides). The samples are centrifuged for 5–20 min depending on the centrifugal force. The clear solution is removed and read at 280 nm. Blanks are prepared by adding the TCA solution *prior* to adding the enzyme.

The results can be reported as increase in  $A_{280\text{nm}}$  with time or can be converted to phenol equivalents by use of a tyrosine standard solution (stock solution of 289.7 mg pure, dry tyrosine, dissolved in 1.00 L of 0.2 M HCl; working solution diluted 10-fold in 0.2 M HCl for use) to give 0.161 mM solution. One unit of protease is defined as the amount of enzyme which yields absorbance (or color value in phenol color method (below)) of 1 mmole of tyrosine per minute under the conditions used (reaction volume, pH, temperature).

A standard activity/trypsin activity curve is shown in Figure 13. Note that the data are linear only at low trypsin concentrations. This is because of limitations imposed by substrate concentration and limitation of "best" peptide bonds to hydrolyze. Absolute specificity of trypsin is for arginine and lysine residues of the substrate on the carboxyl side of the susceptible peptide bond, and relative specificity for the 20 different amino acid residues on the nitrogen side of the susceptible peptide bond.

Other methods are available for determining activity of proteases on casein. These include the phenol color method (52, 53), using the Folin-Ciocalteau phenol reagent to determine the TCA-soluble tyrosine concentration (54). This is less useful than the method above, since phenolic compounds in plant tissues also react with this reagent. The TNBS (2,4,6-trinitrobenzenesulfonic acid (picric acid) reagent is probably the best since it determines the number of peptide bonds hydrolyzed per unit time (55). However, this reagent is difficult to obtain, as it is explosive under some conditions. Ninhydrin can be used to determine the number of peptide bonds hydrolyzed, but it is not as accurate as the TNBS reagent.

Urea-denatured hemoglobin (53) can be used in place of casein under conditions similar to those described for use of casein. As noted above, casein cannot be used in the range of pH 5 ± 1 because it is insoluble. Denatured hemoglobin is soluble in this pH range and is used.

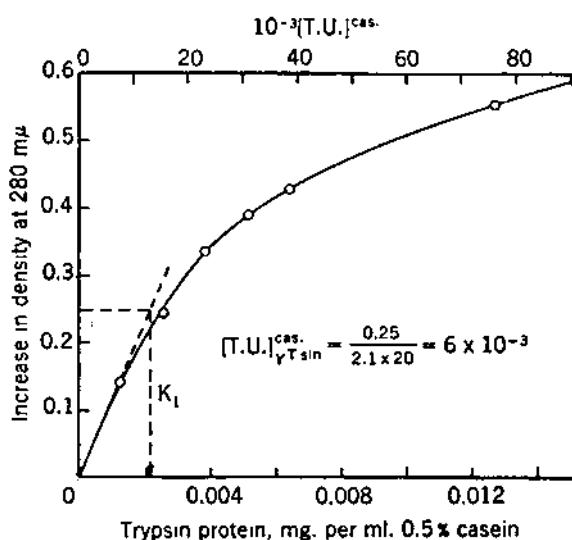

Figure 13 Standard activity curve for trypsin hydrolysis of casein. (From Ref. 49.)

## B. Milk-Clotting Method (56)

The milk-clotting method is done in the pH range of 5.3–6.3. The original Balls and Hoover (56) method is described here, followed by some results by Whitaker (1998, unpublished).

Twenty grams of whole powdered milk (nonfat powder is better in the opinion of this author since storage time has less effect on results) is ground (or stirred to a smooth paste with a small amount of 0.05 M acetate buffer, pH 4.6 (stock solution prepared by mixing two volumes of 1 M acetic acid with one volume of 1 M sodium hydroxide). Stock buffer, 10 mL, is diluted to 85 mL with water and, when added to 20 g added milk powder gives 100 mL substrate. The reconstituted milk is filtered through cheesecloth for use. It is stable for several weeks in the refrigerator under a small layer of toluene.

Portions (1 mL) of serial dilutions of the enzyme are incubated in 15-mm-diameter test tubes with 10 mL milk preparation. When the milk preparation shows a thickening on tilting, the time is recorded. Sulfhydryl proteases (papain, ficin, bromelain) are activated with cysteine or dithiothreitol before use.

My laboratory has made some modifications to this milk-clotting procedure over the years. These include use of nonfat dry milk powder, a pH of 5.3, and the use of total reaction volume of 1 or 2 mL in small test tubes. The tubes are continuously rolled by hand at a 45° angle with a lamp placed immediately over the sample. The time of clotting is when the first granular precipitate occurs on the wall of the tube. Replications are within 0.5-sec of each other.

## C. Gelatin Digestion Method

Papain is a major industrial protease produced from papaya fruit. The proteases are primarily papain and chymopapain, but there are low levels of other proteases. The proteases make up the bulk of the protein (~5% of the liquid which also contains water insoluble latex). The juice is extracted, filtered, and spray-dried at ~65°C without any loss of activity. Several methods for determining activity include the casein digestion method (CDM), the milk-clotting method (MCM), and the gelatin digestion method (GDM). The last method is followed by measuring rate of decrease of viscosity. The United States Pharmacopeia National Formulary (57) and the Food Chemical Codex (FCC; 58, 59) have attempted to standardize the methods used to

measure papain activity to encourage comparison among suppliers and users.

In 1998, Whitaker was asked to compare the three methods using proteins as substrate on a single sample of papain. Triplicate determinations were done under established conditions. The results were obtained within 16 h contiguous time using samples prepared in triplicate. The papain solutions were stored in an ice bath. The results are shown in Figures 14–16, using conditions indicated in the figure legends. In summary, the results, expressed on per-mg papain and per-min basis were: Casein Digestion Method,  $590 \text{ mg}^{-1} \text{ min}^{-1}$ ; Gelation Digestion Method,  $8.34 \text{ mg}^{-1} \text{ min}^{-1}$ ; and Milk-Clotting Method,  $0.125 \text{ mg} \cdot \text{min}$ .

#### D. Synthetic Substrates

The above methods only determine that protease activity is present. To determine the type of protease—chymotrypsinlike or trypsinlike, for example—or endo- or exosplitting, it is necessary to use synthetic substrates. For example, N-acetyl-L-tyrosine ethyl ester (ATEE) is used for chymotrypsinlike enzymes. N-tosyl-L-arginine methyl ester (TAME) is used for trypsinlike enzymes. The ester derivatives are

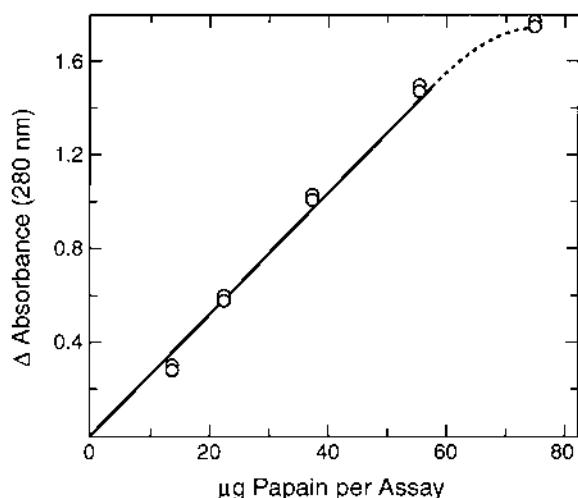

hydrolyzed at a faster rate than the equivalent amide substrates and measured by easier methodology. In many laboratories, there is also a tendency to use the equivalent nitrophenyl esters, which are hydrolyzed even faster, and the reaction can be followed spectrophotometrically by change in absorbance at 420 nm ( $\text{pH} > 7$ ; the  $\text{pK}_a$  of the nitrophenol product is 7.16). At  $\text{pHs} > 7$ , controls must be done to subtract the hydroxide ion-catalyzed hydrolysis of nitrophenyl esters and other ester substrates. Only one method will be described here. Other sources should be consulted for details of other enzymes and synthetic substrates (61, 62).

Chymotrypsin activity can be assayed by spectrophotometry at 256 nm using N-benzoyl-L-tyrosine ethyl ester (BTEE) or N-acetyl-L-tyrosine ethyl ester (ATEE), or N-benzoyl-L-tyrosine-*p*-nitroanilide. It can also be assayed using N-carbobenzoxy-L-tyrosine *p*-nitrophenyl ester at 420 nm. All the reactions for the above substrates are generally done at pH 7.8 and 25° C (61).

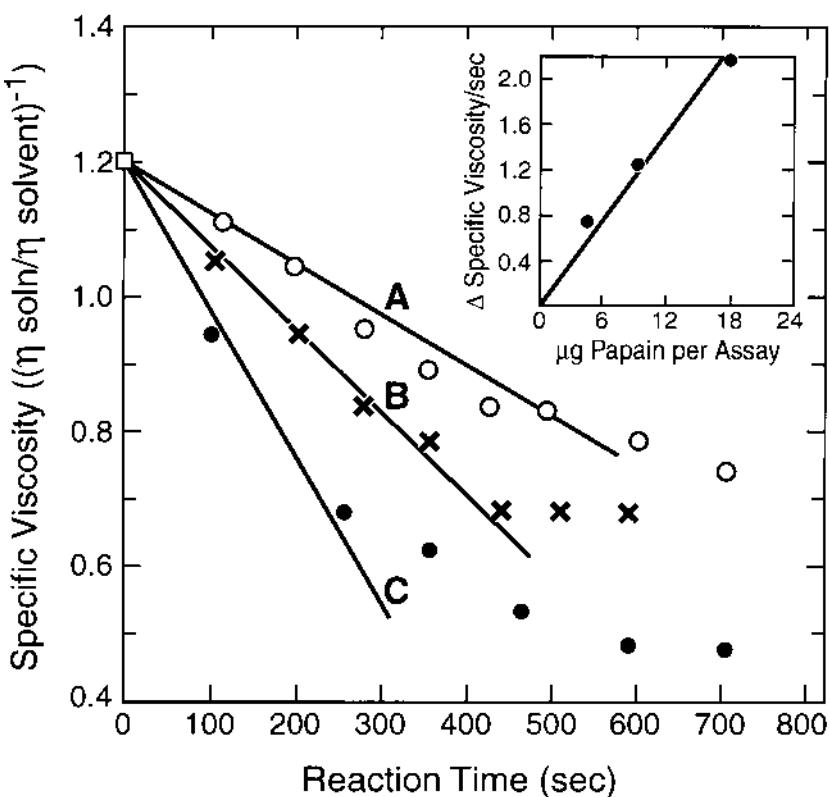

There are also fluorometric methods for the assay of chymotrypsin using N-acetyl-L-tryptophan ethyl ester (63), N-acetyl-L-tyrosine ethyl ester (64), and fluorescein dibutyrate (64) as substrates. Unfortunately, the fluorescein butyrate is also hydrolyzed by lipases, so the substrate should be used only for purified chymotrypsin solutions.

In the potentiometric method of determining chymotrypsin activity, the total reaction volume is generally 3–5 mL and the temperature is 25–35°C. The reaction includes 0.02–0.04 M BTEE or ATEE, 0.01–0.02 M phosphate buffer, pH 7.0–7.5, and sufficient enzyme to produce ~0.02 meq carboxyl groups per min. The reaction is performed for 5–10 min only as the initial velocity is determined. In the potentiometric method, the reaction rate is determined by titrating the acid formed by standard NaOH (0.02–0.05 M) so as to keep the pH constant. This can be done manually or with a pH Stat.

In the spectrophotometric method the change in absorbance at 256 nm is recorded during the reaction time. The absorbance is converted to umoles substrate hydrolyzed per min by use of the Beer-Lambert equation ( $\text{Abs} = \Delta\epsilon_{Mcl}$ ) where  $\Delta\epsilon_M$  = change in extinction coefficient between AT-ATEE (or BT-BTEE) on hydrolysis,  $c$  is concentration of product formed and  $l$  is light path through cuvette (usually 1.0 cm). The change in extinction coefficient,  $\Delta\epsilon_M$ , between acetyl-L-tyrosine (AT) and acetyl-L-tyrosine ethyl ester (ATEE) =  $1.05 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ . The same  $\Delta\epsilon_M$  is found for BT-BTEE.

**Figure 14** Results of the Casein Digestion Method for determining papain activity (57, 58). Plot of change in absorbance at 280 nm after 60 min reaction at 40°C, pH 6.0. Different amounts of papain used per assay (10 mL vol). The USP method (57, 58) was used. (From Whitaker, unpublished data, 1998.)

**Figure 15** Results of the Gelatin Digestion Method for determining papain activity (60). The reaction used 4.5 mL of 2.5% gelatin plus 0.50 mL papain solution in acetate buffer, pH 6.0, 40°C. A, B, C: Specific viscosity change as function of time with 4.73, 9.46, or 18.9  $\mu\text{g}$  papain in the reactions of 5.0 mL. Insert: replot of slope of initial specific viscosity change as function of time vs  $\mu\text{g}$  papain used in the assay. (From Whitaker, unpublished data, 1998.)

Crude samples containing chymotrypsin must be solubilized and clarified before the spectrophotometric method can be used. One of the best methods is that of Schlaeger and Roehr (64a)

#### IV. PURIFICATION OF PROTEASES

Purification of proteases began by classical techniques in the 1930s by Northrup, Kunitz, and Anson at the Rockefeller Institute in New York City and was very successful (65). Classical techniques include selective extraction procedures, followed by ammonium sulfate or acetone precipitation leading eventually to purification or crystallization of the protease.

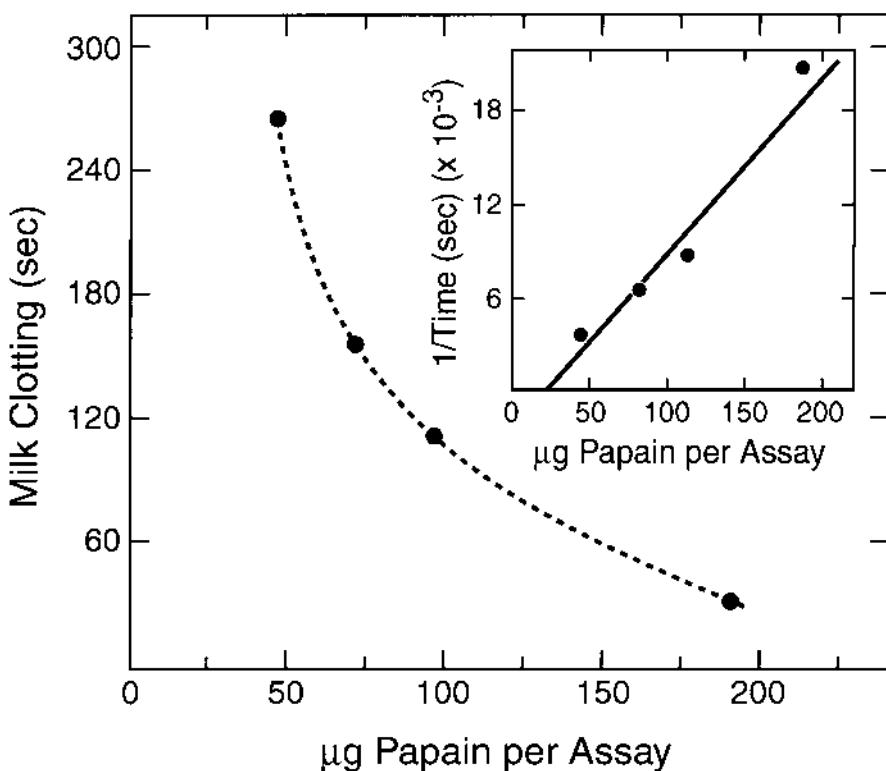

More modern techniques include cation and anion column chromatography, size exclusion chromatography, inverse-phase chromatography, affinity chromatography, hydrophobic chromatography, electrophoresis, etc. Recent methods for the purification of subtilisin,

papain, chymosin, and carboxypeptidase A will be presented here.

##### A. General Purification of Proteases as a Class

Stepanov and Rudenskaya (66) reported that a bacitracin-Sepharose column is effective for the affinity chromatography of aspartyl, serine, metallo- and cysteine proteases (ficin, papain, and bromelain) from various sources. The yield of purified enzyme varied from 50% to 180%. Bacitracin (Fig. 17), a cyclic peptide antibiotic produced by *Bacillus licheniformis*, contains 11 amino acid residues of which four are D- and six are L-isomers and one is a cyclic amino acid. It is resistant to proteolysis. In solution, it inhibits papain, subtilisin, leucinaminopeptidase and pepsin with  $K_i$ s of 5, 4.5, 2, and 2.3 mM, respectively (67, 68).

The conditions used and the results are shown in Figures 18–20. Expanded methodology and discussions are found in Stepanov and Rudenskaya (66). No indication of purity of the preparations were given.

**Figure 16** Results of the Milk-Clotting Method for determining papain activity. The large graph shows plot of time of milk clotting vs.  $\mu\text{g}$  papain in assay. The insert graph is a plot of  $1/(\text{clotting time}, t)$  vs.  $\mu\text{g}$  papain per assay, which is linear but does not go through zero as reported by Greenberg (48). The reason is due to inhibitory effect of one or more compounds in the milk. The reaction contained 5.0 mL of 12% substrate (milk) + 0.20 mL papain solution and was performed at pH 6.3 and 30°C, as recommended by the Chemical Code Method (59).

## B. Purification of Subtilisin

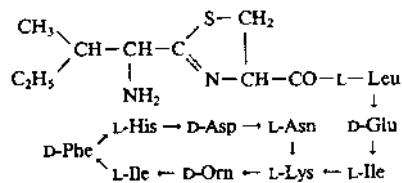

Chandrasekaran and Dhar (69) found that subtilisin can be purified in a single step by affinity chromatography. The affinity matrix was activated CH-Sepharose 4B coupled to the dye 4-(4-aminophenylazo)-phenylarsonic acid. The coupling conditions are given in the paper.

For chromatography, purified crystalline subtilisin (5 mg/mL) was dialyzed overnight against 20 mM acetate buffer, pH 5.9, containing 5 mM CaCl<sub>2</sub>. The dialyzed solution (4.8 mL) was loaded to the column (1 × 51 cm). The column was washed with the starting buffer (used in dialysis) until the A<sub>280</sub> returned to the baseline. The bound subtilisin was eluted with 10 mM Tris-HCl buffer containing 5 mM CaCl<sub>2</sub> and 0.1 M NaCl, pH 9 (Fig. 21, top). The enzyme was purified 1.4-fold (specific activity: 41 U/mg proteins; 98% recovery).

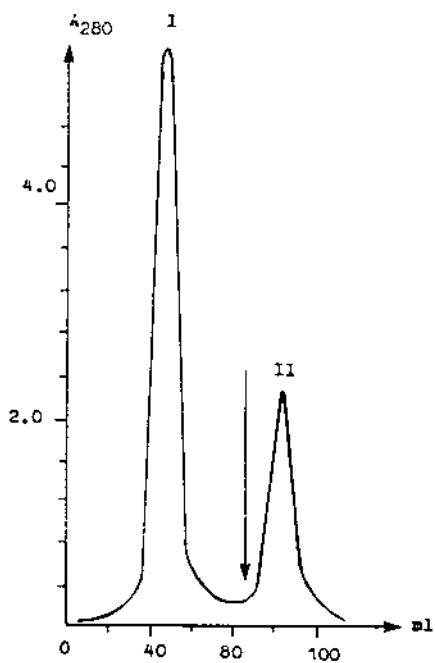

Purification of crude subtilisin used the product Alcalase 2.0 T. Product (2 g/mL) was dissolved in the

starting buffer (above) and centrifuged at 10,000 g for 20 min. The supernatant was dialyzed overnight against the same buffer and 5 mL was loaded onto the column (1 × 51 cm). The chromatography was performed as above (Fig. 21, top). The crude enzyme was purified 211-fold (specific activity of 58 U/mg protein) with 94.4% recovery of activity.

Protease activity was determined by the Kunitz method (49; see Sec. III). Protein concentration was measured by the Lowry method (70) using bovine serum albumin (Sigma) as the standard. The column

**Figure 17** Bacitracin A.

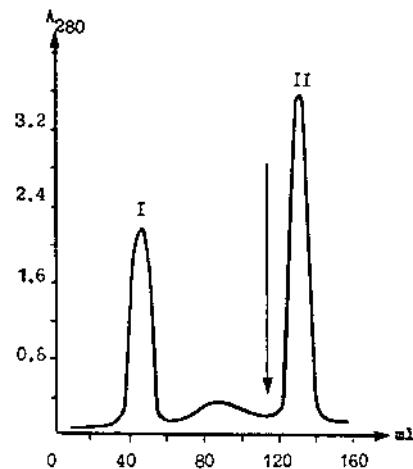

**Figure 18** Chromatography of crude subtilisin 72 on bacitracin-Sepharose column. Preparation (400 mg) in 20 mL of 0.1 M ammonium acetate, pH 6.5, containing 1 mM CaCl<sub>2</sub> was applied to the bacitracin-Sepharose column (1 × 12 cm) equilibrated with the same buffer. The arrow shows the start of elution with 25% isopropanol in 1 M NaCl, pH 6.5. Fraction I contains inert materials; Fraction II, subtilisin (66).

used was estimated to contain ~40 mg of adsorbant. The column binding capacity for subtilisin A was determined to be 190 mg. The eluted subtilisin was determined to be pure by polyacrylamide slab gel electrophoresis.

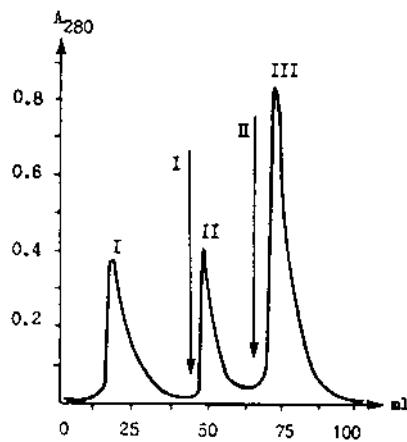

### C. Purification of Papain (71)

Papain might be purified by the method of Stepanov and Rudenskaya (66) on a bacitracin-Sepharose column, but this has not been proved since crude papain contains papain, chymopapain, and an aminopeptidase, which may not be separated by this method.

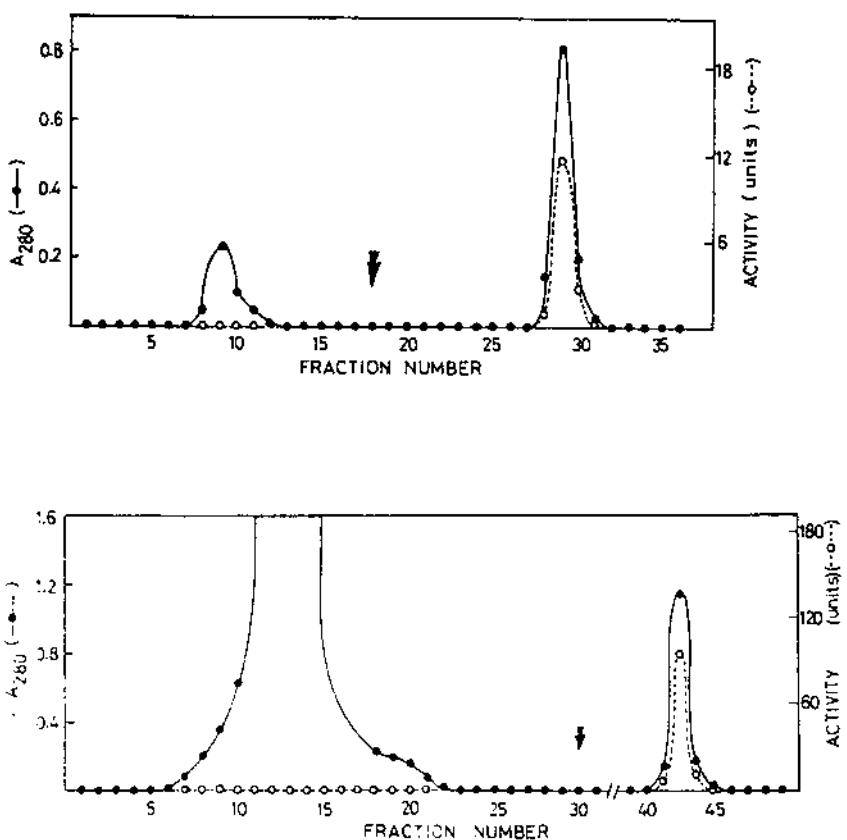

The Kimmel and Smith method (71) described here is an improved method of that of Balls and Lineweaver (72) and gives crystalline papain. They started with hard particles of commercial latex that had to be ground to a fine powder to permit extraction. Currently, papain is separated from the insoluble latex by filtration and dried at ~65°C in a spray drier. The dried material is soluble at 20% and retains

**Figure 19** Chromatography of commercial papain preparation on bacitracin-Sepharose. Papain (70 mg) in 7 mL of 0.1 M phosphate buffer, pH 7.0, containing 0.1 M Na<sub>2</sub>EDTA and 3 mM dithiothreitol was applied to the bacitracin-Sepharose column (1 × 12 cm) equilibrated with the same buffer. The arrow indicates start of elution with 25% isopropanol in 1 M NaCl. Fraction I contained inert material; Fraction II, papain (activity measured against azocasein). (From Ref. 66.)

**Figure 20** Separation of serine proteinase and carboxypeptidase T from *Thermoactinomyces* sp. Enzyme mixture (17.5 mg) dissolved in 7 mL of 0.1 M ammonium acetate, pH 6.5, containing 1 mM CaCl<sub>2</sub>, was applied to the bacitracin-Sepharose column (1 × 12 cm). Arrow I indicates start of elution with 20 mM Na<sub>2</sub>EDTA; arrow II, elution with 25% isopropanol in 1 M NaCl, pH 6.5. Fraction I contained inactive material; Fraction II, carboxypeptidase T (activity measured after reactivation by Ca<sup>2+</sup>); Fraction III serine thiol-dependent proteinase (active against substrate Z-Ala-Ala-Leu-NH<sub>2</sub>H<sub>4</sub>NO<sub>2</sub>). (From Ref. 66.)

**Figure 21** (Top) Affinity chromatography of crystalline subtilisin on a 4-(4-aminophenylazo)phenylarsonic acid-CH-Sepharose column. See text for experimental details. (Bottom) Purification of subtilisin from a crude preparation. See Top and text for details. (From Ref. 69.)

full activity. In water, it has a pH of  $\sim 5.5$  (Whitaker, unpublished data).

The soluble papain (1 L) was carefully adjusted to pH 9.0 with  $\sim 110$  mL of 1 N NaOH which is added slowly with stirring (Fraction 1; Table 4). A fine grayish denatured precipitate formed, which was removed by centrifugation at 2600 rpm for 1 h. The solution should be clear (Fraction 2).

Fraction 2 was cooled to 4°C and brought to 0.4 saturation with solid ammonium sulfate (250 g/L). A white precipitate formed. After 1–2 h at 4°C, the precipitate (Fraction 3) was recovered by centrifugation at 2500 rpm for 1 h. The supernatant fraction was saved for preparation of chymopapain. The precipitate was washed over with 400–500 mL cold (4°C) 50% saturated ammonium sulfate, and the precipitate was separated by centrifugation as above.

Fraction 3 was redissolved in 600 mL of 0.02 M cysteine (pH 7–7.5; freshly prepared), and 60 g of solid sodium chloride was slowly added. Papain was

precipitated as a fine white solid. After standing for 1 h at 4°C, it was centrifuged in the cold for 1 h at 2500 rpm. The supernatant liquid was discharged. The precipitate was Fraction 4.

Fraction 4 was suspended in 400 mL of 0.02 M cysteine at pH 6.5 and adjusted to pH 5 with 1 M HCl as needed. At room temperature, the suspension developed a marked crystalline sheen in  $\sim 30$  min. It was then placed in a cold room (or refrigerator) at 4°C overnight. The light crystals (Fraction 5) were removed by centrifugation at 2000–2500 rpm for 4–5 h. The supernatant liquid may be discarded. After several hours a small, insignificant amount of crystals formed.

Recrystallization was by dissolving Fraction 5 in the minimum amount of distilled water at room temperature and adding very slowly, with stirring 10 mL saturated sodium chloride per 300 mL protein solution. Crystallization began when  $\sim 75\%$  of the 10-mL of saturated sodium chloride was added at room temperature. The suspension was then moved to a 4°C room

**Table 4** Preparation of Crystalline Papain from Dried Papaya Latex<sup>a</sup>

Fraction No. <sup>b</sup>	Volume (ml)	Total protein (g)	$C_1$ <sup>c</sup>	Total activity (units)
1	770	45	0.19	1300
2	860	43	0.23	1500
3		13	0.30	580
3a	735	36	0.25	1470
4a	530	8	0.18	215
5	Crystals	2.1	0.84	270
5a	400	3.8	0.12	72
6	2 recrystallizations	1.2	1.06	190

<sup>a</sup>180 g dried latex used as starting material.

<sup>b</sup>Fractions 4a and 5a were discarded. Fraction 3a was saved for the isolation of chymopapain.

<sup>c</sup>The proteolytic coefficients ( $C_1$ ) were determined with benzoyl-L-argininamide as substrate at 39°C, pH 5.5, in the presence of 0.005 M cysteine and 0.001 M EDTA. The units of activity are calculated by multiplying the  $C_1$  value by the total amount of protein N in the fraction

overnight and the crystals were collected as described for Fraction 5. They were dissolved and recrystallized again as for Fraction 5.

The second crystallization is Fraction 6 in Table 4. About 1.2 g of crystals was obtained with a specific activity of 1.06. If desired, they may be recrystallized as mercuripapain with a specific activity of 1.15–1.20. This is done by dissolving the twice-recrystallized papain at room temperature in 70% ethanol/water containing 0.001 M HgCl<sub>2</sub>. The protein concentration should be 1.5–2.0% for best results. If the solution is slightly turbid, the solution is filtered (before crystals form) and then stored at 4°C. Within 24 h a white crystalline precipitate forms, and after 3–4 days 90% of the activity crystallizes from solution. The large, heavy crystals are easily removed by centrifugation.

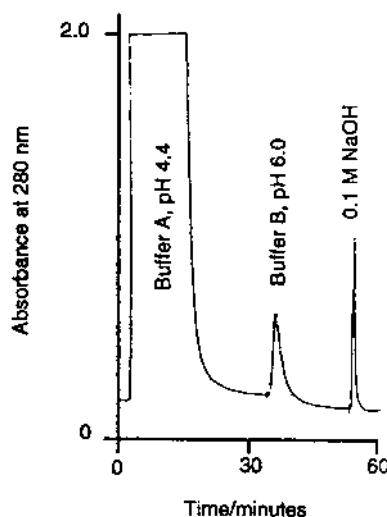

The mercuripapain has no activity. Activity is restored by treatment with a solution of 1 mM EDTA-5 mM cysteine. Specific activity was 1.19.

#### D. Purification of Calf Chymosin

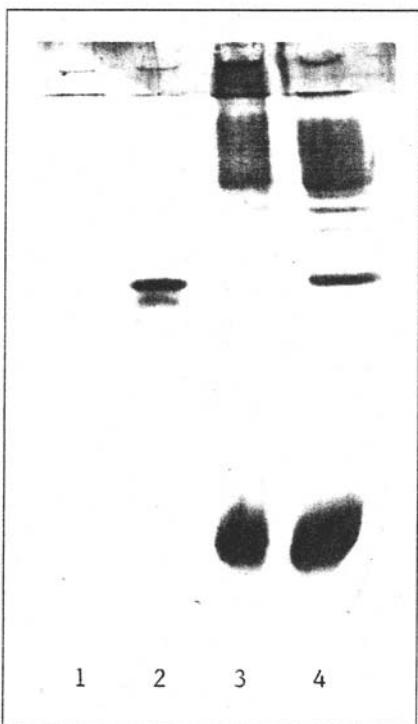

##### 1. Affinity Chromatography Method (73)

An affinity chromatographic column was used to purify crude chymosin (73). The 1.5-mL affinity column was packed with succinyl-Val-dLeu-Pro-Phe-Phe-Val-dLeucinamido-propyl Perloza. The column was equilibrated with buffer A (10 mM citrate, pH 4.4). A 5-mL sample of liquid containing chymosin ~0.3 mg/mL was diluted with 10 mL water, and the pH was adjusted to 4.4 using 1 M HCl. The chymosin-containing solution was loaded onto the column, which was then washed with buffer A until the  $A_{280}$  returned to

baseline. The chymosin was eluted with buffer B (10 mM citrate, pH 6.0). The column was washed with 0.1 M NaOH to remove remaining protein. The results are shown in Figure 22; chymosin was eluted in buffer B. No chymosin activity was present in peaks 1 or 3. The purity of the chymosin is shown in Figure 23, lane 2. The nature of the small lower peak was not explained. Crude recombinant chymosin is shown in lane 4, as a single band. The binding capacity of the affinity column resin was determined to be 27 mg/mL of chymosin per ml of resin (column support material).

**Figure 22** Chromatography of crude recombinant chymosin using succinyl-Val-dLeu-Pro-Phe-Phe-Val-dLeucinamido-propyl Perloza column. (From Ref. 73.)

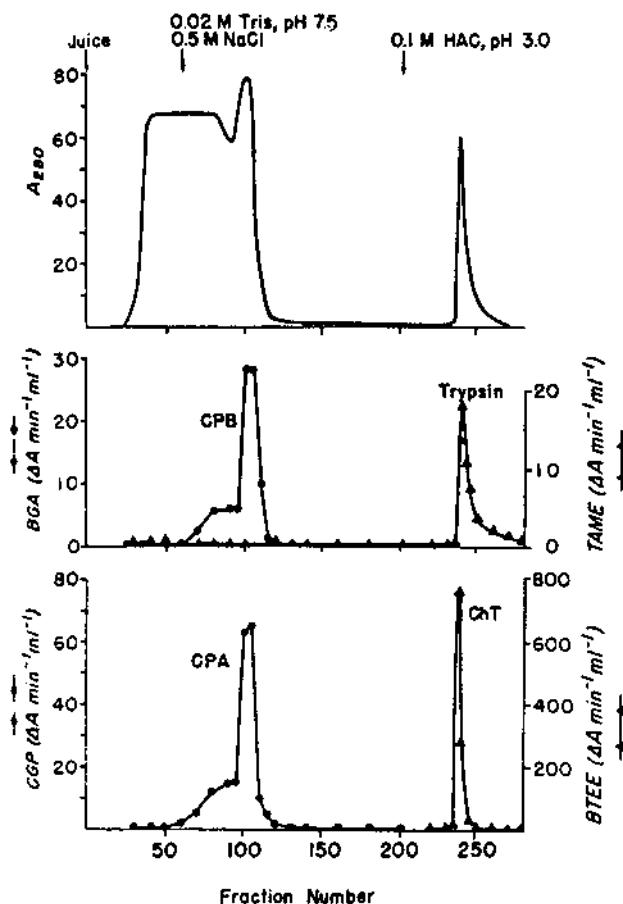

**Figure 23** SDS-PAGE analysis of fractions from chromatography of crude recombinant chymosin. Lane 1, 0.1 M NaOH wash; lane 2, pH 6.0 buffer B elution; lane 3, pH 4.4 buffer A breakthrough; lane 4, unchromatographed crude recombinant chymosin. (From Ref. 73.)

## 2. Purification of Recombinant Calf Chymosin (74)

Prochymosin produced by *Escherichia coli* following insertion of the calf prochymosin gene is insoluble and denatured. The cell lysis procedure (75), based on lysozyme/sodium deoxycholate and ultrasonic treatment, was used to disrupt the cells. The chymosin inclusions were pelleted by centrifugation (6000g, 5 min, 5°C) and were washed with 50 mM Tris-HCl, pH 8.0, containing 1 M EDTA, and then with 50 mM CaCl<sub>2</sub> containing 0.5% (v/v) Triton X-100 and 1.0 M EDTA. The inclusions were collected by centrifugation. Solubilization was achieved by holding the prochymosin for 1 h at 31°C, pH 10.4, in 8 M urea or 50 mM KH<sub>2</sub>PO<sub>4</sub>, 1 mM EDTA, 50 mM NaCl, 8 M urea, pH 10.7. After 40 min the pH was adjusted with HCl to pH 8 within 10 min. If turbid, it was centrifuged at 12,000g for 10 min at 5°C.

The crude prochymosin was purified by ion exchange chromatography at room temperature (figure not shown in publication). The urea/alkaline extract

was diluted approximately two times with distilled water to ~38 µs, the same as the conductivity of the 20 mM Tris-HCl, 1 mM EDTA, 50 mM NaCl, pH 8.0 buffer (Buffer B). The diluted extract was applied to the DEAE-Sephadex (Pharmacia) column (0.9 × 1.6 cm; equilibrated with Buffer B above at a flow rate of 100 mL/h). The column was washed with four volumes of Buffer B with the NaCl concentration raised to 100 mM. The prochymosin was eluted with four volumes of Buffer B when the salt concentration was raised to 500 mM at the flow rate above. Fractions were collected.

**Figure 24** Chromatography of activated bovine pancreatic juice on soybean trypsin inhibitor-Sepharose column. Fraction volume was 25 mL. CPB, carboxypeptidase B (activity determined by substrate benzoylglycyl-L-arginine); CPA, carboxypeptidase A (activity determined by substrate carbobenzoxyglycyl-L-phenylalanine); trypsin (activity determined with substrate *p*-tosyl-L-arginine methyl ester); chymotrypsin (activity determined by N-benzoyl-L-tryosine ethyl ester). (From Ref. 79.)

The prochymosin was activated to chymosin by acidification to pH 2.0 (76). The activity of chymosin was assayed by a modified turbidimetric milk-clotting activity assay of McPhil (77) calibrated with crystalline calf chymosin prepared by the method of Foltmann (78). A typical recovery of correctly refolded chymosin was  $\sim 2$  mg/33 mg applied protein.

### E. Purification of Carboxypeptidases A and B (79)

Earlier sections of this chapter have not included carboxypeptidase B. Carboxypeptidase B is a metal-containing exopeptidase similar to carboxypeptidase A, but it is specific only for arginine and lysine residues at the carboxy-terminal end of proteins and peptides. Carboxypeptidase A can remove C-terminal amino acids other than arginine or lysine residues.

These two exopeptidases are found in the pancreas of animals. Figure 24 and Table 5 show the chromatography of activated proenzymes (converted to enzymes) from bovine pancreatic juice on a column of soybean trypsin inhibitor-Sepharose. The pancreatic juice (160 mL) was applied to the column. The column was then equilibrated with starting 0.02 M Tris buffer, pH 7.5, containing 0.5 M NaCl. The two carboxypeptidases were eluted together from the column under these conditions. Trypsin and chymotrypsin were eluted only when a 0.1 M sodium acetate, pH 3.0, buffer was applied.

The concentrated (to 210 mL volume by ultrafiltration) initial eluate from the column containing carboxypeptidases A and B was dialyzed for 36 h against a

large excess of 0.02 M Tris, pH 7.5. A precipitate formed containing 91% of the carboxypeptidase A activity, while only 1% of the carboxypeptidase B activity precipitated. The carboxypeptidase A precipitate was collected by centrifugation, dissolved in 10% LiCl, and crystallized by dialysis against distilled water (80). Chromatography of the crystalline enzyme on a column of DE-52 cellulose by the method of Petra and Neurath (81) resulted in a single symmetrical peak corresponding to carboxypeptidase A <sub>$\beta$</sub> <sup>Val</sup> (Fig. 25).

The solution from dialysis for 36 h against 0.02 M Tris buffer, pH 7.5, contained carboxypeptidase B. It was dialyzed overnight against 0.02 M Tris, pH 8.0, at a protein concentration not exceeding 0.5 mg/mL. It was then applied to a 2.5  $\times$  40 cm column of DE-52 cellulose which had been equilibrated with the same 0.02 M Tris buffer, pH 7.5, except ZnCl<sub>2</sub> was added to give 1 10<sup>-4</sup> M concentration. After adding all the solution to the column, elution was achieved with a linear salt gradient from 0.0 to 0.1 M NaCl in a total volume of 2000 mL of 0.02 M Tris, pH 8.0, containing 10<sup>-4</sup> M ZnCl<sub>2</sub>. Carboxypeptidase B eluted in three peaks; they are labeled Native CPB, CPBI, and CPBII (Fig. 26).

The overall purification of carboxypeptidase B is summarized in Table 5. The purification sequence resulted in a 56-fold purification of carboxypeptidase B, with a yield of 71% of the original enzyme activity in the pancreatic juice.

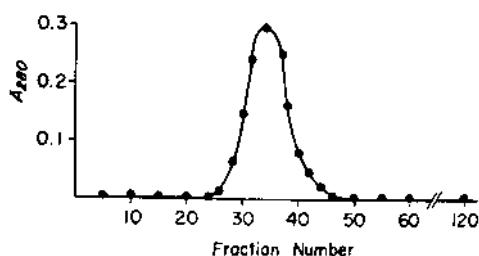

In summary, the procedure permitted the purification of carboxypeptidase A from the supernatant from Fraction 2 on the soybean trypsin inhibitor-Sepharose column. Carboxypeptidase B was purified from

**Table 5** Purification of Bovine Carboxypeptidase B

Preparative step	Volume (mL)	Enzyme conc; $\Delta A \text{ min}^{-1} \text{ ml}^{-1}$	Total units ( $\Delta A \text{ min}^{-1}$ )	Protein (mg · mL <sup>-1</sup> )	Specific activity ( $\Delta A \text{ min}^{-1} \text{ mg}^{-1}$ )	Yield (%)	Purification (fold)
1. Pancreatic juice	1600	0.784	1254	3.87	0.097	100	1.0
2. Carboxypeptidase fraction from soybean trypsin inhibitor-Sepharose column (concentrated by ultrafiltration)	210	5.51	1157	5.86	0.448	92	4.6
3. Supernatant from dialysis against 0.02 M Tris, pH 7.5	230	4.62	1063	1.21	1.82	85	21
4. Sample for DE-52 column	73	13.4	978	1.37	4.65	78	48
5. Carboxypeptidase B fractions from DE-52 column	1000	0.889	889	0.078	5.45	71	56

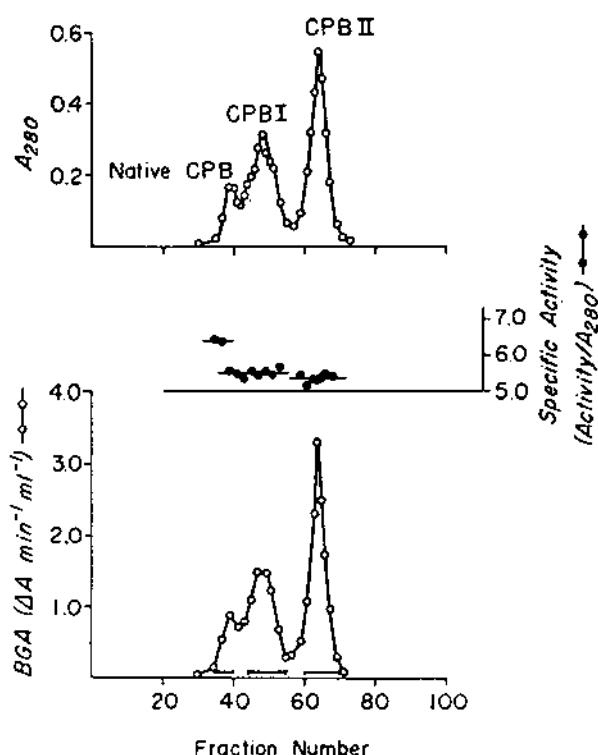

Protein concentration was determined by absorbance at 280 nm assuming  $A^{0.1\%} = 2.1$ .

Source: Ref. 79.

**Figure 25** Chromatography of carboxypeptidase A obtained from step 2, Table 5 (from soybean trypsin inhibitor-Sepharose chromatography and dialysis) run on DE-52 cellulose column. The column was developed by flowing 0.05 M Tris, pH 7.5, containing 5 mM  $\beta$ -phenylpropionate and 0.04 M LiCl, at a flow rate of 39 mL/h on a 1.5  $\times$  100 cm column. The fraction volume was 13 mL. (From Ref. 79.)

Fraction 2 dialysis as described above. Trypsin and chymotrypsin could also be purified from the first step of the procedure. Unfortunately, not all purification procedures are so rewarding.

**Figure 26** Chromatography of carboxypeptidase B (purified to step 5, Table 5, from activated bovine pancreatic juice) on a DE-52 cellulose column. The fraction volume was 25 mL. (From Ref. 79.)

## Thermolysin

Kuniyo Inouye

*Kyoto University, Kyoto, Japan*

### I. INTRODUCTION

#### A. History

Thermolysin is a natural metalloproteinase produced in culture broth of *Bacillus thermoproteolyticus Rokko* (1) which was isolated from a hot spa (Arima Onsen, Hyogo-ken) in Japan in 1962. Thermolysin is very heat stable, and is one of the first thermophilic enzymes reported. This enzyme has been extensively characterized; its amino acid sequence (Fig. 1) (2), nucleotide sequence (3), and three-dimensional structure by x-ray crystallography at 1.6 Å (Fig. 2) (4,5) are known. The heat stability (6, 7) and substrate specificity (8) have been studied.

#### B. Chemical Reactions Catalyzed

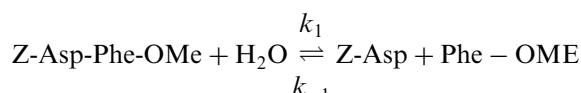

##### 1. Peptidase Activity

Thermolysin catalyzes specifically hydrolysis of peptide bonds (-X-Y-) containing hydrophobic amino acid residues, especially at the P1' site (the nomenclature used for the amino acid residues (P) of the substrate and for naming the subsites (S) of the active site is that of Schechter and Berger (9). In the peptide bond (-X-Y-), the amino acid residue (X) of the amino terminal side of the cleavable bond is at the P1 site, and (Y) is at the carboxyl terminal side, the P1' site. Thermolysin is an endopeptidase, and does not act on the peptide bonds next to free amino- or carboxyl-terminal amino acid residues.

The specificity constant ( $k_{\text{cat}}/K_m$ ) in the hydrolysis of *N*-[3-(2-furyl)acryloyl](FA)-Gly-Y amide is, in the order of the Y residue: L-Phe = L-Leu > L-Val > L-Ala. The enzymatic rate in the hydrolysis of FA-X-L-Ala amide is, in the order of the X residue: L-Phe > L-Leu > Gly (10). Thermolysin has been shown not to hydrolyze a number of esters, e.g., hippuryl phenyllactate,  $\alpha$ -N-benzoyl-L-arginine ethyl ester,  $\alpha$ -N-tosyl-L-arginine methyl ester,  $\alpha$ -N-acetyl-L-tyrosine ethyl ester, or carbobenzoxy-glycine *p*-nitrophenyl ester. On the other hand, a series of aliphatic alkyl esters, esters in the form of depsipeptides, such as *N*-benzoyl(Bz)-Gly-OPhe-L-Ala, Bz-Gly-OLeu-L-Ala, and FA-Gly-OLeu amide, are hydrolyzed at rates three- to eightfold slower than their peptide analogs (11). It is noted that OLeu is 2-hydroxylisocaproic acid, OPhe, 2-phenyllactic acid, and OGly, glycolic acid.

##### 2. Peptide Synthesis

Thermolysin catalyzes effectively the reverse reaction of the hydrolysis of peptide bonds, resulting in the synthesis of peptides such as the precursor of an artificial sweetener, aspartame (L-Asp-L-Phe methyl ester) (12, 13). In the case of the thermolysin-catalyzed hydrolysis of *N*-carbobenzyloxy (Z)-L-Asp-L-Phe methyl ester (Z-Asp-Phe-OMe),

Figure 1 Primary structure of thermolysin. (From Ref. 2.)

the equilibrium constant,  $K_{eq}$ , is given by the following equation:

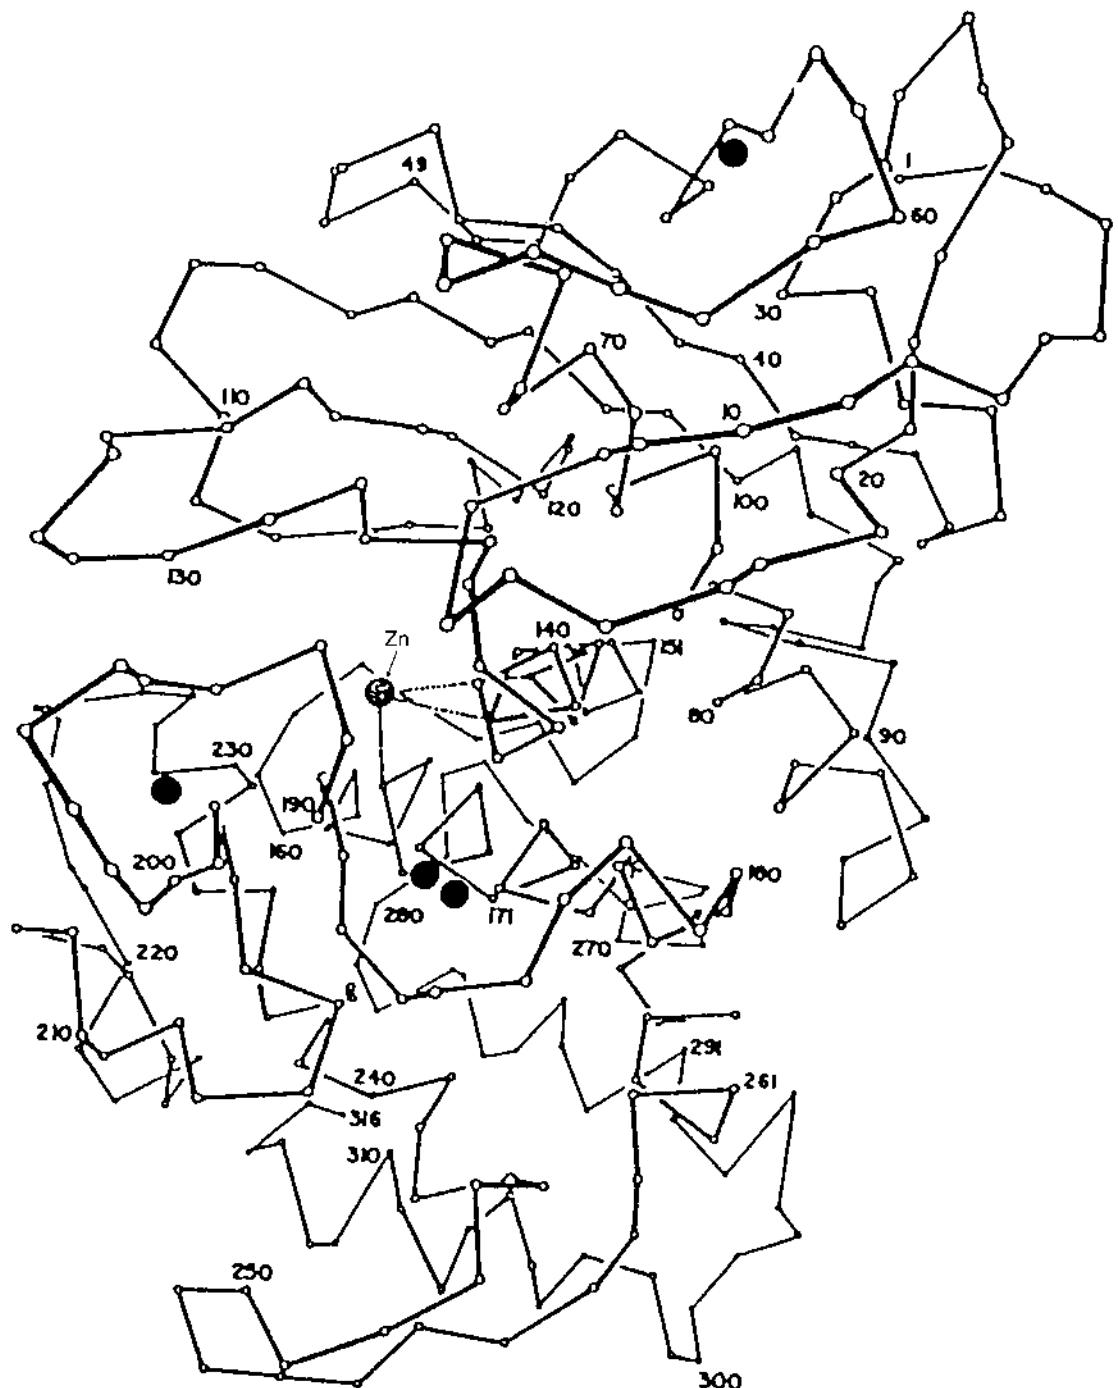

$$K_{eq} = \frac{[Z\text{-Asp}][\text{Phe-OMe}]}{[Z\text{-Asp-Phe-OMe}] [\text{H}_2\text{O}]} = k_1/k_{-1}$$

The  $K_{eq}$  value is not changed in the absence or presence of catalysts. When thermolysin enhances the reaction

rate ( $k_1$ ) of the hydrolysis, the reaction rate ( $k_{-1}$ ) of the peptide synthesis can be also enhanced by the same degree as the hydrolysis.

### C. Chemical Structure of Substrates

The substrate specificity of thermolysin is primarily for an aromatic amino acid residue in P1', although it is

**Figure 2** Three-dimensional structure of thermolysin. The catalytic zinc atom (Zn) is coordinated with three ligands (His142, His146, and Glu166). The linkages are shown diagrammatically as broken lines. The four calcium atoms are shown as solid black spheres. (From Ref. 4.)

somewhat broad, and it may be attributable to the wider substrate binding site.

#### D. Classification According to Enzyme Commission Nomenclature

Thermolysin is classified as a metalloendopeptidase, and the Enzyme Commission number is EC 3.4.24.27 (14).

## II. IMPORTANCE TO FOOD INDUSTRY

The most remarkable quality of thermolysin is its application to the synthesis of peptides especially the artificial peptide sweetener, aspartame (*L*-Asp-*L*-Phe-OMe). Sweetener peptides *L*-Asp-*L*-Phe-OEt and *L*-Asp-*L*-Tyr-OMe are also synthesized by thermolysin. Thermolysin has been used to digest animal and plant proteins, and the hydrolysates are used as seasonings and condiments and for production of amino acids. Soy protein hydrolysates are used as raw materials in production of soy sauce and as an alternative to soy sauce. It has been reported that peptides produced by digesting soy proteins, fish proteins, etc., with thermolysin show some physiological effects such as hypotensive effect, opioidlike effect, bowel contraction, repression of Alzheimer's disease, etc. By hydrolysis of dried bonito muscle by thermolysin, eight inhibitory peptides against angiotensin-I converting enzyme have been isolated. Among them, *L*-Leu-*L*-Lys-*L*-Pro-*L*-Gln-*L*-Met shows the most potent inhibitory activity ( $IC_{50} = 2.4 \mu M$ ) (15). Based on these results, designer foods containing physiologically active peptides have come on the market.

## III. PROPERTIES AS A PROTEIN

### A. Molecular Weight

The molecular weight is 34,600 based on the amino acid composition (316 amino acids) plus one zinc atom and four calcium atoms (2, 4, 5). Thermolysin is a monomeric protein (34.6 kDa) in the concentration range up to 1.0 mg/mL in the presence of 0–4 M NaCl as determined by a low-angle laser light-scattering photometer (16).

### B. Primary, Secondary, Tertiary, Quaternary, and Macromolecular Structures

#### 1. Homology with Other Proteins

Thermolysinlike neutral metalloproteinases have been isolated from the culture broth of various *Bacillus* spp. (17–20). The gene *nprM* coding for a thermostable proteinase, NprM, in *B. stearothermophilus* MK232 has been cloned, and the nucleotides have been sequenced (17). The amino acid sequence of protein NprM predicted on the basis of the nucleotide sequence is identical to that found by the Edman method of sequencing of the mature thermolysin except for two amino acid substitutions (Asp37 of thermolysin is asparagine, and Glu119 of thermolysin is glutamine) in the 316 residues of the entire sequence. The amino acid sequence of thermolysin predicted on the basis of its nucleotide sequence has been reported to be the same as that of NprM (3). The residues at positions 37 and 119 of thermolysin have now been found to be asparagine and glutamine, respectively (21). Accordingly, thermolysin and NprM seem to be the same despite their different origins. Recently, we have found two mutant forms of thermolysin from thermolysin-producing *Bacillus thermoproteolyticus* which has been treated with chemical mutagens (Japan patent No. H9-255, 1997). In a mutant enzyme, Ala73 is converted to valine, and in another one, Val 140 is converted to alanine. Substrate specificity of the mutant enzymes is changed slightly from the wild-type enzyme, suggesting these two residues have some involvement in the substrate recognition, although both of them are located some distance from the active site of the native enzyme.

#### 2. Domain Structure of Thermolysin

Thermolysin is composed of two domains, an N-terminal domain (residues 1–135) and a C-terminal domain (residues 136–316) (see Fig. 1). Both domains have characteristic domain structures; namely, the N-terminal domain is composed mainly of  $\beta$ -sheets (all  $\beta$ -domain), and the C-terminal domain is composed mainly of  $\alpha$ -helices (all  $\alpha$ -domain) (4, 5). The active site is in the crevice formed between the two domains. Interestingly, residues supposed to be involved in the catalysis are located in the C-terminal domain (see Sec. IV.B). It has been shown that the spatial relationship of the two domains changes on substrate binding to the enzyme, suggesting an allosteric phenomenon in a single-chain protein (22).

### 3. Isoforms

Thermolysin was formerly classified as EC 3.4.24.4 (1984 Recommendations of the Nomenclature Committee) but is now reclassified to EC 3.4.24.27 (14). This is in keeping with reclassification of other bacterial neutral metalloproteinases such as aeromolysin (EC 3.4.24.25) from *Aeromonas proteolytica*, pseudolysin (EC 3.4.24.26) from *Pseudomonas aeruginosa*, bacillolysin (EC 3.4.24.28) from *Bacillus subtilis*, aureolysin (EC 3.4.24.29) from *Staphylococcus aureus*, coccolysins (EC 3.4.24.30) from *Staphylococcus thermophilus*, and mycolysin (EC 3.4.24.31) from *Streptomyces griseus*.

Aeromolysin is thermostable and shows preferential cleavage of bonds with bulky hydrophobic amino acids in the P2 and P1' positions (23). Pseudolysin (or *Pseudomonas elastase*) causes tissue damage by degrading proteins including elastins, collagen types III and IV, and fibronectin generally with bulky hydrophobic groups at the P1' position. The cleavage pattern of insulin B chain by pseudolysin is similar to that of thermolysin (24–26). The cleavage pattern of substrates by bacillolysin is similar but not identical to that of thermolysin (27, 28). Variants of this enzyme have been found in species of *Bacillus* including *B. subtilis*, *B. amyloliquefaciens*, *B. cereus*, and *B. stearothermophilus* (29). The cleavage pattern of insulin B chain by aureolysin is similar to that of thermolysin, and it prefers a hydrophobic residue at the P1' position (30). Coccolysins are found intracellularly in *Streptococcus thermophilus* and *S. diacetilactis*, and extracellularly in *S. faecalis* (31, 32). It cleaves preferentially hydrophobic bulky residues (L-Leu, L-Phe, and L-Tyr) at the P1' position. Mycolysin is a component of pronase, and is produced by *Streptomyces griseus*, *S. naraensis*, and *S. cacaoi* (27, 33, 34). The substrate specificity is similar to that of thermolysin and preferential to bonds with hydrophobic residues at the P1' position.

Recently, the classification of metalloproteinases into five distinct subfamilies has been proposed on the basis of the active-site sequence and metal ligands (35, 36). Thermolysin belongs to the M4 family (thermolysin family) of the MA clan. The MA clan proteases contain a Glu residue which completes the zinc-binding site in addition to two histidines of the active-site consensus sequence His-Glu-Xaa-Xaa-His (or HEXXH) (37, 38). According to the amino acid sequence of thermolysin, His142, His146, and Glu166 are the zinc ligands. It is noted that enzymes from pathogens (e.g., *Legionella*, *Listeria*, *Pseudomonas*,

*Vibrio*) are members of this family (23, 25). Thermolysin and its precursor lack Cys residues, but this is not the case for all members of this family. Although amino acid sequence and enzymatic properties are different among the families, all families except for the thermolysin family have the consensus sequence HEXXHXXXGXXH, where the three histidines are zinc ligands.

### 4. Small Metalloproteinases

Metalloproteinases related to thermolysin, which have been described above, have molecular weights ~35,000. On the other hand, there are reports of metalloproteinases with considerably small molecular sizes. *Streptomyces caespitosus* neutral proteinase is composed of 132 amino acids, and its molecular weight is 15,000 (39, 40). This enzyme belongs to the *Streptomyces* extracellular neutral protease (M7) family (35), and specifically hydrolyzes the peptide bond at the amino side of aromatic residues. *Penicillium citrinum* metalloprotease, penicillolysin, is composed of 177 amino acids with a molecular weight of 18,000 (41).

*Aspergillus oryzae* neutral proteinase II is a zinc proteinase with three disulfide bonds. It consists of 177 amino acids, and its molecular weight is 19,000 (42). Penicillolysin has a sequence 68% homologous with that of *Aspergillus oryzae* neutral proteinase II. The zinc ligands of both metalloproteinases are considered to be His128, His132, and Glu65, suggesting that their zinc ligands correspond to those of thermolysin (41). Topological diagrams of these small metalloproteinases are similar to that of the C-terminal domain of thermolysin, notwithstanding differences in amino acid sequence (40). It should be mentioned that a matrix metalloproteinase (MMP), MMP7 or matrilysin, isolated from human colon cancer cells has a molecular weight of 19,000 (43). MMPs, except MMP7, contain the C-terminal hemopexinlike domain, and their molecular weights are in the range of 28,000–84,000. These single-domain metalloproteinases with molecular weights of 15,000–19,000 might be accepted as a new type of proteinase.

## IV. PROPERTIES AS ENZYME

### A. Substrate Specificity

The  $k_{cat}/K_m$  values at 0 M NaCl are  $43\text{ M}^{-1}\text{sec}^{-1}$  for *N*-[3-(2-furyl)acryloyl](FA)-Gly-L-Ala amide,  $2.2 \times 10^4\text{ M}^{-1}\text{sec}^{-1}$  for FA-Gly-L-Leu amide, and  $6.9 \times 10^2$

$M^{-1}sec^{-1}$  for FA-L-Leu-L-Ala amide in 40 mM Tris-HCl buffer containing 10 mM CaCl<sub>2</sub>, pH 7.5, at 25°C (10, 44). For FA-Gly-L-Leu amide, the specificity constant,  $k_{cat}/K_m$ , is  $2.2\text{--}3.0 \times 10^4 M^{-1}sec^{-1}$ , and  $K_m$  and  $k_{cat}$  are estimated to be  $> 3$  mM and  $> 66\text{--}90 sec^{-1}$ , respectively. For *N*-carbobenzyloxy (Z)-L-Asp-L-Phe methylester (Z-Asp-Phe-OMe),  $K_m$  is 0.35 mM and  $k_{cat}$  is  $2.73 sec^{-1}$  (44). With FA-L-Leu-L-Ala amide,  $K_m$  is 0.80 mM and  $k_{cat}$  is  $0.56 sec^{-1}$ , and with FA-L-Phe-L-Ala amide,  $K_m$  is  $83 \mu M$  and  $k_{cat}$  is  $5.7 sec^{-1}$  (10). The  $K_m$  and  $k_{cat}$  values for the degradation of [L-Leu 5]-enkephalin are 0.50 mM and  $95 sec^{-1}$  (3). A fluorescent substrate, 7-methoxycoumarin-4-yl)acetyl-L-Pro-L-Leu-Gly-L-Leu-[ $N^3$ -(2,4-dinitrophenyl)-L-2,3-diamino-propionyl]-L-Ala-L-Arg-NH<sub>2</sub> (MOCAc-PLG(Dpa)AR) is used for thermolysin assay (43, 45). The specificity constant,  $k_{cat}/K_m$ , is  $8.0 \times 10^4 M^{-1}sec^{-1}$  in 40 mM Tris-HCl buffer containing 10 mM CaCl<sub>2</sub>, pH 7.5, at 25°C (Inouye, unpublished data).

### B. Effect of pH and Temperature on Activity and Reaction Mechanism

Using FA-Gly-L-Leu amide as substrate, at 0 M NaCl, the optimal pH was 6.7–7.0, the p $K_{a1}$  and p $K_{a2}$  value were 5.4 and 7.9 (46). The imidazole of His231 is considered to be the dissociable residue with p $K_{a2}$ , and the carboxyl group of Glu143 might be the p $K_{a1}$  group (47). Recently, a water molecule coordinated to the active site zinc has been considered to be responsible for p $K_{a1}$  instead of Glu143 (46, 48). The temperature at which a 30-min incubation reduces the enzyme activity by half is 86.9°C (49, 50). The optimum temperature is 80°C when casein is used as a substrate, and thermolysin is stable in the temperature range of 30–90°C.

### C. Effect of Environmental Factors

#### 1. Role of Zinc

A zinc ion is essential for activity, but it can be replaced with a cobalt ion (51). The activity of the cobalt thermolysin is 200–250% higher than that of the native (zinc) enzyme.

#### 2. Effect of Salts on Activity

The activity of thermolysin in the hydrolysis and synthesis of peptide substrates such as *N*-[3-(2-furyl)acryloyl] (FA)-Gly-L-Ala amide (FA-Gly-L-Leu amide) and *N*-carbobenzyloxy (Z)-L-Asp-L-Phe methyl ester (Z-Asp-Phe-OMe) is enhanced markedly in the presence

of high concentrations (1–5 M) of neutral salts such as NaCl, NaBr, KCl, or KBr (44). The activity increases in an exponential fashion with increasing salt concentration; in the presence of  $x$ M NaCl at pH 7 and 25°C, the degree of activation is expressed by  $1.9^x$ . Accordingly, at 4 M NaCl, the activity is enhanced 13–14 times. The salt activation has been shown to increase the molecular activity,  $k_{cat}$ , while the Michaelis constant,  $K_m$  is not altered (10). The salt-dependent activation is dependent on pH and temperature and on organic solvents added to the reaction mixture (46). Activation by addition of NaCl shows a bell-shaped pH dependence with the peak at pH 7, and is only twofold at pH 5 and 10 with 4 M NaCl. Activation is greater at lower temperatures; it is 20-fold at 5°C and fivefold at 45°C in the reaction medium at pH 7.

### 3. Solubility of Thermolysin

The solubility of thermolysin is low, being 1.0–1.2 mg/mL in conventional buffers at low ionic strength (e.g., 40 mM Tris-HCl buffer, pH 7.5) in the temperature range between 0 and 60°C. The solubility increases on addition of salts (16). With NaCl, the solubility shows a bell-shaped curve with increasing NaCl concentration; the maximum solubility (10–12 mg/mL) is at 2.0–2.5 M NaCl. With LiCl and NaI, solubility increases to 20–50 mg/mL with increasing salt concentration up to 5 M. Thermolysin is a cold-soluble protein only in the presence of salts; it decreases in solubility with increasing temperature from 0 to 60°C. In the presence of 4 M NaCl, it is 6–7 mg/mL at 0°C and 2 mg/mL at 60°C. In the absence of NaCl, the temperature dependence is not observed.

### D. Halophilic Properties of Thermolysin

Neutral salts increase not only the solubility of thermolysin but also its activity and stability. Addition of salts permits preparation of enzyme solutions of high concentration with enhanced activity. These conditions reduce reaction time and enhance industrial application of the enzyme. With maximally solubilized thermolysin solution using 4 M NaCl or NaBr, the total activity is enhanced 55 and 360 times, respectively, compared with that in the absence of salts. In the case of 1 M NaSCN, the solubility of enzyme is 88 mg/mL at 25°C, and the activity enhancement is 3.2-fold. Thus, the total activity could be enhanced 280-fold. Industrial application of thermolysin is limited

because of its low solubility. This limitation can be overcome by adding a high concentration of salts.

## E. Inhibitors

Divalent metal chelators such as EDTA and *o*-phenanthroline (52) inhibit thermolysin by removing the catalytic zinc ion. Phosphonamidate transition-state analogs such as *N*-carbobenzyloxy (*Z*)-Gly<sup>P</sup>-L-Leu-L-Leu and *Z*-L-Phe<sup>P</sup>-L-Leu-L-Ala, where Gly<sup>P</sup> shows Gly in which the carbonyl carbon is replaced with phosphorus, and naturally occurring phosphonamidates, *N*( $\alpha$ -L-rhamnopyranosyloxyphospho)-L-Leu-L-Trp (or phosphoramidon) and *N*-(6-deoxy- $\alpha$ -L-talopyranosyloxyphospho)-L-Leu-L-Trp (or talopeptin), are tight-binding inhibitors. *Z*-L-Phe<sup>P</sup>-L-Leu-L-Ala is the tightest-binding inhibitor described to date ( $K_i = 0.068$  nM) (53). Inhibition of thermolysin by phosphoramidon and talopeptin is much weaker ( $K_i = 60$  nM) (54).

*Z*-Gly-D-Phe is a competitive inhibitor, and it is used as an affinity ligand for affinity chromatography of thermolysin (45, 55). Reagents which ligate to the catalytic zinc ion have been shown to be good inhibitors. Representative monodentate ligands containing a thiol group, i.e., thiophan, and bidentate hydroxamate ligand, i.e., hydroxyamino-carbonyl-2-benzyl-1-oxopropyl-glycine, have  $K_i$  values of 1.6 and 3.1  $\mu$ M, respectively (56). Inhibition by Ag<sup>+</sup>, Hg<sup>2+</sup>, Zn<sup>2+</sup>, and other metals, citrate, phosphate, mercaptoethylamine, cyanide, thioglycolate, 2,2'-bipyridine, imidazole, and  $\beta$ -phenylpropionyl-L-Phe have been observed (57).

## F. Subsite Structure

Subsite structure in the active site of thermolysin has been proposed on the basis of the 3D structure (53, 54). The substrate is fixed in the active site with the aid of hydrogen bonds formed between peptide chains of the substrate and the subsites. Trp115 forms the S2 subsite, Ala113 and Arg203 form the S1' subsite, and Asn112 forms the S2' subsite. The  $\alpha$ -carbonyl group of the P1 residue of the substrate coordinates with the catalytic Zn, and the  $\alpha$ -NH group of the P1' residue coordinates with Ala113. The peptide bond between these  $\alpha$ -position groups is cleaved in the catalysis. Not only the main chain but also the side chain of Trp115 is essential for catalysis (48). Site-directed mutagenesis of Trp115 indicated that aromatic amino acids such as Trp, Tyr, and Phe are essential for enzyme activity, and the mutant enzymes containing Leu, Ile, Val, Ala, etc., do not show any activity.

## G. Superactivation by Chemical Modification

Acylation of thermolysin with amino acid *N*-hydroxysuccinimide esters enhances the activity markedly. Thermolysin covalently modified with acetyl L-Phe shows 100 times higher activity toward the substrate FA-Gly-L-Ala-Gly (59). It has been considered that an acetyl L-Phe moiety binds to a tyrosyl residue in the active site to form an ester bond, although the targeted residue has not been identified because of instability of the modified residue.

## V. ASSAY AND PURIFICATION

### A. Thermolysin Assay

Two assay methods are described. One is based on casein digestion, and the other is based on the digestion of synthetic peptides (52).

Casein 3 mL (1.33%, w/v) and 1 mL of thermolysin (4–120 nM) are mixed in 40 mM Tris-HCl buffer, pH 7.5, at 25°C. After digestion of casein by thermolysin at 25°C for 10 min, the hydrolysate (4 mL) is treated with a solution (4 mL) consisting of 0.11 M trichloroacetic acid (TCA), 0.22 M Na acetate, and 0.33 M acetic acid, to remove undigested casein. The precipitate is removed by centrifugation at 3000g or filtration on a Whatman paper filter. The extent of digestion is measured by the amount of unprecipitated products measured at 280 nm or by the Lowry method. One unit of thermolysin activity is defined as an amount of the enzyme producing 1  $\mu$ g tyrosine per min (1). Practically, when the solution (filtrate or supernatant) gives an absorbance of 0.83 at 280 nm, the tyrosine concentration is 0.1 mg/mL—namely, 1000 units of enzyme in 1 mL of the solution.

Thermolysin is assayed using synthetic substrates such as carbobenzoxy (*Z*)-Gly-L-Phe amide, *Z*-L-Thr-L-Leu amide, and furylacryloyl (FA)-Gly-L-Leu amide. The extent of hydrolysis is measured by a colorimetric ninhydrin method which estimates the number of  $\alpha$ -amino groups liberated after hydrolysis of the peptide bonds, Gly-L-Phe, L-Thr-L-Leu, and Gly-L-Leu. The products of the peptide substrates can be determined by reversed-phase HPLC (35). Typical reaction conditions are 5–10 nM thermolysin and 1–20 mM substrates in 40 mM Tris-HCl buffer containing 10 mM CaCl<sub>2</sub>, pH 7.5, at 25°C (standard conditions). In the case of FA-dipeptides, especially FA-Gly-L-Leu amide (FAGLA), the hydrolysis is measured by following the decrease in absorbance at 345 or 322 nm (44, 60). The molar absorptivity differences at 345 nm and 322 nm

due to hydrolysis are  $-3.10 \times 10^2$  and  $-2.05 \times 10^3 \text{ M}^{-1}\text{cm}^{-1}$ , respectively, in the standard conditions. Hydrolysis of Z-Asp-L-Phe methyl ester (Z-Asp-Phe-OMe) can be measured by following the decrease in absorbance at 224 nm, which is due to peptide bonds (44). The molar absorptivity difference on the hydrolysis of Z-Asp-L-Phe-OMe into Z-L-Asp and L-Phe-OMe is  $-4.93 \times 10^2 \text{ M}^{-1}\text{cm}^{-1}$ , under the standard conditions described above.

Fluorogenic substrates for thermolysin have been reported (43, 45). The  $K_m$  and  $k_{cat}$  values of dansyl (Dns)-Gly-L-Phe-L-Ala are 0.080 mM and  $1.6 \text{ sec}^{-1}$ . Those for 2-aminobenzoyl-anthraniloyl (Abz)-L-Ala-Gly-L-Leu-L-Ala- (4-nitrobenzylamide) are 0.14 mM and  $290 \text{ sec}^{-1}$ , respectively (61).

## B. Purification of Thermolysin

The purification procedure of thermolysin is essentially that described by Endo (1). The culture broth (sample I; 10 L) of *Bacillus thermoproteolyticus* is filtered with the aid of Celite, and the enzyme in the filtrate (sample II; 9.7 L) is precipitated by 45% saturation with ammonium sulfate, pH 7.0, at  $4^\circ\text{C}$ . After centrifugation, the precipitate is dissolved in 20 mM Ca-acetate buffer (1.5 L), pH 7.0, and the solution (sample III) is brought to 30% saturation with ammonium sulfate. The precipitate is removed by centrifugation, and the supernatant is brought to 45% saturation with ammonium sulfate. After centrifugation, the precipitate is dissolved in 20 mM Ca-acetate buffer (1.0 L), pH 7.0. The solution (sample IV) is dialyzed overnight against 10 mM Ca-acetate buffer, pH 7.0, at  $5^\circ\text{C}$ . To the dialyzed solution (sample V; 1.1 L), chilled acetone (0.88 L,  $0^\circ\text{C}$ ) is added and the precipitate formed is removed. Chilled acetone (1.88 L, at  $0^\circ\text{C}$ ) is added slowly, and the precipitate is collected. The precipitate is dissolved in 20 mM Ca-acetate buffer (0.2 L), pH 7.0; the enzyme activity in the solution should be  $100 \times 10^3 \text{ U/mL}$ . The solution is kept at  $4^\circ\text{C}$ . Crystals of thermolysin appear within 30 min. The solution is held overnight. Crystals (sample VI; 1.55 g) are collected by centrifugation. A lyophilized preparation of these crystals shows an activity of  $6.5 \times 10^3 \text{ U/g}$ . In the same manner, crystallization is repeated three times. The activities of the two-times- and three-times-crystallized preparations (samples VII and VIII) are  $8.5 \times 10^3$  and  $10.0 \times 10^3 \text{ U/g}$ , respectively. Crude preparations (lyophilized acetone precipitate of culture broth) and three-times-crystallized preparations of thermolysin are available from Daiwa Kasei (Osaka, Japan). The purification process is summarized in Table 1.

**Table 1** Purification of Thermolysin

Sample No.	Volume or weight	Activity	Total activity ( $\times 10^6$ units)	Yield (%)
I	10 L	$3.5 \times 10^3 \text{ U/mL}$	35	100
II	9.7 L	$3.3 \times 10^3 \text{ U/mL}$	32	91
III	1.5 L	$19.0 \times 10^3 \text{ U/mL}$	29	83
IV	1.0 L	$25.0 \times 10^3 \text{ U/mL}$	25	71
V	1.1 L	$21.0 \times 10^3 \text{ U/mL}$	23	66
VI	1.55 g	$6.5 \times 10^3 \text{ U/g}$	14	40
VII	1.25 g	$8.5 \times 10^3 \text{ U/g}$	12	34

Chromatographic procedures for purification of thermolysin from the crude preparation have been reported. Ion exchange chromatography with DEAE-Sephadex A-25 and A-50 has been used (62). Affinity chromatographic procedures using acetyl-d-Phe, succinyl-d-Leu (63), and Gly-d-Phe (64) covalently attached to Sepharose matrix, and Bacitracin-silica (65) have been used successfully in a one-step purification of thermolysin.

### I. INTRODUCTION

Pectate lyases (EC 4.2.2.2) cleave the  $\alpha$ -1,4-D-galacturonosidic linkage by  $\beta$ -elimination resulting in the formation of a  $\Delta$ 4,5-unsaturated newly formed nonreducing end as is shown in Figure 1. Pectin lyases (EC 4.2.2.10) perform the same reaction. However, this class of enzymes requires the galacturonic acid residues adjacent to the scissile bond to be methylesterified. Based on their names and the Enzyme Commission classification one would expect a strict separation of the substrate specificities for the pectate and pectin lyases. However, this is not true. Indeed for several pectin lyases the specific activity increases with increasing degree of methylesterification (DM) whereas for many pectate lyases highest specific activity was recorded using pectins of moderate DM (20–50%) instead of pectin with 0% DM. The only discriminating factor between pectate and pectin lyases is the absolute requirement for  $\text{Ca}^{2+}$  ions for catalysis by pectate lyases. In some cases, as for the cytosolic *Erwinia chrysanthemi* 3937 PelW (formerly known as KdgC),  $\text{Ca}^{2+}$  is substituted by  $\text{Mn}^{2+}$  (15).

Despite the classification into two groups (EC 4.2.2.2 and EC 4.2.2.10), the classification based on the amino acid similarity by Coutinho and Henrissat (14) groups most of the pectate lyases and all known pectin lyases into family 1 of polysaccharide lyases. So far, five additional families (polysaccharide lyase

families 2, 3, 9, 10, and 11) of pectate lyases have been recognized. These additional families each contain only a small number of pectate lyases.

Unfortunately there is a large discrepancy between the rapidly expanding number of pectate and pectin lyases encoding nucleotide sequences available nowadays, and the actual number of corresponding enzymes thoroughly characterized biochemically. For many pectate and pectin lyases which have been biochemically characterized in the past no nucleotide sequences are available. This makes it difficult to relate certain biochemical properties to a particular family. However, biochemical data are available for at least one member of each of the six pectate lyase families. These will be discussed later.

**Figure 1** Elimination reaction carried out by pectate (and pectin) lyases.

### A. Pectate Lyases

Initially, pectate lyases were only isolated from bacteria and fungi. Notably phytopathogenic microorganisms appeared to possess one or more pectate lyases. For several bacteria, systematic mutagenesis programs have been carried out aimed at making knockouts of the pectate lyase genes. These studies have revealed that particular pectate lyases have an important role in the infection process whereas other pectate lyases secreted by the same organism have only limited impact on infection. The bacteria *Erwinia chrysanthemi* and *E. carotovora* are among the best-studied microorganisms in this respect (16, 17). Recently, through cDNA sequencing of plant tissue specific cDNA libraries, putative pectate lyases have been identified in plants (19–22), and one of these cDNAs, obtained from *Zinnia elegans* and expressed in *Escherichia coli*, indeed encoded  $\text{Ca}^{2+}$ -dependent pectate lyase activity (22).

In *E. chrysanthemi* strain 3937 at least eight endoacting pectate lyases (PelA–PelE, PelI, PelL, and PelZ (23–26) have been identified, cloned, individually overexpressed, and biochemically characterized. In addition, an oligogalacturonan lyase (EC 4.2.2.6) and an exopeptate lyase (EC 4.2.2.9) were identified and characterized (15, 27, 28).

### B. Pectin Lyases

Pectin lyases (EC 4.2.2.10) have so far only been identified in and isolated from microorganisms. Unlike the pectate lyases, which have predominantly been isolated from bacteria, the pectin lyases have mostly been identified in fungi such as *Neurospora*, *Botrytis*, penicillia, and aspergilli. Currently, only endoacting pectin lyases are known.

## II. ENDOGENOUS PECTATE LYASES IN PLANTS

As mentioned above, so far, only (putative) pectate lyases have been identified in plants. The first clear-cut demonstration of plant pectate lyase activity was reported by the group of McCann for *Zinnia elegans* (22). The gene encoding the pectate lyase (ZePel) appeared to be induced by auxin in a *Zinnia* mesophyll cell system at the onset of *trans*-differentiation into tracheary elements. It was proposed that the enzyme is involved in remodelling the cell wall during cell elongation and differentiation (22).

Based on the presence of cDNA-encoding putative pectate lyases, these activities have also been inferred in the ripening of strawberries (20) and bananas (19) and in the development of pollen in lily (18), tobacco, and *Arabidopsis* (21). Thus, although endogenous pectate lyases seem to be important for plant and fruit development, the appreciation of their role(s) is in its infancy.

## III. APPLICATION OF PECTATE AND PECTIN LYASES

Pectate lyases have not found any application in the food industry owing to their high pH optima, which generally are above pH 8.0, and their calcium requirement. It should be pointed out, however, that pectate lyases may well be present in commercial pectic enzyme preparations used in the food industry. Such preparations may contain various pectic activities such as pectin methylesterases, polygalacturonases, rhamnogalacturonases, rhamnogalacturonan lyases, and pectate and pectin lyases. Although pectin lyases generally have lower pH optima than the pectate lyases and do not require calcium for activity, they are not applied in the food industry as individual enzymes. Rather, these enzymes are part of pectic enzyme preparations.

## IV. BIOPHYSICAL PROPERTIES OF PECTATE AND PECTIN LYASES

As mentioned before, Coutinho and Henrissat (14) have classified the pectate and pectin lyases. The pectic lyases were classified in six families. To date the largest is family 1 which contains > 50 members with established activity and > 30 members based on sequence identity. Surprisingly, all known pectin lyases are part of family 1, which primarily contains pectate lyases. The molecular masses of the enzymes in family 1 range from 33 to 49.4 kDa. Family 2 so far contains only four members (three from *Erwinia* sp. and one from *Yersinia pseudotuberculosis*), and their molecular masses are virtually the same (60–64 kDa). Family 3 is the second largest and contains at present 14 members. Most of the pectate lyases in this family are fairly small (22.8–25.6 kDa) with two exceptions: pectate lyase B from *E. carotovora* (37.4 kDa), and pectate lyase I from *E. chrysanthemi* (36.8 kDa). The four members of family 9 are the largest pectate lyases with molecular masses of 45.5, 72.6, 79.6, and 82.3 kDa. The latter two enzymes are the only known exopeptate lyases. The smaller one is from *E. chrysanthemi* strain 3937 (28),

and the larger one is from *E. chrysanthemi* strain EC16 (27). Finally, family 10 of pectate lyases contains only two very recently described genes, one from *Azospirillum irakense* (29) encoding a 47-kDa enzyme, and the other, *pelE*, from *Bacillus* sp. KSM-P15 (30) encoding a 35.6-kDa enzyme. Family 11 contains one rhamnogalacturon lyase and is, strictly speaking, neither pectate nor pectin lyase.

#### A. Three-Dimensional Structures of Pectate and Pectin Lyases

Currently, 3D structures are only available for family 1 lyases although the structure of PelL from *E. chrysanthemi* (family 9) was recently solved as well (J. Jenkins, personal communication). For pectate lyase from *Pseudomonas fluorescens*, which belongs to family 10, a structure has also been solved; however, the coordinates are not yet publicly available.

The *E. chrysanthemi* strain EC16 PelC structure (PDB code 2PEC) was the first to be solved by Jurnak and coworkers (4). Soon, the structure of the *Bacillus subtilis* pectate lyase (PDB code 1BN8) followed (5). In this structure a  $\text{Ca}^{2+}$  atom was found to be coordinated by three acidic residues at the bottom of the proposed substrate binding cleft, thus providing the first indication of a role for  $\text{Ca}^{2+}$ . The third structure (PDB code 1PCL) that became available was for PelE from *E. chrysanthemi* EC16 (31). Following the pectate lyase structures, three pectin lyases structures were solved. Mayans and coworkers (6) solved two structures of pectin lyase A (PLA) from *Aspergillus niger*. One of these structures (PDB code 11DJ) was solved at pH 6.5 (strain CBS120.49), and the other (PDB code 11DK) at pH 8.0 (strain 4m-147). Apart from some amino acid substitutions, the main difference between the two structures centers around Asp186, which is in a completely different position in the two structures. At pH 8.0 this residue is in an outward position and has been implicated in the reversible inactivation of the enzyme at pH 8.0 (6). Pectin lyase (PLB) (PDB code 1QCX) is the latest pectin lyase for which the structure has been solved (7).

The pectic lyases for which structures are known all have the same topology; the enzymes consist of a right-handed parallel  $\beta$ -helix. When it was first described for PelC this structure was unique. The unique properties of  $\beta$ -helical proteins and the origin of their stability were discussed by Jurnak and coworkers (32). The most recent pectate lyase structure is PelL from *E. chrysanthemi* 3937. This enzyme belongs to family 9, and it appears that the topology is the same as found

for the family 1 pectic lyases (J. Jenkins, personal communication). Nowadays this  $\beta$ -helical structure is considered to be common among pectic enzymes except for the rhamnogalacturonan acetyl esterase which has an alpha-beta-alpha structure (12). The  $\beta$ -helix conformation was found for a rhamnogalacturonase (10), for two polygalacturonases (8, 9), and very recently for a bacterial pectin methylesterase (11). The evolutionary relationship between pectate and pectin lyases and tail spike protein (another right-handed  $\beta$ -helical enzyme) was discussed by Jenkins et al. (13). The reasoning they follow for the significant sequence variation between the enzymes with concomitant conservation of the topology can easily be extrapolated to the other pectic enzymes. Surprisingly, the family 10 *P. fluorescens* pectate lyase does not adopt the  $\beta$ -helical topology (G. Davies and G. Black, personal communication).

The main difference between the pectate and pectin lyases is found in the substrate-binding cleft as a result of the difference in charge of the preferred substrates. Whereas pectate lyases preferentially attack the charged polygalacturonic acid or pectin with a very low degree of esterification, with still a high degree of charges, pectin lyases prefer to act on fully or highly methylesterified pectin. As a result, the substrate binding cleft of the pectin lyases contains a very high number of aromatic (Trp, Tyr, Phe) and apolar residues (Val, Leu, Ile, Ala). In contrast, the substrate-binding cleft of the pectate lyases is occupied by polar (Ser, Thr, Asn) and charged (Asp, Glu, Arg, Lys) residues.

Recently, Scavetta and coworkers (33) solved the 3D structure of pectate lyase C from *E. chrysanthemi* EC16 in complex with a pentagalacturonide. This structure is the first of a pectic enzyme in complex with its substrate and clearly shows that the initially proposed substrate binding cleft indeed accommodates the substrate. In addition, the structure provides insight into the necessity of  $\text{Ca}^{2+}$  for catalysis by pectate lyases. This will be discussed below in Section V, on biochemical properties of pectate and pectin lyases.

#### B. Isoforms of Pectate and Pectin Lyases

The advances in molecular-biology techniques and tools in the past decade have allowed the rapid accumulation of nucleotide sequences of genes encoding pectate and pectin lyases. Comparison of the number of pectate lyase sequences and pectin lyase sequences present in databases shows that the pectate lyases strongly outnumber the pectin lyases. This is exemplified by an organism like *E. chrysanthemi* 3937. For this organism so far only one pectin lyase and nine pectate

lyases have been identified which have representatives in families 1, 2, 3, and 9 of polysaccharide lyases. However, *A. niger* appears to harbor at least six pectin lyase genes (34) and only one pectate lyase gene (Benen, unpublished). For other organisms, e.g., *Fusarium solani* (35–38), families of pectate lyases have been identified as well. Thus, from a genetic point of view there are many isoforms. This is not surprising in view of the complexity of the pectin molecule.

There has been no report to date of isoforms of pectinases as a result of proteolytic processing. Of course, since most of the pectinases are extracellular enzymes, they are processed by the proteases of the secretory pathway during export.

Eukaryotic organisms have the option to glycosylate secreted proteins either via N-linked glycosylation of Asn residues, provided the N-linked sequon Asn-X-Ser/Thr is present, or via O-linked glycosylation of serine residues. So far, only one detailed analysis of the glycosylation patterns of a pectate lyase has been published (39). For the overexpressed *A. niger* pectate lyase two forms were obtained. Although the two isoforms did not differ with respect to specific activity, they differed with respect to glycosylation: whereas one isoform was not N-glycosylated, the other isoform carried an N-glycon of the high mannose type (39). It is not known whether the N-glycosylation is involved in the stability of the enzyme.

## V. BIOCHEMICAL PROPERTIES OF PECTATE AND PECTIN LYASES

### A. Substrate Specificity

As mentioned in the introduction of this chapter, there is no strict separation of the substrate specificity between pectate and pectin lyases. Rather, the pectate lyases prefer pectin with a low DM or 0% DM whereas the pectin lyases prefer pectin with a high DM. One other property distinguishes the pectate lyases from the pectin lyases: the pectate lyases require calcium ions for catalysis.

#### 1. Pectate Lyases

The 3D structure of the *B. subtilis* PEL revealed the presence of a  $\text{Ca}^{2+}$  ion tightly bound to the enzyme (5). However, the kinetic analysis of pectate lyases where  $\text{Ca}^{2+}$  is used as the varied substrate in many cases reveal sigmoidal curves instead of rectangular hyperbolic curves (upward curvature in Lineweaver-Burk plots instead of straight lines). If  $\text{Ca}^{2+}$  would only

serve as a tightly bound cofactor, then the plots would be normal. Atallah and Nagel (40) analyzed the role of  $\text{Ca}^{2+}$  ions for a pectate lyase from a *Cephalosporium* sp. Using tetragalacturonide and  $\text{Ca}^{2+}$  in a two-substrate kinetic analysis, they concluded that the substrate binds as a  $\text{Ca}^{2+}$  tetragalacturonide complex and that  $\text{Ca}^{2+}$  might act as an activator of the enzyme. The 3D structure of the *E. chrysanthemi* EC16 PelC-pentagalacturonide complex (33), in which only four sugar moieties were seen, showed that in addition to the  $\text{Ca}^{2+}$  ion coordinated by four acidic amino acid residues, three more  $\text{Ca}^{2+}$  ions were present, each making contact to one of the carboxylic functions of the substrate and an acidic residue of the enzyme. Thus, kinetic studies as well as the 3D structure now demonstrate that  $\text{Ca}^{2+}$  is indeed involved in the binding of the substrate to pectate lyases. It is obvious that the number of  $\text{Ca}^{2+}$  ions involved in the binding will depend on the preferred DM of the substrate. The preference of the substrate will be based on the actual architecture of the subsites. A subsite which accommodates a methylesterified galacturonate residue will be different from one which accommodates a nonesterified galacturonate. Thus, by variation of the subsite composition numerous pectate lyases can be made with different substrate specificity.

The *E. chrysanthemi* 3937 pectate lyases, although not the first enzymes studied, represent the most complete set of pectate lyases from one organism thoroughly characterized (23–26, 28, 41).

Table 1 provides an overview of the biochemical properties of these enzymes. This table clearly shows the preferred DM of the substrate for the individual enzymes. Although six of the lyases belong to family 1, a considerable variation in substrate preference and reaction rates exists within this group of enzymes. It is even questionable whether polygalacturonic acid or even the partially methylesterified pectins are the natural substrates for PelA and PelZ (41). Moreover, although PelA, PelB, and PelD belong to family 1, they differ with respect to tissue maceration: PelA is devoid of this activity, PelB is moderately active, and PelD is very active in tissue maceration (16). This again demonstrates that the enzymes differ in their substrate specificity. The actual pectin structure(s) preferentially attacked during tissue maceration have not been identified.

For PelX, PelW, and oligogalacturonan lyase (OGL), it has been shown that the preferred substrates are oligogalacturonides rather than polymeric substrates (15, 28). From the localization of these enzymes

**Table 1** Biochemical Properties of *E. chrysanthemi* 3937 Pectate Lyases (Kinetic Parameters Determined Using Polygalacturonic Acid)

Enzyme	Family	Mode of Action	pH opt.	% DM (range)	Cofactor(s)	$K_m$ (mg/mL)	$V_{max}$ (U/mg)	Ref.
PelA	1	endo	8.5	0 (0–30)	0.1 mM Ca <sup>2+</sup>	0.3	46	23
PelB	1	endo	9.3	31 (0–50)	0.1 mM Ca <sup>2+</sup>	0.03	2448	23
PelC	1	endo	9.2	31 (0–45)	0.1 mM Ca <sup>2+</sup>	0.02	762	23
PelD	1	endo	8.8	0 (0–25)	0.1 mM Ca <sup>2+</sup>	0.28	670	23
PelE	1	endo	8.0	0 (0–25)	0.1 mM Ca <sup>2+</sup>	0.42	3803	23
Pell	3	endo	9.2	31 (10–55)	0.6 mM Ca <sup>2+</sup>	0.12	230	26
PelL	9	endo	8.5	31 (0–70)	0.1 mM Ca <sup>2+</sup>		5	25
PelZ	1	endo	8.5	7 (0–45)	0.2 mM Ca <sup>2+</sup> 0.2 mM Mn <sup>2+</sup>	0.15	9	46
PelX	9	exo	8.0	0 (0–25)	0.1 mM Ca <sup>2+</sup>	0.25	90	28
PelW	2	exo	8.5	45 (0–60)	0.1 mM Mn <sup>2+</sup> or Zn <sup>2+</sup>	0.01	6	15

this is logical. PelX is localized in the periplasmic space where polymeric substrates are unlikely to be present (27). This enzyme is most active on tetragalacturonic acid (G4):  $K_m$  (G4) 25  $\mu$ M and  $V_{max}$  520 U/mg. PelW and OGL are both intracellular enzymes. The preferred substrates are trigalacturonate (G3) and digalacturonate (G2) for PelW and OGL, respectively (15). The kinetic parameters are: PelW  $K_m$  (G3) 7  $\mu$ M and  $V_{max}$  30 U/mg; OGL  $K_m$  (G2) 150  $\mu$ M and  $V_{max}$  80 U/mg. PelX and PelW both retain activity on polymeric substrates and their mode of action is exolytic on such substrates, cleaving off unsaturated dimers from the reducing end. An early report on an OGL from *Pseudomonas* sp. described an exolytic activity that cleaved off unsaturated monomers from the reducing end which were spontaneously converted into 2-keto-4-deoxygluconate (42). So far, no representative of family 10 lyases has been found in *E. chrysanthemi* 3937.

Recently, the *Azospirillum irakense* PelA which belongs to family 10 was characterized (29). It appeared that this endoacting enzyme prefers pectin with 28% methylesterification. The kinetic parameters for this enzyme using polygalacturonic acid as a substrate are:  $K_m$  0.076 mg/mL and  $V_{max}$  23 U/mg. The  $V_{max}$  is of the same order as found for the *E. chrysanthemi* PelA although the  $K_m$  is lower for the *Azospirillum irakense* PelA. Furthermore, the pH optimum and the Ca<sup>2+</sup> concentration for optimal activity are similar to the family 1 enzymes as is the preference for low-DM pectin. Thus, although the pectate lyases can be grouped into five different families based on their primary sequences, no correlation is found with the kinetic data obtained so far.

## 2. Pectin Lyases

This interesting group of enzymes has recently received little attention. Only few detailed biochemical studies have been carried out in the past. The most exhaustively characterized enzymes are those obtained from *Aspergillus* pectinase preparations (43, 44). From *A. niger* N400 six genes were cloned encoding pectin lyases (34) among which are two genes, *pelA* and *pelD*, encoding pectin lyase A and D, respectively. These enzymes correspond to pectin lyase II and I, enzymes previously characterized by Van Houdenhoven (44). Kester and Visser (45) characterized PLB, the third pectin lyase from *A. niger*. This enzyme was obtained via overexpression of the *pelB* gene.

All these pectin lyases prefer high-DM pectins. The pH optima are ~ pH 6, with the exception of PLB for which a pH optimum of 8.5 was recorded. PLB was also greatly stimulated by the presence of a high salt concentration (0.5 M NaCl). Furthermore, the activity of PLB on 95% DM pectin,  $K_m$  9.4 mM and  $V_{max}$  1288 U/mg, is much higher than those reported for PLI ( $K_m$  10.0 mM and  $V_{max}$  125 U/mg) and PLII ( $K_m$  1.5 mM and  $V_{max}$  44 U/mg) (45). Voragen, studying three different pectin lyases, showed that using pectins with lower DM not only lowered the activities but the pH optimum also shifted to lower pH. The shift of the pH optimum and the decrease in activity were also related to the distribution of the methyl groups (43). Detailed kinetic studies revealed that upon lowering DM  $V_{max}$  remained constant whereas  $K_m$  increased (43). However, by lowering the pH, the affinity for the lower DM pectins increased. It was also noted that

lyase activity was higher, using pectins of the same DM, when the pectin was deesterified by a pectin methylesterase instead of alkaline treatment. The alkaline treatment results in a random removal of methyl groups whereas the enzymic saponification results in a blockwise removal of methyl groups (see also Chap. 68 on the pectin methylesterases).

Although pectin lyases do not require  $\text{Ca}^{2+}$  for activity,  $\text{Ca}^{2+}$  appears to influence the activity of the enzymes. At pH values above the optimum,  $\text{Ca}^{2+}$  stimulated the activity, notably on partially alkaline deesterified substrates. Addition of  $\text{Ca}^{2+}$  to the reaction mixtures also resulted in a lowering of the pH optima (43).

Since pectin lyases prefer high-DM pectin as substrate, it is plausible that  $V_{\max}$  remains constant and  $K_m$  increases using blockwise deesterified substrates since the actual concentration of the "high-DM" substrate decreases. Using alkaline treatment the high-DM nature of the substrate is lowered, so the substrate changes and therefore  $V_{\max}$  also changes. Upon lowering the pH of the reaction mixture, more of the deesterified groups become protonated and thus the net charge of the substrate decreases. Therefore, the affinity for the substrate will increase at lower pH. A similar effect can be expected from  $\text{Ca}^{2+}$  which interacts with the carboxylates of the substrate. This effect will be stronger at higher pH as was observed.

## B. Effect of Environmental Factors

Obviously, chelating compounds like EDTA dramatically reduce the activity of pectate lyases. For some pectate lyases it has been shown that other divalent ions can partially substitute for  $\text{Ca}^{2+}$ , i.e., PelX from *E. chrysanthemi* (28), or even require  $\text{Mn}^{2+}$  in addition to  $\text{Ca}^{2+}$  as has been observed for *E. chrysanthemi* PelZ (46). However, the five major *E. chrysanthemi* pectate lyases (A–E) (22) and the *A. irakense* PelA are inhibited by other divalent ions (29). The cytoplasmic *E. chrysanthemi* lyases PelW and OGL require  $\text{Mn}^{2+}$  or  $\text{Mg}^{2+}$  instead of  $\text{Ca}^{2+}$  (15). This is plausible since the actual concentration of  $\text{Ca}^{2+}$  in the cell is very low ( $\mu\text{M}$  range).

$\text{Ca}^{2+}$  is apparently not only required for catalysis but it also renders the pectate lyases more resistant to thermal inactivation. The pectate and the pectin lyases are generally stable up to 50°C, their activity increasing with increasing temperature.

For the pectin lyases, so far no inhibitor molecules have been identified. The major *E. chrysanthemi* 3937 pectate lyases as well as a pectate lyase from

*Colletotrichum gloeosporioides* were inhibited by epicatechin with  $K_i$  between 0.1 and 0.2 mM (23, 47). The *E. chrysanthemi* pectate lyases were also inhibited by salicylic acid ( $K_i$  between 0.2 and 0.4 mM) (23). Both compounds generally occur in plants and may be involved in the protection against attack of phytopathogenic microorganisms.

The pectin lyases from *A. niger* appear quite sensitive to the pH and the ionic strength of the medium. Both PLA and PLB reversibly inactivate at low ionic strength and higher pH (44, 45). For PLB this was accompanied by a change in the surface charge as inferred from the change in chromatographic behavior (45), and for PLA this was accompanied by changes in fluorescence (44) and in a structural change observed by x-ray crystallography (6).

## C. Specific Mechanism of Action

The pectate and pectin lyases cleave the substrate by  $\beta$ -elimination (see Fig. 1). It is not known whether the anomeric configuration of the newly formed reducing end is retained or inverted. To initiate the reaction the proton must be removed from C5. This is to be accomplished by a base. The electron-withdrawing power of the methylesterified carboxyl group is much stronger than a carboxylic function without esterification. Thus, the  $pK_a$  of the proton at C5 will be lower in pectin than in pectate. Hence, a weaker base is necessary to initiate the reaction for pectin lyases. This may correlate with the observation that pectin lyases generally have lower pH optima than pectate lyases. Next, the glycosidic linkage must be broken, which has to be accomplished by an acid. The nature of the base and the acid were unknown until recently, when the 3D structure of the *E. chrysanthemi* EC16 PelC R218K-substrate complex was solved (33). The 3D structure of the complex could only be solved for this mutant enzyme PelC R218K which appeared strongly impaired in catalysis (48).

To lower the  $pK_a$  of the C5 proton the carboxylic acid of the substrate interacts with two  $\text{Ca}^{2+}$  ions and a Lys residue. In the mutant enzyme no obvious base is present. However, superposition of the wild-type structure revealed that Arg218 may serve as the base: one of the guanidium nitrogens is at 2.6 Å from the C5 proton while the other is at 2.7 Å from an oxygen of the carboxylic group (33). It was suggested that the latter interaction can be responsible for the lowering of the  $pK_a$  of the C5 proton and the former acts as the base (33). The nature of the acid is still unknown. Either a water molecule can be activated by one of the  $\text{Ca}^{2+}$  ions or the proton abstracted from C5 by Arg218

can be transferred to the glycosidic bond. This may be tested experimentally by kinetic isotope studies.

For the pectin lyases, a similar mechanism may be operating as the Arg218 counterpart is strictly conserved among pectate and pectin lyases. Furthermore, a site-directed mutagenesis studies on pectin lyase A and B from *A. niger* have shown that mutagenesis of this conserved Arg residue completely abolishes activity (Sanchez-Torres et al., unpublished).

#### D. Subsites in Binding to the Substrate

Polysaccharide-depolymerizing enzymes generally have multiple subsites, each interacting with one sugar residue of the polymer. As a rule of thumb, the exoacting enzymes have only a small number of subsites, and the endoacting enzymes have a larger number. By convention, subsites are consecutively numbered starting from the active site. Toward the reducing end the subsites are numbered starting from +1. Toward the nonreducing end the numbering starts at -1 at the subsite adjacent to subsite +1.

As mentioned above, the actual amino acids that constitute a subsite define its binding characteristics. A first partial study on pectate lyase was reported by Preston et al. (49) who analyzed *E. chrysanthemi* EC16 pectate lyases. Their data show that the four enzymes studied each have a distinct product progression profile during polygalacturonic acid degradation. Initially, larger oligomers are formed, distinctive for endocleaving enzymes, which are subsequently converted into typical smaller oligomers like unsaturated dimers and/or trimers; for instance PelC primarily generated unsaturated trimers and a smaller fraction of unsaturated dimers (49, 33). In fact, these studies helped to identify the actual active site in the PelC-substrate complex (33). A more detailed characterization of five *E. chrysanthemi* 3937 pectate lyases (PelA, PelB, PelD, PelI, and PelL) was carried out by Roy and coworkers (41). In addition to the product progression, the bond cleavage frequencies and cleavage rates of oligogalacturonides (degree of polymerization [DP] 2–8) of defined length were studied as well. These latter studies provide insight into the number of subsites and the location of the active site in the array of subsites. As a rule of thumb, endoacting enzymes show increasing rates of turnover as a function of the length of the oligomers used until the full array of subsites is filled. Actually a plot of  $\log V_{\max}$  vs.  $n$  ( $n$  = chain length) shows a plateau or peak when  $n$  equals or exceeds the number of subsites (50). This is also reflected in

**Table 2**, where the bond cleavage frequencies and the rates of the five pectate lyases are presented.

The easiest to interpret are the data for PelD. The product progression on polygalacturonate is characterized by a strong accumulation of unsaturated dimer from the beginning of the reaction and only a small transient increase of oligomers with  $DP > 3$ . For all oligogalacturonides used the second bond from the reducing end is the preferred bond cleaved, and the highest reaction rate was recorded for tetragalacturonide. From this it was concluded that PelD most likely has only four subsites which stretch from -2 to +2 (41).

More complex was the behavior of PelA. For this enzyme a peak in rate was recorded at DP 4 and even higher activities at DP 7 and 8. Also, a shift in the preferred bond cleaved was observed depending on the chain length. Based on these observations it was concluded that PelA is composed of more than four subsites of which subsites -2 to +2 have the highest affinity for the homogalacturonan substrate (41). For PelB the array of subsites stretches from -3 to +3, with a strong preference to cleave off unsaturated trimers from the reducing end (41). Thus, despite PelA, PelB, and PelD belonging to the same family of lyases, their subsite compositions are quite different. This is further strengthened by the observation that for pectin lyase A from *A. niger*, belonging to the same family, 10 subsites were rationalized based on kinetic studies, stretching from -7 to +3 (44), which were recently confirmed by molecular modeling (P. Swaren, personal communication).

#### E. Synthetic Substrates

Applying complex carbohydrate synthesis chemistry Magaux and coworkers (51) and Kester and coworkers (52) generated monomethylesterified di- and trigalacturonides carrying the monomethyl group at a defined position. These substrates were used to test 11 different pectinases for the effect of the presence of a methylated galacturonate at subsites -2, -1, +1, or +2. This study included the *E. chrysanthemi* 3937 PelX, PelW, and Ogl, enzymes known to prefer small substrates. It was confirmed that OGL was five times more active on the unmethylated dimer than on the unmethylated trimer (15, 52). In addition it was shown that OGL can accommodate a methylated galacturonate at subsite +1 and still retain high activity (78% on 1-Me-GalpA)<sub>2</sub> and 51% on 1-Me(GalpA)<sub>3</sub>) at the substrate concentration used, whereas the presence of methylated galacturonate at subsite -1 was not tolerated (52). For PelX

**Table 2** Bond Cleavage Frequencies and Specific Activities of *Erwinia chrysanthemi* 3937 Endopeptidase Lyases PelA, PelI, PelL, PelD, and PelB Acting on Oligogalacturonates of Defined Chain Length<sup>a</sup>

<sup>a</sup>Conditions: 0.5 mM oligogalacturonate (*n* = 3–8), 1 mM CaCl<sub>2</sub>, 20 mM Tris/HCl, pH 8.0 (PelA, PelD, and PelL) or 20 mM amino-methyl-propanol/HCl pH 9.0 (PelB and PelI) at 37°C. Bond cleavage frequencies are given in percentages. The reducing end of the oligogalacturonates is printed in bold. *n*, degree of polymerization.

and PelW, both cleaving off unsaturated dimers, it was shown that none of the dimers were substrates. Furthermore, it was demonstrated that at subsite +2 a methylated galacturonate was tolerated, 33% and 39% activity remaining on 1-Me-(GalpA)<sub>3</sub> for PelX and PelW, respectively, whereas subsite +1 absolutely required an unmethylated galacturonate. Only PelW was able to cleave 3-Me-(GalpA)<sub>3</sub>, albeit at a very low rate, demonstrating that for PelX and PelW an unmethylated galacturonate at subsite –1 is important as well (52).

## VI. QUALITATIVE AND QUANTITATIVE DETERMINATION OF ACTIVITY

### A. Substrate Preparation

Pectate and notably pectin show  $\beta$ -elimination at elevated pH. Any activity determination should therefore be corrected for this chemical breakdown by running the proper control reactions. A second, very important aspect is the fact that demethylation occurs quite readily at higher pH. To increase the shelf life of stock solutions of substrates, these are best prepared at pH values < 7 in distilled water rather than buffers. Since pectin in solution is viscous, for ease and accuracy of pipetting stock solutions, they can best be prepared at concentrations < 1% w/v. Before pectate or pectin can be dissolved in water, they should be hydrated. Therefore, 96% ethanol is added to the powder until the resulting slurry has a glossy shine. Next, an amount

of water is added to allow pH adjustment, and then final volume adjustment should be done. In their acidic form pectate and to a lesser extent high-DM pectin do not readily dissolve as the starting pH will be < 4. Only after careful pH adjustment to a pH value > 4 will the pectate or pectin completely dissolve. Care should be taken to avoid pH overshoot (spontaneous quick demethylation). Pectate or pectin forms a buffer with a  $pK_a$  between 3.5 and 4. Initially quite large volumes of hydroxide are needed (use 1 M NaOH or less!), but when the pH reaches 4 the amount needed drastically decreases. To obtain solutions with minimal substrate interference in spectrophotometric assays the resulting solutions should be centrifuged for 15 min at 5000–7000g and decanted into a fresh container.

When selecting commercial pectin sources to be used as polymers, the product with the highest molecular mass and highest anhydrogalacturonic acid content should be chosen. The choice of DM is dependent on the purpose. When partially demethylated pectins are needed, attention should be paid to the method of demethylation which can be either enzymatic (plant or fungal pectin methylesterase) or an alkaline treatment. These methods result in different distributions of the methyl groups.

Oligogalacturonides are not commercially available. They should be prepared from polygalacturonic acid by partial digestion with either an endopolygalacturonase or a pectate lyase in case unsaturated oligogalacturonides are wanted. Methods to separate oligomer mixtures have been described (43, 53). The preparation

of methylated oligogalacturonides has also been described (54) as has the method to obtain reduced oligogalacturonides (55).

## B. Assay Conditions

Pectate and pectin lyase activity are most conveniently measured spectrophotometrically at 235 nm in 1-cm light-path quartz cuvettes (1 or 3 mL). The unsaturated bond that results from the action of the lyases specifically absorbs UV light of this wavelength. For pectate the molar extinction coefficient ( $\epsilon_{235}$ ) is  $4800\text{ M}^{-1}\text{cm}^{-1}$  and for pectin  $\epsilon_{235}$  is  $5200\text{ M}^{-1}\text{cm}^{-1}$  (56). By using the spectrophotometric method instead of a method based on the reducing sugar content, only the lyase activity is determined rather than all pectin-degrading activities like polygalacturonase activity that can be present as a contaminant.

For pectate lyase attention should be paid to the choice of the buffer as many anions interact with  $\text{Ca}^{2+}$ . In addition, for both the pectate and the pectin lyases the buffer should not absorb at 235 nm. Suggested buffers are: for pectin lyases McIlvaine buffers (pH 2.5–8.0), and for pectate lyases Tris/glycine/HCl or 2-amino-methyl propanol/HCl. It is known that Tris can have an inhibitory effect on some pectate lyases.

The amount of substrate to be used should ensure straight traces during the early stages of the reaction to allow the calculation of reaction rates. For kinetic analysis substrate concentration can vary between 0.01 and 5 mg/mL. For a standard assay any concentration between 0.2 and 3 mg/mL is adequate. For pectate lyase it should be kept in mind that  $\text{Ca}^{2+}$  will form gels with the substrate when the  $\text{Ca}^{2+}$  concentration is too high.

There are two methods to determine whether the enzyme is endolytic or exolytic. The first method relies on the reduction of the viscosity in relation to the reducing sugars formed. The second method is based on the analysis of the reaction mixture by thin-layer chromatography (TLC) or by high-performance anion exchange chromatography (HPAEC). The latter method allows accurate quantification. For the preparation of samples the reaction can be stopped either by boiling the sample or by lowering the pH below the activity region (to pH 4–5 for pectate lyase or to pH 3 for pectin lyase) by the addition of a predetermined adequate volume of acetic acid (pectate lyase) or hydrochloric acid (pectin lyase). Boiling the sample can sometimes lead to inaccurate data, as the enzyme activity initially increases until inactivation occurs.

## C. Assay for Screening Purposes

To screen larger numbers of colonies (bacteria, fungi) for the production of pectate lyase, plates should be prepared in duplicate and include, in addition to all necessary compounds, 0.25% polygalacturonic acid and 0.1 mM  $\text{CaCl}_2$ . One of the plates serves as the master plate, and the second will be stained with Ruthenium Red. After growth in a 0.1% solution of Ruthenium Red, water has to be poured over the plate. Ruthenium Red will stain polygalacturonic acid but not degradation products thereof. The entire plate will therefore turn red/purple with a lighter halo around colonies that produce a pectate lyase. The method will not work for pectin lyases.

## VII. PURIFICATION

Microbial pectic enzymes are generally secreted; they can therefore easily be recovered from the culture fluid by adsorption to an appropriate ion exchange resin. The choice of the resin depends on the isoelectric point of the enzyme, which is known to vary extensively from one enzyme to the other. For an individually overproduced enzyme, two or three chromatography steps are generally sufficient (57). When *Escherichia coli* is used to produce a recombinant pectinase, for initial characterization, no purification is necessary, as *E. coli* itself does not produce any pectinases. For the purification of a single enzyme from a pectinase preparation, many chromatography steps, including anion and cation exchange and gel filtration, may be necessary. In the past, crosslinked pectate and crosslinked alginate have successfully been applied for the purification of pectate lyases (58, 59).

## Alliinases

**Edna C. Ramírez**

*University of California, Davis, Davis, California, U.S.A.*

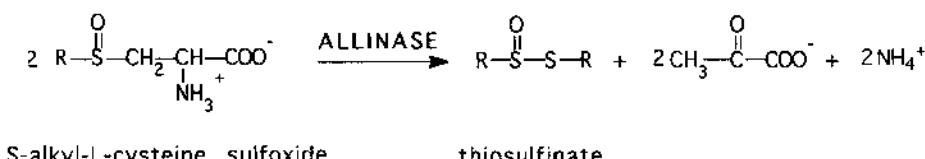

### I. INTRODUCTION

Alliinases [S-alk(en)yl-L-cysteine sulfoxide lyase; alliin lyase; EC 4.4.1.4] cleave S-alk(en)yl-L-cysteine sulfoxides by  $\beta$ -elimination producing thiosulfinate, pyruvate, and ammonia (Fig. 1). This enzyme requires pyridoxal-5'-phosphate (PALP) as a cofactor. The pungent flavors and aromas of a number of species in the Amaryllidaceae family are due to the action of this enzyme. As is the case with other lyases, the enzyme is separated from the substrate in the intact tissue, and the reaction takes place upon rupture of cells.

The first alliinase to be described was from garlic bulbs by Stoll and Seebeck (1). They determined the effect of pH and temperature on the alliinase reaction from a crude extract of garlic and conducted studies on specificity based on substrate structure and configuration. Since then, alliinases from Chinese chive (2), garlic (3), leek (4), onion (5, 6), and Welsh onion (7) have been purified. Although they belong to the same genus, their individual alliin lyases are different in their physical and chemical properties.

### II. IMPORTANCE TO QUALITY OF FOOD

Garlic and onion have been used for centuries by many cultures as foods, medicines, spiritual objects, etc. (8). Although they have nutritional and therapeutic values in diets, they are consumed around the world for their flavor and their ability to enhance the flavors of other foods. In garlic, diallylthiosulfinate (allicin) is the principal sulfur compound which gives its characteristic aroma. This thiosulfinate is the result of the  $\beta$ -elimination reaction on S-2-propenyl-L-cysteine sulfoxide (alliin) by alliinase, through the intermediary 2-propenesulfenic acid (9). In onions, there are three flavor precursors: S-1-propenyl-L-cysteine sulfoxide, S-methyl-L-cysteine sulfoxide, and S-propyl-L-cysteine sulfoxide (in the order of concentration abundance). The different thiosulfinate formed by the action of alliinase on these substrates give the distinct flavor of onions, depending on their concentrations (8). Other *Allium* spp. have different mixtures of these substrates as well as S-2-propenyl-L-cysteine sulfoxide; this last compound is absent in onion (9). The lachrymatory

**Figure 1** Alliinase general reaction.

factor in onion (propanethial sulfoxide) is derived from S-1-propenyl-L-cysteine sulfoxide (10).

Although the metabolic role of alliinase in plants has not been conclusively determined, the importance of this enzyme in defense mechanisms has been proposed by many researchers.

### III. LOCATION

It is generally accepted that alliinases and their substrates are separated in vivo and only react upon wounding of the cells. High concentrations of alliinases are typically found in the bulbs of members of the genus *Allium*. In the onion bulb (*Allium cepa*), this enzyme is found in the vacuoles (11). In this study, the alliinase activity in vacuoles was found to be comparable to the total alliinase activity in protoplasts. Furthermore, vacuoles contained negligible amounts of alkyl-cysteine sulfoxides, but a considerable amount was found in cytoplasm of the protoplasts.

In garlic (*Allium sativum*), alliinases and lectins are the major proteins found in the clove (12). The total alliinase activity in the bulb of a mature plant of garlic is 10 times higher than that in the leaves (13). Ellmore and Feldberg (14) studied the location of alliinase deposits in garlic cloves through general histology, autofluorescence, and immunoblotting with enzyme-specific antibodies. Their results show alliinase to be concentrated in bundle sheaths, near phloem, scattered among storage mesophyll cells.

Analysis of the nectar from leek (*Allium porrum* L.) flowers also reveals the occurrence of two major proteins: lectin and alliinase (15). Researchers have not reported an explanation for the protein composition resemblance between garlic cloves (specialized storage tissue) and leek nectar. The discovery of the metabolic role of alliinases could provide some insight into this question.

### IV. UTILITY OF THIS ENZYME IN FOODS

Alliinases are responsible for the initial reaction that produces characteristic flavors and aromas in vegetables of the genus *Allium*. The retention of full enzymatic flavor potential is the main challenge of food processors dealing with garlic and onion. To maintain this flavor potential, the retention of active alliinase and, especially, of the substrates must be considered during processing design and evaluation. Some pre- and postharvest practices are followed to increase the flavor potential of alliaceous foods; environmental fac-

tors affecting flavor intensity include sulfur content of soil, growing temperature, and water supply (8). In the case of onions, flavor potential increases with storage of the ripe bulb for a few months (10). In nature, as much as half of the S-1-propenyl-L-cysteine sulfoxide is bound as a peptide,  $\gamma$ -L-glutamyl-S-allyl-L-cysteine sulfoxide. It has been suggested that during storage, the substrate is released by the action of  $\gamma$ -glutamyl transferase.

During dehydration of onions, most of the flavor potential is lost because of the disappearance of the substrate rather than the enzyme. Thirty percent of the potential alliinase substrate is converted to cycloalliin during the initial dehydration stages (Fig. 2). Neither cycloalliin nor the S-alkyl-L-cysteines are substrates for alliinase. Reconstituted onion powder contains only a third of the onion aroma of fresh onion juice (10). Careful consideration of the drying speed is important during the design of the dehydration process to minimize substrate loss; a longer process usually results in better yields.

The action of alliin lyase may also result in the formation of unwanted pigments in alliaceous vegetables, such as pinking of onions and leek, and green pigment development in garlic (16). Although alliinase catalyzes the initial reaction and formation of thiopropanal-S-oxide (in the case of onion), the pigment formation depends on the carbonyl concentration and could vary from pink to red depending on the composition (Fig. 3).

Diallylthiosulfinate (allicin) is the antibacterial compound which has been used (as garlic extract) for thousands of years by many cultures (1). This and other medicinal properties attributed to garlic and onion are due to sulfurous compounds produced through enzymatic and nonenzymatic reactions following the reaction of alliinase on S-alk(en)yl-L-cysteine sulfoxides (10). Current research is focused on the specific compounds which give extracts from alliaceous plants their properties as antimicrobial, anticancer, anti-blood clotting, and hypoglycemic agents, as well as

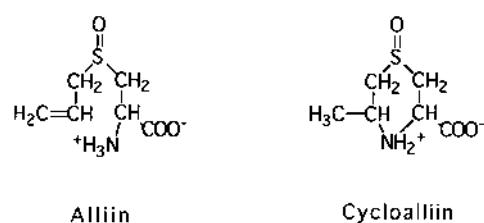

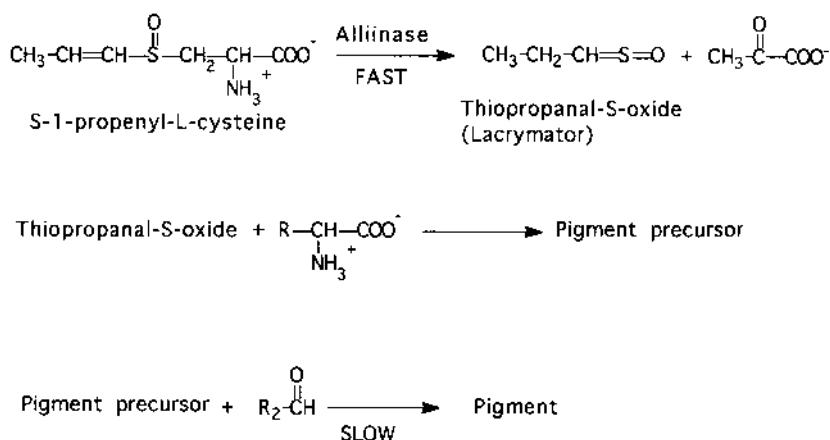

Figure 2 Structure of alliin and cycloalliin.

**Figure 3** Formation of pigments in onion.

heavy-metal poisoning antidote and reductor of serum cholesterol and serum triglycerides (17). Garlic extract pills claiming extraordinary health benefits are very popular in the “nutraceutical” industry. Most of these extracts, however, depending on the methods used for preparation, may or may not contain the desired *Allium* organosulfur compounds due to their instability (thermodynamic) and reactivity (kinetic) (9).

## V. PROPERTIES AS PROTEIN

Alliin lyases vary in molecular weight depending on the source of the enzyme. Reported values of alliinase molecular weight include 67 kDa for Chinese chive (2); 85 kDa for garlic (3); 150 kDa (5) and 59, 170, and 393 kDa for onion (6); 220 kDa for Welsh onion (7); and 386 and 580 kDa for leek (4).

The number of subunits of alliin lyase is different depending on the source, but a common characteristic among the alliin lyases is that all the subunits have approximately the same size. All reports, with the exception of Clark et al. (6), indicate that the individual proteins have subunits of the same molecular weight, showing only one band by SDS-PAGE. The number of subunits (and MW) reported to date are 1 (48 kDa) for Chinese chive (2); 2 (42 kDa) for garlic (3); 3 (50 kDa) (5) and 1, 3, and 6 or 7 (53.5 and 51.6 kDa) for onion (6); 4 (52 kDa) for Welsh onion (7); and 8 and 12 (48 kDa) for leek (4).

Pyridoxal-5'-phosphate (PALP) is a known cofactor of alliinase. The molar ratio of PALP to alliin lyase has been determined as one mole of PALP per subunit for Chinese chive, garlic, and onion (2, 3, 5). The

amino acid residue involved in the PALP binding site of the onion and Chinese chive alliinase has been identified as Lys285 (18) and Lys280 (2), respectively.

Information has been reported on the amino acid composition and primary structure of alliinase by several groups. In 1992, Van Damme et al. (19) reported the cDNA sequence for alliinase from garlic, onion, and shallot, and other groups have recently obtained deduced sequences for garlic (13) and Chinese chive (2) alliinases. Onion and shallot alliinases primary sequences have the highest degree of homology (98%); those from onion and garlic showed 88% similarity (19). Deduced amino acid sequence of alliinase from Chinese chive showed homologies with those from garlic (64.3%), onion (69.1%), and shallot (69.2%) (2) (Fig. 4). No information has been reported on the secondary or tertiary structure of alliinase.

Results using the Dubois method or by staining of PAGE by periodic acid-Schiff base reagent indicate that garlic (3), leek (4), onion (5, 6), and Welsh onion alliin lyases (7) are glycoproteins. Alliinase from garlic contains 6% natural sugars and can form a complex with garlic mannose-specific lectin, the second-most-abundant protein from garlic. Asn146 has been identified as the glycosylation site of garlic alliinase (20).

Importance of glycosylation of this enzyme is apparent through the study of the degree of homology of the alliinases from garlic, onion, and leek, and the  $\beta$ -cystathionase from spinach based on the cross-reactivity of rabbit polyclonal antibodies raised against the enzymes (21). Results showed that glycosylated garlic alliinase antibodies reacted not only with glycosylated and deglycosylated garlic enzyme, but also with the

**Figure 4** Comparison of deduced primary sequences of alliin lyase from Chinese chive (*Allium tuberosum*), garlic (*A. sativum*), onion (*A. cepa*), and shallot (*A. ascalonicum*). (From Ref. 2.)

native onion, leek, and spinach enzymes. Antibodies to the deglycosylated garlic enzyme reacted strongly with both native and deglycosylated garlic enzymes, less strongly with the native onion enzyme, and weakly, if at all, with native leek and spinach enzymes. Antibodies produced by deglycosylated onion enzyme reacted exclusively with native and deglycosylated onion enzyme.

## VI. PROPERTIES AS ENZYME

Although alliinases are able to catalyze reactions using many S-alk(en)yl-L-cysteine sulfoxides, the pool of sulfur amino acids is different depending on the *Allium* sp. It is presumed that this difference in accumulation of S-alk(en)yl-L-cysteine sulfoxides results in the different aromas and flavors of these group of plants. The predominant natural substrate in onion is S-(1-propenyl)-L-cysteine sulfoxide, but also present are other S-alkyl-L-cysteine sulfoxides. Garlic accumulates S-(2-propenyl)-L-cysteine sulfoxide predominantly, with presence of S-alkyl derivatives. Chinese chive contains all the S-alk(en)yl-L-cysteine sulfoxides previously mentioned (2), and in leek, methyl, allyl, and propyl derivatives have been identified (4).

The affinity for substrate, expressed as  $K_m$ , is typically determined for S-ethyl-L-cysteine sulfoxide; reported values are 2.7 mM for the alliinase from Chinese chive (2), 5.7 mM for garlic (3), 5.8 mM for Welsh onion (7), 6 mM for onion (5), and 13 mM for leek (4). Alliinase is inhibited by hydroxylamine, sodium cyanide, and amino-oxyacetate (2, 5), as expected for enzymes requiring PALP as a cofactor.

There has been no report on the temperature optimum for this enzyme; however, room temperature is universally used by the different research groups for activity assays. The pH optimum varies depending on the species and the buffer used, ranging from 6.5 (garlic) (3) to 8.5 (Chinese chive in Tris-HCl buffer) (2). The pH optimum of alliinase from Chinese chive changes to 6.5 in phosphate buffer; onion also shows a pH optimum of 7.6 in phosphate buffer and 8–8.5 in tricine buffer (5).

## VII. DETERMINATION OF ACTIVITY

The major substrate in garlic for alliin lyase is alliin (S-allyl-L-cysteine sulfoxide). Although the enzymatic activity could be determined by measuring any of the products of the reaction, most researchers measure the pyruvate production by a modification of the method

by Friedemann and Haugen (22) for keto acids. The pyruvate reacts with dinitrophenylhydrazine to produce pyruvyl hydrazone which absorbs at 450 nm. In general, S-ethyl-L-cysteine sulfoxide is used as the substrate to determine enzymatic activity. S-ethyl-L-cysteine is commercially available, and the sulfoxide can be synthesized by oxidation with  $H_2O_2$  as described (1).

Recently, a simple and rapid spectrophotometric method has been developed for determination of alliinase activity (23). It is based on the reaction of 2-nitro-5-thiobenzoate (NTB) with allicin (diallylthiosulfinate). The reaction is followed spectrophotometrically at 412 nm, measuring the consumption of NTB and the formation of S-allylmercapto-NTB. This method has the advantages of being direct, quantitative, and dependent on the initial velocity rather than the activity at fixed times. It requires the synthesis of NTB and alliin (S-allyl-L-cysteine sulfoxide). Both methods will be described in this chapter.

### A. Pyruvate Measurement by Dinitrophenylhydrazone Formation

#### 1. Enzymatic Reaction

The reaction mixture contains 40 mM S-ethyl-L-cysteine sulfoxide, 100 mM phosphate buffer, pH 6.5 (for garlic), 25  $\mu$ M PALP, and 50–500  $\mu$ g (protein) of enzyme in a total volume of 1 mL. Appropriate buffer adjusted to pH 8.0 (tricine, bicine) should be used when assaying alliinase from onion or leek. The mixture is incubated for 5–15 min (depending on enzyme concentration) at 23°C, and the reaction is stopped by the addition of 1 mL of 10% (612 mM) trichloroacetic acid (TCA). The precipitated protein is removed by centrifugation, and pyruvate is measured in the supernatant. A blank is prepared by adding 1 mL of 10% TCA solution to reaction mixture prior to enzyme addition.

#### 2. Pyruvate Determination

Supernatant (0.5 mL) from the enzyme reaction is added to a mixture containing 2.5 mL of 10% TCA solution and 1 mL of 0.1% (5.10 mM) dinitrophenylhydrazine (DNPH) in 2 M HCl. The mixture is incubated for 5 min at 30°C and stopped with the addition of 5 mL of 2.5 M NaOH. Absorbance at 450 nm is measured after 10 min. A standard curve is made with known concentrations of sodium pyruvate. A unit of activity corresponds to the production of 1  $\mu$ mol of pyruvate per min.

## B. Allicin Measurement Using 2-Nitro-5-Thiobenzoic Acid

### 1. Preparation of NTB

2-Mercaptoethanol (5 mL) is added to a solution of 5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB) (1.0 g in 50 mL of 0.5 M Tris-HCl buffer, pH 8.0). After 5 min the solution is acidified to pH 1.5 by the addition of 6 N HCl and kept overnight at 4°C. The orange crystals formed are filtered, washed with diluted HCl, and vacuum-dried over P<sub>2</sub>O<sub>5</sub>. NTB (dry powder) can be stored in the dark at room temperature for > 10 years. The yield is 57%.

### 2. Preparation of Alliin

It can be synthesized by oxidation of S-allyl-L cysteine with H<sub>2</sub>O<sub>2</sub> as described (1).

### 3. Enzymatic Reaction

The reaction mixture contains 0.1 mM NTB, 50 mM phosphate buffer, pH 6.5, 1 mM EDTA, 20 μM PALP, 10 mM alliin, and 0.0025–0.01 units of enzyme in a total volume of 1 mL. Reaction is started by the addition of alliin, and the initial velocity is recorded by the decrease in absorbance at 412 nm. The concentration of NTB consumed in the reaction is calculated using the molar extinction coefficient ( $\epsilon = 14,150 \text{ M}^{-1} \text{ cm}^{-1}$ ). A unit of activity corresponds to the production of 1 μmol of pyruvate per min (1 mol of NTB is equivalent to 0.5 mol of allicin and thus 1 mol of pyruvate).

## VIII. PURIFICATION

Alliinases have been purified from Chinese chive, garlic, leek, onion, and Welsh onion. The steps used for the purification vary depending on the plant source and research groups. There are certain common operations in most protocols such as ammonium sulfate precipitation and size exclusion and cation exchange chromatographies. The fact that alliinase is a glycoprotein is used by some researchers to purify the enzyme using a Concanavalin A-Sepharose column. The addition of PALP and glycerol in buffers is recommended to help stabilize the enzyme during purification. Table 1 illustrates the steps used by different groups to purify alliinase from different plant materials.

In this chapter we will describe the conditions used for the purification of alliin lyase from garlic cloves (3). Peeled garlic cloves are blended with buffer A (0.02 M Na phosphate/10% glycerol/5% NaCl, 0.05% 2-mercaptoethanol/1 mM phenylmethylsulfonyl fluoride (PMSF), pH 7.0), 1:1 (w/v) and 5% insoluble polyvinylpolypyrrolidone (PVPP) for 1 min, and the homogenate is filtered through two layers of cheesecloth. The homogenate is centrifuged and the supernatant is decanted and saturated to 35% with (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> with constant stirring for 30 min, followed by centrifugation. The precipitate is redissolved in a minimal amount of buffer B (0.05 M Na phosphate/10% glycerol/20 μM PALP/1 mM PMSF, pH 7.0), and the suspension is dialyzed against the same buffer. The solution is clarified by centrifugation to remove insoluble materials.

The enzyme solution is fractionated through a fast-flow hydroxyapatite column and the active enzyme is

## Cystine Lyases in Plants

**Edna C. Ramírez**

*University of California, Davis, Davis, California, U.S.A.*

### I. INTRODUCTION

Cystine lyases (cystathionine L-homocysteine-lyase; EC 4.4.1.8) cleave L-cystine through a  $\beta$ -elimination reaction producing thiocysteine (cysteine persulfide), pyruvate, and ammonia (Fig. 1). Although this enzyme has been studied in detail, its substrate specificity remains controversial. In fungi and bacteria, cystine lyase and  $\beta$ -cystathionase activities are found together. In plants, however, cystine lyase does not recognize  $\beta$ -cystathionine as a substrate.

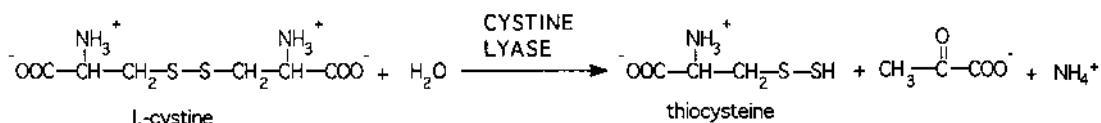

Cystine lyase activity was first detected in plants in 1966 by Tishel and Mazelis (1). They observed the ability of homogenates of cabbage leaves to degrade L-cystine, but not L-cystathionine, to pyruvate. The requirement for pyridoxal-5'phosphate (PALP) as a cofactor for this enzyme was also noted.

### II. IMPORTANCE TO QUALITY OF FOOD

Cystine lyases are responsible for the initial reaction that produces characteristic flavors and aromas in important vegetables of the genus *Brassica*.

Cruciferous vegetables (broccoli, Brussels sprouts, cabbage, cauliflower, etc.) have characteristic sulfurous flavors and aromas as a result of these enzymatic reactions following the maceration of tissue. In broccoli, cystine lyase was determined to be the principal enzyme responsible for the off-aroma deterioration (2). Purified cystine lyase added to blanched broccoli and presented to a panel reproduced the aroma descriptors characteristic of unblanched broccoli.

In 1993, Chin and Lindsay (3) identified the sulfur compounds formed in disrupted tissues of cabbage as methanethiol (MT), dimethyl disulfide (DMDS), and dimethyl trisulfide (DMTS). All of these compounds, although characteristic of *Brassica* vegetables, are undesirable to the consumer. This presents a problem, particularly in the use of modified atmospheres, where the unpleasant sulfurous odors limit consumer acceptance. The mechanisms of formation of these sulfur compounds in cabbage, following the activity of cystine (cystine sulfoxide) lyase, were elucidated (4). They found no significant difference in the formation of DMDS under aerobic and anaerobic conditions; however, DMTS was detected only in the absence of oxygen.

**Figure 1** Cystine lyase general reaction.

Several treatments have been used to reduce the amounts of these objectionable volatiles in broccoli stored under modified atmospheres, including dipping the vegetable in caraway (*Carum carvi*) seed extract, tertiary butylhydroquinone (TBHQ), ascorbic acid (500 ppm), phosphoric acid (0.1 M), and sodium hydroxide (0.01 M) (5). Although all these treatments reduced the sulfurous aroma intensity, the alkaline treatment had the highest effect on the intensity and on suppressing the formation of dimethyl disulfide. Obenland and Aung (6) found that the formation of DMDS and MT in intact broccoli florets could be enhanced 2.8 times over the control by the infiltration of S-methyl cysteine sulfoxide prior to anaerobiosis, and nearly eliminated by infiltration of hydroxylamine (a cystine lyase inhibitor).

### III. LOCATION

Location of cystine lyase in the cells has not been determined. In broccoli and cauliflower, the activity of cystine lyase in the florets is, on average, three to five times higher than in the stalks of the vegetables (Ramírez, personal observation).

### IV. UTILIZATION OF THIS ENZYME IN FOODS

The metabolic role of cystine lyase in plants has not been determined.  $\beta$ -Cystathionase is involved in the methionine cycle, cleaving L-cystathionine to produce homocysteine.

Currently, in the frozen food industry, peroxidase is the enzyme used as the indicator for proper blanching in most vegetables, including broccoli. Results from experiments on blanching broccoli in water showed that cystine lyase is less heat stable than peroxidase (7). The use of a proper indicator enzyme could lead to blanching optimization; cystine lyase would be the logical choice in the case of broccoli. The employment of this enzyme by the frozen food industry could potentially reduce blanching times and therefore decrease the detrimental changes associated with blanching (loss in texture, color, flavor, and nutritional quality), as well as conserve energy.

### V. PROPERTIES AS PROTEIN

Molecular weights of cystine lyases vary depending on the source of the enzyme. Reported values of cystine

lyase molecular weight include 150,000 (8), 400,000, and 440,000 (9) for turnip cystine lyase; 110,000 (10) and 152,000 (11) for the broccoli enzyme; and 150,000 and 240,000 (12) for cabbage cystine lyase.

The number of subunits of cystine lyase varies depending on the source, but a common characteristic among the cystine lyases is that all the subunits have approximately the same size. The number of subunits (and MW) reported to date are 2 (48,000) (10) and 3 subunits (49,000) for broccoli (11), and 12 subunits (34,000 and 38,000) for turnip (9).

Results from our laboratory (10) for subunit molecular weight agree with those reported by Hamamoto and Mazelis (11); the molecular weight of the complete holoenzyme found is, however, different and therefore also the conclusion on the number of subunits. We found evidence by three different techniques that the molecular weight of cystine lyase is 100,000 ( $\pm$ 10,000), and therefore the enzyme is a dimer. Supportive evidence that the enzyme has only two subunits comes from the results of the molar ratio of PALP to cystine lyase (2 moles of PALP/mol protein).

No information has been reported to date on the structure of cystine lyase, other than amino acid composition for broccoli (10, 11) and turnip root (9).

Results using the Dubois method indicate that broccoli (10, 11) and turnip root (9) cystine lyases are glycoproteins.

### VI. PROPERTIES AS ENZYME

The substrate specificity of cystine lyase in plants is controversial. In fungi and bacteria (*Neurospora*, *Saccharomyces*, *Paracoccus denitrificans*, *E. coli*, etc.),  $\beta$ -cystathionase activity has been found together with cystine lyase activity (13, 14). These enzymes show a higher specificity for L-cystathionine than for L-cystine. While some researchers propose that a single enzyme is responsible for both the cystine lyase and the  $\beta$ -cystathionase activities and according to this criterion it is reported as such by the Enzyme Commission (15), others have found that highly purified protein peaks from plants only have cystine lyase activity. The only exception in plants is the  $\beta$ -cystathionase in spinach (16). This enzyme used L-cystathionine, L-djenkolic acid, and L-cystine as substrates with a relative activity of 100:126:17, respectively, but not L-cystine or its alkyl sulfoxides. All other cystine lyases from plants purified to date show negligible activity toward L-cystathionine.

Cystine lyase activity was first detected in plants in 1966 by Tishel and Mazelis (1). The requirement of pyridoxal-5'-phosphate (PALP) as a cofactor for this enzyme was noted. A year later (17), other species of the *Brassica* genus were investigated for the presence of cystine lyase activity and partial purification of cystine lyase from rutabaga (*Brassica napobrassica*) was achieved. It was noted the enzyme required PALP for activity and the stimulation of activity by exogenous PALP was dependent on the species. While addition of PALP was essential for rutabaga lyase activity, activity was present in the case of turnip roots (*B. rapa*) and mustard leaves (*B. hirta*), but specific activity doubled in the presence of exogenous PALP. No difference in specific activity was found in the absence or presence of exogenous PALP for varieties of the *Brassica olearacea* species (cabbage, cauliflower, and kale). Table 1 summarizes the properties of cystine lyases purified from different plant sources.

## VII. DETERMINATION OF ACTIVITY

The true substrate in nature for cystine lyase has not been determined. L-Cystine is used as the substrate to determine enzymatic activity. Although the enzymatic activity could be determined by measuring any of the

products of the reaction (pyruvate, thiocysteine, and ammonia), most researchers measure the pyruvate production by a modification of the method of Friedemann and Haugen (21) for keto acids. The pyruvate reacts with dinitrophenylhydrazine to produce pyruvyl hydrazone which absorbs at 450 nm. Another method for measuring cystine lyase activity by pyruvate formation is the coupling of the reaction with lactate dehydrogenase.

The author chose to follow enzymatic activity during our purification by measuring thiocysteine by a modification of the method by Ellman (22) for sulphydryl groups. This method provides advantages over other methods. Activity can be measured fast in many samples, and the method relies on initial velocity rather than activity at fixed times; this is particularly important in this reaction since it has been reported by early investigations that the formation of pyruvate is not linear with time (17). Both methods will be described in this chapter.

<sup>a</sup>Ref. 1. <sup>b</sup>Ref. 17. <sup>c</sup>Ref. 8. <sup>d</sup>Ref. 19. <sup>e</sup>Ref. 20. <sup>f</sup>Ref. 11. <sup>g</sup>Ref. 9. <sup>h</sup>Ref 10.

b. *Cystine Solution.* 96 mg of L-cystine dissolved in 0.60 mL of 1.5 M NaOH and diluted to 10 mL with water (9.6 g/L, 40 mM). Cystine undergoes  $\beta$ -elimination in the presence of high concentrations of NaOH (23), so only the minimum amount of NaOH (2 moles of NaOH/mol of cystine) was used to solubilize it.

c. *PALP Solution.* 0.25 g/L (1.0 mM) of pyridoxal phosphate (PALP).

d. *TCA Solution.* 100 g/L (612 mM) of trichloroacetic acid (TCA).

e. *Sodium Pyruvate Standard Solution.* 0.11 g/L (1.0 mM) of sodium pyruvate.

f. *HCl Solution.* 167 mL/L (2.00 M) of concentrated hydrochloric acid.

g. *DNPH Solution.* 1.00 g/L (5.10 mM) of dinitrophenylhydrazine dissolved in 2.00 M HCl.

## 2. Procedure

a. *Enzymatic Reaction.* The reaction mixture contains 12 mM L-cystine, 150 mM bicine, 25  $\mu$ M PALP, and 10–300  $\mu$ g (protein) of sample in a total volume of 1 mL. The mixture is incubated for 5–10 min (depending on enzyme concentration) at 30°C, and the reaction is stopped by addition of 1 mL TCA solution. The precipitated protein is removed by centrifugation, and pyruvate is measured in the supernatant. A blank is prepared by adding 1 mL TCA solution to the reaction mixture prior to enzyme addition.

b. *Pyruvate Determination.* 2.5 mL of TCA solution and 1 mL DNPH solution are added to 0.5 mL of the supernatant from enzymatic reaction. Reaction is incubated for 5 min at 30°C and stopped with the addition of 5 mL NaOH. Absorbance at 450 nm is read after 10 min. Amount of pyruvate is determined using a standard curve (pyruvate range: 0–300 nmoles). A unit of activity corresponds to the production of 1  $\mu$ mol of pyruvate per min.

## B. Thiocysteine Measurement Using 5,5'-Dithiobis-(2-Nitrobenzoic Acid)

### 1. Reagents

a. *Borate Buffer.* 30.92 g/L of boric acid (0.500 M). pH adjusted to 8.4 with 2.5 M NaOH.

b. *Cystine Solution.* 96 mg L-cystine dissolved in 0.60 mL of 1.5 M NaOH and diluted to 10 mL with water (9.6 g/L, 40 mM).

c. *PALP Solution.* 0.25 g/L (1.0 mM) of pyridoxal phosphate (PALP).

d. *DTNB Solution.* 3.964 g/L of 5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB) (10.00 mM) in borate buffer. DTNB is insoluble in water and it is reduced by bicine or Tris buffers.

## 2. Procedure

The reaction mixture contains 12.00 mM L-cystine, 312.5 mM borate, 250.0  $\mu$ M DTNB, 25.00  $\mu$ M PALP, and 10–300  $\mu$ g (protein) of enzyme sample in a total volume of 1 mL. All reagents are mixed except for the enzyme and let stand for 2 or 3 min (while non-enzymatic reduction of DTNB takes place). Enzyme is added and mixed quickly, and the increase in absorbance at 412 nm is recorded for 60 sec (formation of colored aryl mercaptan). Blank is prepared by mixing all reagents except enzyme. The thiocysteine production is calculated using the molar extinction coefficient determined for these conditions ( $\epsilon = 8000 \text{ M}^{-1}\text{cm}^{-1}$ ). A unit of activity corresponds to the production of 1  $\mu$ mol of thiocysteine per min.

## VIII. PURIFICATION FROM BROCCOLI FLORETS

The steps used for the purification of cystine lyase vary depending on the plant sources and research groups. There are certain common operations in most protocols such as ammonium sulfate precipitation and anion exchange chromatography. The addition of PALP in all buffers is used universally to help stabilize the enzyme during purification. Table 2 illustrates the steps used by different groups to purify cystine lyase from different plant materials.

In this section we will describe the conditions used for the purification of cystine lyase from broccoli florets (10). Broccoli florets are blended with buffer (0.05 M phosphate/0.05 M citric acid/5% NaCl, pH 6.4), 1:1 (w/v) and 5% insoluble polyvinylpolypyrrolidone (PVPP) for 30 sec, and the homogenate is filtered through two layers of cheesecloth. The pH of the homogenate is adjusted to 4.0 by slow addition of HCl (6 N) with thorough stirring continued for 15 min at 25°C. The homogenate is centrifuged and the supernatant is decanted and saturated to 40% with  $(\text{NH}_4)_2\text{SO}_4$ , constantly stirring for 30 min, followed by centrifugation. Supernatant is then saturated to 60%  $(\text{NH}_4)_2\text{SO}_4$ , constantly stirring for 30 min and centrifuged. The precipitate is redissolved in a mini-

mal amount of buffer (0.02 M phosphate/20 μM PALP buffer, pH 6.4) and the suspension is dialyzed against the same buffer (Spectrapor membrane, MW cutoff 12,000–14,000). The solution is clarified by centrifugation and concentrated by ultrafiltration (Amicon microconcentrator, Diaflo PM10 membrane).

The enzyme solution is fractionated based on size through a Fractogel TSK HW 55(S) column with buffer (0.02 M phosphate/20 μM PALP/0.1 M NaCl/0.02% NaN<sub>3</sub> pH 6.4) using a peristaltic pump. Active fractions are pooled, concentrated, and dialyzed. The dialysate is applied to a LKB DEAE-Trisacryl M column connected to an FPLC system. The enzyme is eluted from the column with 0.02 M phosphate buffer, pH 6.4, using a linear NaCl gradient (0–1 M). Active fractions are pooled. Table 3 shows the quantitation of each step in purifying cystine lyase from broccoli.

Enzyme purification is monitored with activity determination by thiocysteine measurement using DTNB and protein quantification by biuret method (24). Temperature was controlled at 4°C and purity

of enzyme is assessed by native PAGE at two different pHs.

## Xylose (Glucose) Isomerase

**Onno Misset**

*DSM Patents & Trademarks, Delft, The Netherlands*

### I. INTRODUCTION

Xylose (glucose) isomerase (EC 5.3.1.5) is one of the “oldest” industrial enzymes. Since its introduction in the starch-processing industry in the mid-1960s, it has been the subject of extensive research involving its biochemical and enzymological properties. As a consequence, there exists an enormous amount of literature. Much of the information summarized here was taken from the recent (1995) review (with 188 literature references therein) by Bhosale et al. (1) and the one by Chen (2). Other sources for information include the Enzyme Handbook (much quantitative data from 23 references; 3) and the SWISS-PROT and TrEMBL databases that are publicly available on the INTERNET (<http://expasy.hcuge.ch>). These databases contain the most updated information on amino acid sequences as well as links and references to the Brookhaven Protein Data Bank for the three-dimensional structures.

### A. Chemical Reaction Catalyzed

Xylose isomerase catalyzes the reversible isomerization of monomeric keto sugars to their enol isomers. The natural substrate of this enzyme is D-xylose that is isomerized to D-xylulose. In the food industry, only the isomerization of D-glucose to D-fructose is of importance since this is the final step in the production of high-fructose corn syrups (HFCS; for the industrial application of glucose isomerase see Sec. II.B) (4–6).

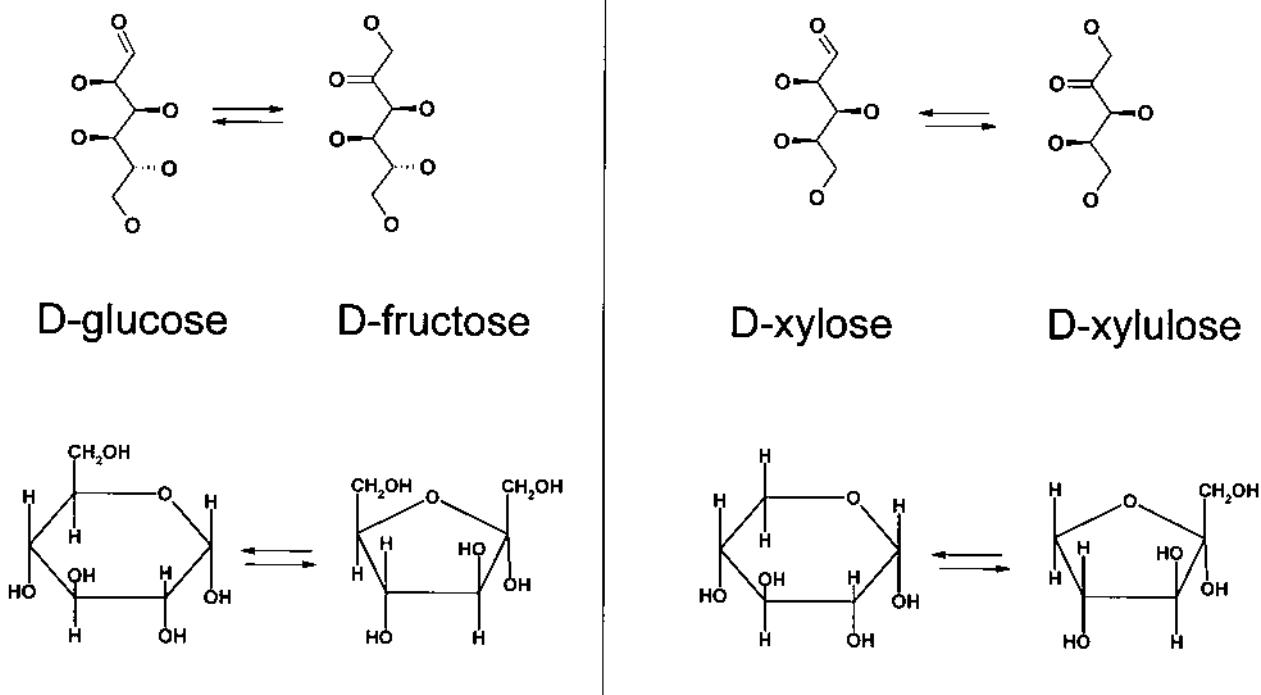

These HFCSSs are used as sweeteners in soft drinks and other food products. Therefore, the enzyme is usually referred to as glucose isomerase in both the industry and the scientific community. Other sugars that are substrates for this enzyme are L-arabinose, L-rhamnose, D-ribose, and others (1–6).

### B. Chemical Structure of Substrate

Figure 1 shows the open and closed configurations of D-xylose, D-xylulose, D-glucose, and D-fructose, respectively. In aqueous solution, glucose and fructose exist as an equilibrium mixture of several tautomeric structures as depicted in Table 1 (7, 8). The importance of the different configurations of substrates and products will be described in Section IV.C.

### C. Classification According to Enzyme Commission Nomenclature

Xylose isomerase is classified as EC 5.3.1.5. The enzyme belongs to the class of isomerases (group 5), catalyzing intramolecular redox reactions (subgroup 3), involving aldose and ketose substrates (sub-subgroup 1). The systematic name for the enzyme is D-xylose ketol-isomerase, and the recommended name is xylose isomerase. Nevertheless, since the usage of the name glucose isomerase is so common and widespread, it will be used preferentially in this review.

**Figure 1** Chemical structures of various sugars.

## II. IMPORTANCE TO QUALITY OF FOOD DURING GROWTH, MATURATION, STORAGE, AND PROCESSING

### A. Natural Occurrence of Glucose Isomerase

Glucose isomerase is a microbial enzyme and widely distributed in prokaryotes (1–3, 6). The majority of enzymes are located intracellularly. The glucose isomerases that are used in the industry are derived from only a few selected microorganisms (Table 2). These enzymes exhibit the best performance under application conditions. Because of the recent acquisitions that took place among manufacturers of industrial enzymes, the number of enzyme products has been reduced considerably.

### B. Production of High-Fructose Corn Syrups

High-fructose corn syrup is a mixture of glucose and fructose produced from cornstarch (4–6). HFCSSs find widespread use in the food industry. Their most important application is as a sweetener in soft drinks where they replace beet and/or cane sugar. They have the advantage that at an equal sweetener level (see Table 3), they are some 10–20% cheaper than sucrose and are

less caloric because of the lower resorption of fructose. A technical advantage of HFCS is the better solubility of glucose and fructose compared to sucrose and therefore the lesser tendency to crystallize in a wide range of food products. This has led to their application in confectionery, jam and jellies, ice cream, canned products, baking, pickles, sauces, meat products, etc. (5).

High-fructose corn syrups are produced in a process that comprises three consecutive enzymatic steps (Fig. 2). The raw material used in this process is starch, mainly derived from corn. Starch consists of two polymers of D-glucose: the linear amylose and the branched amylopectin (Fig. 3). In amylose and in the

<sup>a</sup>Genencor acquired the industrial enzyme activities of Gist-brocades in 1995 and that of Solvay in 1996. These acquisitions included the transfer of the (immobilized) glucose isomerase products Maxazyme GI (Gist-brocades) and Optisweet and Takasweet (Solvay). These enzyme products are no longer commercially available (personal communication, H. Messchendorp).

Source: Refs. 1, 3.

main chain of amylopectin, the glucose moieties are linked through  $\alpha$ -1,4-glycosidic bonds. The branches are made up of  $\alpha$ -1,6 linkages. The relative amounts of amylose and amylopectin in starch vary with the source of starch.

In the first enzymatic process step, the starch, produced by wet milling of the corn grains, is subjected to liquefaction by using a thermostable bacterial  $\alpha$ -amylase (EC 3.2.1.1) from *Bacillus* spp. such as *B. licheniformis* or *B. stearothermophilus* (see Fig. 2 for the process conditions). This enzyme cleaves the  $\alpha$ -1,4 linkages in an endo-fashion and produces a dextrin solution with a DE (dextrose equivalent) of  $\sim$  10 (starch has a DE of zero and glucose has a DE of 100 by definition).

In the subsequent step, glucoamylase (also named amyloglucosidase; EC 3.2.1.3) further hydrolyzes the dextrans in an exo-fashion, liberating single glucose moieties from the nonreducing end. Since glucoamylase displays a higher activity toward the  $\alpha$ -1,4-glycosidic bonds compared to the 1,6-branch points, in some processes a debranching enzyme (e.g., pullulanase—EC 3.2.1.41) is used as well. The resulting glucose solution has a DE of  $\sim$  95.

In the third enzymatic process step, glucose isomerase converts glucose into fructose until a concentration of 42% (molar fraction based on total sugars). This reaction is unique in that it is carried out in a column reactor using the enzyme in an immobilized form. As such, glucose isomerase was one of the first enzymes to

be used as immobilized biocatalyst on an industrial scale. Typical glucose isomerase processes operate with the enzyme encapsulated in 1- to 2-mm particles in a packed-bed column reactor (5). Columns can be 1.5 m in diameter and 4–5 m in height. Such a system would contain up to 4000 kg enzyme and would produce up to 500,000 kg fructose (dry weight) per day. High-glucose syrup (DE = 95) resulting from the previous glucoamylase reaction and which has been

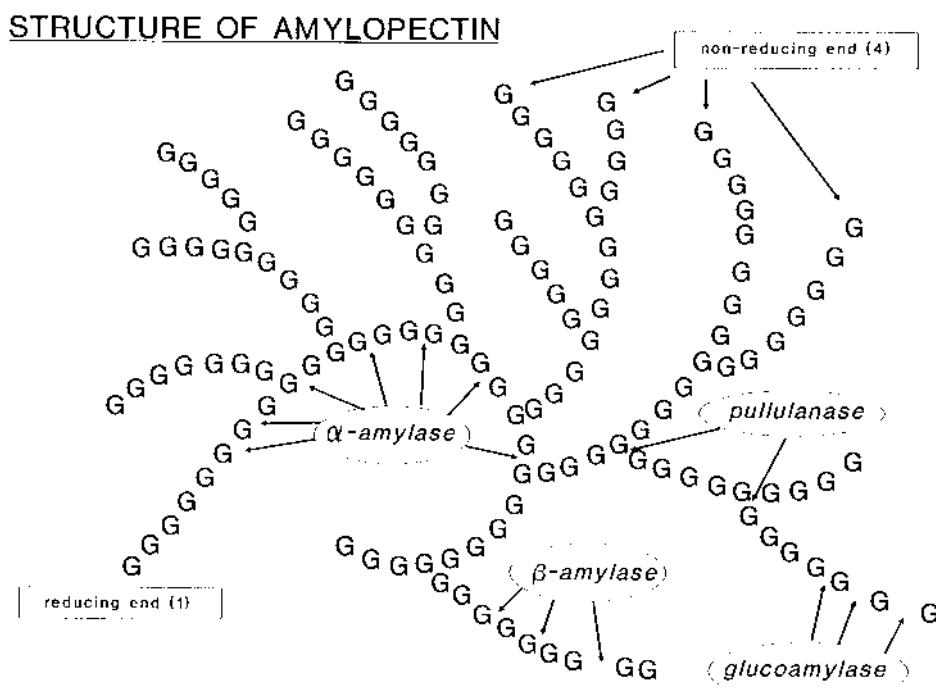

Figure 3 Schematic structure of the starch components amylose and amylopectin.

concentrated to 45% solids and adjusted to pH 7.5, is pumped continuously through the column. The flow rate and the temperature of the system are determined by several factors. The flow rate must be appropriate to give sufficient residence time to allow production of 42% fructose. Low flow rates increase the risk of microbial contamination, and too-high rates do not give enough conversion and cause channeling through the support material. Temperatures  $< 55\text{--}60^\circ\text{C}$  increase the viscosity of the syrup and increase the risk of microbial contamination. High temperatures reduce the stability of the enzyme and cause the formation of undesired byproducts through chemical reactions (i.e., Maillard reactions). In practice, temperatures  $\sim 55\text{--}60^\circ\text{C}$  are used.

The inactivation of the enzyme is compensated for by adjusting the flow rate of the glucose stream so as to maintain the desired conversion. Under the conditions mentioned, these processes can run for several weeks until the activity of the enzyme has become too low. After reaching that point, the columns are dismantled and repacked with a batch of fresh biocatalyst or, in the case of ion exchange columns, regenerated by washing off the enzyme and adsorbing a new batch.

The sugars present in the final HFCS comprise fructose (42%), glucose (54%), and oligosaccharides up to 4%.

### III. PROPERTIES AS PROTEIN

#### A. Molecular Weight

The XYLA genes in the various microorganisms code for a variety of glucose isomerase subunits that can roughly be divided into two groups based on the number of amino acids and derived molecular weights ([Table 4](#)).

Group I includes the enzymes from actinomycetes like *Actinoplanes*, *Streptomyces*, and the like, and can be regarded as “small” enzymes with an average of  $390 \pm 4$  amino acids. This corresponds to calculated subunit molecular weights ranging from 42,675 to 43,900 daltons. Group II includes the “large” enzymes from *Bacillus*, *Escherichia*, *Clostridium*, *Lactobacilli*, and others. The subunits of these enzymes have some  $442 \pm 7$  amino acids, resulting in calculated molecular weights ranging from 49,700 to 50,893 daltons.

Almost all glucose isomerases are tetramers, built up of four identical subunits as was concluded from experimental techniques and 3D structure determinations. Therefore, the native molecular weights are in the order of 170,000 and 200,000 daltons for the

group I and group II enzymes, respectively. Only the glucose isomerase from *Streptomyces olivochromogenus* was found to be a dimer (38).

Experimentally, the molecular weights can be determined under either non-dissociating or dissociating conditions. Subunit molecular weights are obtained under dissociating conditions using techniques such as polyacrylamide gel electrophoresis (PAGE) in the presence of the denaturant sodium dodecyl sulfate. Native molecular weights are obtained under non-dissociating conditions such as gel exclusion chromatography, sedimentation coefficients, or density gradient centrifugation. It was found that the experimental molecular weights for various glucose isomerases correspond reasonably well with the calculated values mentioned.

#### B. Primary, Secondary, Tertiary, and Quaternary Structures

The primary (amino acid) sequences of many xylose isomerases are known. [Figure 4](#) shows in total 28 aligned sequences for Group I and Group II glucose isomerases. [Table 5](#) shows that within groups I and II there exists a high amino acid sequence homology ( $> 50\%$ ) whereas the overall homology between the groups is low (25–30%). It will be explained later that amino acids involved in substrate and metal ion binding, as well as catalysis, are completely conserved. The  $\sim 50$  additional amino acids in the Group II glucose isomerases are located mainly at the N-terminus (Fig. 4).

The secondary and tertiary structures of glucose isomerases are known in great detail, because many 3D structures have been determined by x-ray crystallography. [Table 6](#) summarizes the 3D structures that are currently available in the public domain (Brookhaven Protein Databank). In the late 1980s and early '90s, several research groups focused on the structure elucidation of a few, mainly *Actinomycete*, glucose isomerases (12, 14, 15, 39–48). Only recently are structures from glucose isomerases originating from thermophilic bacteria becoming available (50). Today, some 60 different structural datasets are available in the Brookhaven Protein Databank, representing 11 different glucose isomerases. Per enzyme, multiple structures were determined under different experimental conditions, e.g., presence of ligands (substrates, substrate analogs, metal ions, etc.). In addition to 3D structures of the wild-type enzymes, various structures have also been determined of mutant enzymes that

The number of amino acids (# aa) and calculated subunit molecular weights were taken from the SWISS-PROT database.

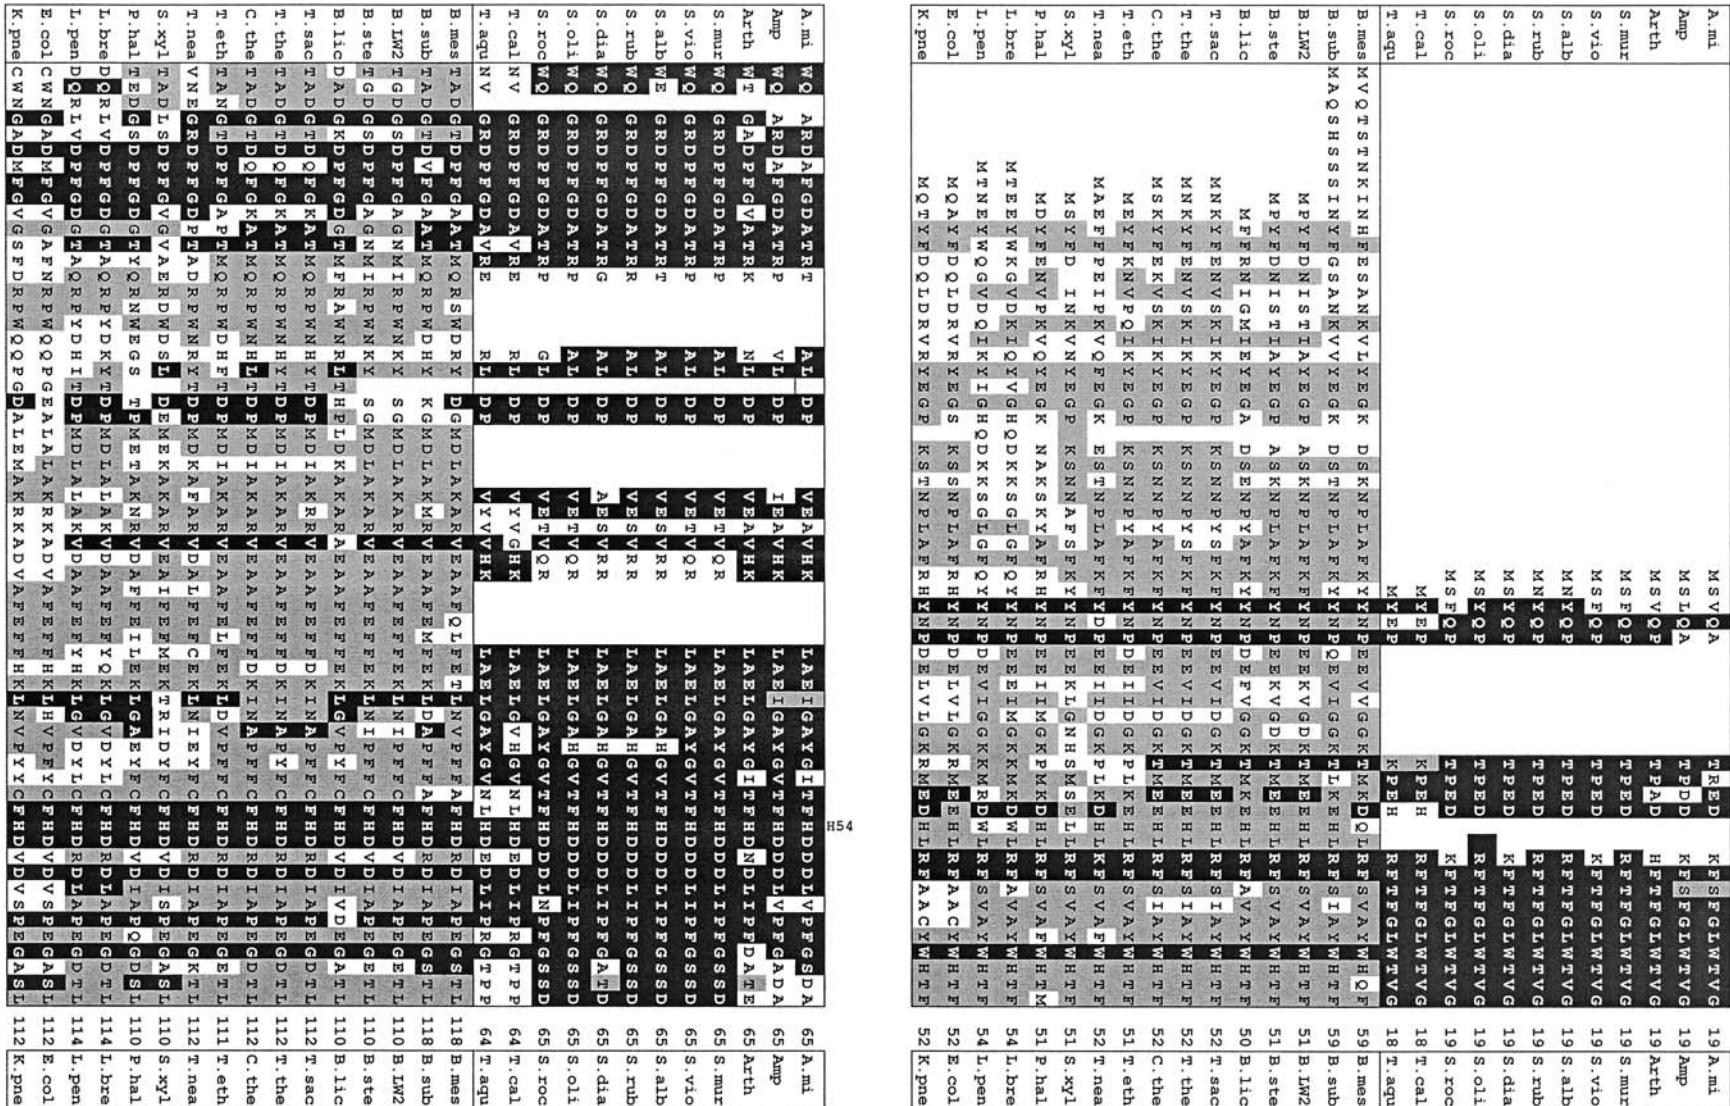

were considered for different purposes (e.g., stability improvement, role in mechanism).

The 3D structures of the different enzymes appear to be very similar which is also suggested by the high amino acid sequence homology. Figure 5 shows a schematic representation of the subunit structure of the *Actinoplanes missouriensis* enzyme. The monomeric subunit consists of two domains. The N-terminal domain is the catalytic domain and consists of an eight-stranded parallel  $\beta$ -barrel with eight connecting  $\alpha$ -helices also known as the TIM barrel, referring to the first enzyme (TIM = triose phosphate isomerase) in which this topology was found (51). The smaller, C-terminal domain only contains  $\alpha$ -helices and forms a looplike structure away from the larger N-terminal

domain. It overlaps (“embraces”) the larger N-terminal domain of an adjacent subunit so that a tightly bound dimer is formed. Two of these dimers form the tetramer which therefore can be regarded as a dimer of dimers (41). With the exception of the enzyme from *Actinoplanes missouriensis* where the dimer is inactive, all other dimers tested possess enzymatic activity. The monomers are enzymatically inactive.

### C. Isoforms

All the different microbial glucose isomerases known today are encoded by a single XylA gene per host organism (Table 4). This means that within one microorganism, no isoforms of the enzyme are found.

**Figure 4** Amino acid sequence alignment of group I and group II glucose isomerases. For abbreviations and references see Table 4. Group I and group II sequences were aligned as separate groups using the Multiple Alignment Tool from PIR at <http://www.ncbi.nlm.nih.gov/PIR/> which makes use of ClustalW. Subsequently, sequences 8–12 from group I and 13–18 from group II were aligned in order to establish the alignment between the two groups. Residues that are highly conserved in group I (and also found in group II) are indicated by white letters and a black background. Residues that are highly conserved in group II (and also found in group I) are indicated by black letters and a gray background.

**Table 4** Glucose Isomerase Amino Acid Sequence Entries in the PIR and SWISS-PROT Databases Available on the Web (<http://www-nbrf.georgetown.edu/pirww/pirhome.html> and <http://expacy.hcuge.ch>, respectively)

Since glucose isomerase seems to be exclusively found in prokaryotes, none of the enzymes are glycosylated as a result of a secretory pathway. In addition, no other forms of (chemical) posttranslational modification during biosynthesis has been reported. Since glucose isomerases are predominantly intracellular enzymes, no pre- or pro-enzyme intermediates exist in the biosynthetic pathway that require a proteolytic step for maturation. Also, no other proteolytic events have been reported as posttranslational modification.

In the presence of high concentrations of glucose the glucose isomerase from *Actinoplanes missouriensis* loses its tetrameric structure and dissociates into dimers and monomers which is accompanied by inactivation (Misset et al., unpublished data). It has been postulated that this inactivation, which also occurs during its industrial application, is caused by a process called glycation. Glucose from the substrate stream may then react with one or more lysine resi-

dues in the subunit interface. During this reaction, initially Schiff-base intermediates are formed that subsequently undergo rearrangement to Amadori products. Finally, dissociation of the subunits occurs (52–54).

Stabilization of this enzyme could be achieved by applying rational protein engineering. By site-directed mutagenesis of the *Actinoplanes missouriensis* enzyme, the lysines were mutated to arginine since this residue is much less sensitive to glycation. One of the mutants thus constructed, K253R (i.e., K = lysine at position 253 substituted with R = arginine), indeed showed an increased half-life under application conditions (52). In addition, the specific activity of the mutant enzyme was the same as that of the wild-type enzyme, and pH optimum was only slightly shifted. Researchers at Gist-brocades developed a new production process for the enzyme, and the new product was tested on an industrial scale (Misset et al., unpublished data). The stability increase found in laboratory application

**Figure 5** Schematic representation of the subunit structure of the *Actinoplanes missouriensis* enzyme.

tests was also found on industrial scale. Therefore, this mutant enzyme is a very good second-generation enzyme and a potential substitute for the original product.

Lysine at position 253 is well conserved in Group I glucose isomerases (see Fig. 4). Therefore, it is very likely that also these enzymes will undergo glycation in the presence of high glucose concentrations under the conditions employed during the industrial isomerization step. Consequently, the protein engineering solution found for the *A. missouriensis* enzyme can serve as a general solution (55). Glucose isomerase from *T. aquaticus* is the only group I enzyme in which nature has already substituted the lysine with an arginine (Fig. 4).

#### IV. PROPERTIES AS ENZYME

##### A. Substrate Specificity

Glucose isomerase catalyzes the reversible isomerization of monomeric keto sugars to their enol isomers. The natural substrate of this enzyme is D-xylose that is isomerized into D-xylulose. Other substrate/product combinations are: D-glucose/D-fructose, L-arabinose/L-ribulose, L-rhamnose/L-rhamnulose, D-ribose/D-ribulose, and others (2, 3).

The kinetic properties of the wild-type glucose isomerase from *Actinoplanes missouriensis* with xylose, glucose, and fructose were investigated (56–64). The results from Hosteaux (56) are summarized in Table 7. The data clearly show that the enzyme has a preference for xylose compared to glucose. The  $K_M$  values

for xylose are, independent of the metal ion used, almost 2 orders of magnitude smaller than those for glucose or fructose. This means that the apparent affinity for xylose is 2 orders of magnitude higher. Furthermore, the  $k_{cat}$  values with xylose are twofold to 10-fold higher than with glucose or fructose (depending on the metal ion).

Consequently, the specificity constant ( $k_{cat}/K_M$ ) for xylose is also much larger than for glucose. This means that in a solution containing equal concentrations of xylose and glucose, glucose isomerase will convert xylose at a much faster rate than glucose. Similar results were obtained for glucose isomerases from other sources (2, 3).

##### B. Effect of Environmental Factors

Under industrial conditions, glucose isomerase is used for several months at elevated temperatures (55–60°C) and at given pH. Therefore, the effects of the temperature and of the pH on both the activity and the stability of the enzyme are equally important parameters that determine the overall performance of the enzyme. The performance can be regarded as the product of the initial activity of the enzyme product times its stability as a function of time.

In general, the rate of an enzyme catalyzed reaction increases with temperature until a point where it starts to decrease again (temperature optimum). The reasons for this decrease may be twofold. First, the enzyme becomes so flexible at these temperatures that binding of the substrate (expressed by the  $K_M$ ) becomes weaker. Secondly, the enzyme becomes unstable and starts to denature at a rate comparable with the time scale of the reaction. Most glucose isomerases have their temperature optimum ~75–85°C (2, 3). Table 6 shows that the  $k_{cat}$  values of glucose isomerase from *Actinoplanes missouriensis* with the different sugars are much higher at 60°C than at 35°C. However, the  $K_M$  values also increase, which may counteract the effect on the  $k_{cat}$  in case the substrate concentration is below the  $K_M$  values.

The rate of an enzyme-catalyzed reaction depends also on the pH. This is caused by titratable groups present on the amino acid residues in the enzyme and in the substrate and product. In the case that these groups are involved in substrate/product binding or the catalytic event, the change in charge will affect the rate. On the other hand, the stability of the enzyme may be affected by the pH as well. The pH optimum for glucose isomerases varies from microorganism to microorganism but is in general between 7 and 9.

Source: Ref. 56.

Table 7 shows that for the enzyme of *Actinoplanes missouriensis* k<sub>cat</sub> increases when the pH increases from 5 to 7.5.

Since the pH dependence of the stability is more toward the acidic side and that for the activity more toward the alkaline side, the pH optimum for the industrial performance (= productivity) is somewhere between the optima for activity and stability (6).

Glucose isomerase has been the subject of extensive protein engineering studies. Not only has site-directed mutagenesis been used to determine the role of many amino acids in the mechanism of the reaction, but also it was used to increase the operational stability of the enzyme (52–55) and to modify the substrate specificity (60, 61) as well as the pH activity profile (62–64). Today, however, no mutant glucose isomerases are used in industrial processes.

### C. Specific Mechanism of Action

The currently accepted pathway for the isomerization reaction involves the preferential binding of the sugar in the closed configuration ( $\alpha$ -pyranose form for xylose and glucose and  $\alpha$ -furanose form for fructose), followed by ring opening, extension of the substrate, and then proton transfer on the substrate (65). Because glucose isomerase is a metalloenzyme and requires Mg<sup>2+</sup>, Mn<sup>2+</sup> or Co<sup>2+</sup> for its activity, in contrast to triose phosphate isomerase, which does not require metal ions for its activity and uses base catalysis to shuttle the proton between the C<sub>1</sub> and C<sub>2</sub> position of its linear substrate, it is now generally believed that glucose isomerase uses an alternative mechanism based on a 1,2-hydride shift as proposed by Farber et al. (15).

From the various 3D structures of the enzyme that were determined in the presence of metal ions and substrate, product, or their analogs, it has been concluded that there are two metal ion binding sites (15, 44). The role of these metal ions is to form a bridge between the enzyme and the sugar in the enzyme:substrate complex.

Metal site 1 is four-coordinated and tetrahedral in the absence of substrate and is six-coordinated and octahedral in its presence. Ligands are the carboxylates of Glu181, Glu217, Asp245, and Asp292 according to the *Actinoplanes missouriensis* numbering (59). Oxygen atoms O<sub>2</sub> and O<sub>4</sub> of the substrate bind to this metal ion 1. Metal site 2 is octahedral in all cases and is involved in the binding of oxygen atoms O<sub>1</sub> and O<sub>2</sub> of the substrate. Ligands are Glu217, Asp255, Asp257, and His220 (59).

**Figure 4** shows that the amino acid residues that are the ligands for both metal ions are highly conserved in all glucose isomerases known today. Table 8 sum-

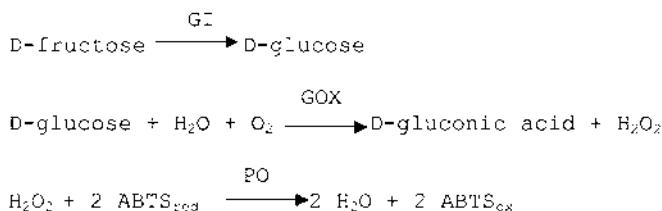

marizes the conserved amino acid residues that play a role in the kinetic mechanism.

## V. FACILITATION OF ACTIVITY DETERMINATIONS BY OTHER ENZYMES

The most convenient assay method for glucose isomerase is the one-step reaction using glucose or xylose as a substrate and sorbitol dehydrogenase and NADH in a coupled reaction (**Fig. 6**) (58, 67). The activity of xylose isomerase is measured at 35°C in a solution containing 0.028 M veronal-acetate buffer pH 7.0, 0.12 M NaCl, 10 mM MgCl<sub>2</sub>, 0.15 mM NADH, and 0.06–0.6 units of sorbitol dehydrogenase (SDH). Depending on the type of experiment, the sugar concentration can be varied (for *k*<sub>cat</sub> and *K*<sub>M</sub> determinations) or is fixed at, e.g., 50 mM (for specific activity measurements). The disappearance of NADH is measured spectrophotometrically

**Table 8** Role of Amino Acid Residues in Glucose Isomerases

No.	AA	Conserved in group I/II	Role	Ref.
54	His	yes/yes	Not essential for catalysis Involved in anomeric selection and stabilization of the acyclic transition state by hydrogen bonding to O5	66
94	Phe	yes/yes	Not essential for catalysis Stabilizes the acyclic extended transition state directly by hydrophobic interactions and/or indirectly by interactions with Trp137 and Phe26	66

183	Lys	yes/yes	Functions structurally by maintaining the position of Pro187 and Glu186 and catalytically by interacting with acyclic-extended sugars	66
217	Glu	yes/yes	Mutants have little or no activity; no ring opening occurs	59
220	His	yes/yes	Ligand for metal binding site 1 and 2	59
			Ligand for metal binding site 1	66
			Mutants have little or no activity no ring opening occurs	66
245	Asp	yes/yes	Ligand for metal binding site 1	59
253	Lys	no/no	Stabilization of dimer interface Subject to glycation	59
255	Asp	yes/yes	Ligand for metal binding site 2	59
257	Asp	yes/yes	Ligand for metal binding site 2	59
292	Asp	yes/yes	Ligand for metal binding site 1	59

**Figure 6** One-step assay for glucose isomerase using glucose or xylose as a substrate.

at 340 nm and quantified using an extinction coefficient of  $6220 \text{ M}^{-1} \text{ cm}^{-1}$ .

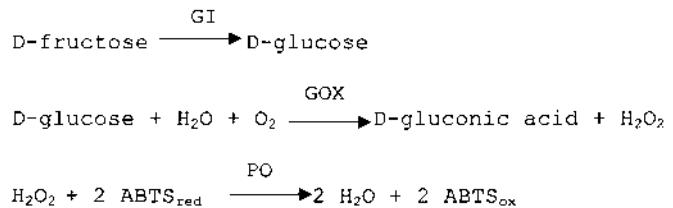

The thermostability of sorbitol dehydrogenase prohibits carrying out this assay at more elevated temperatures (e.g.,  $> 40^\circ\text{C}$ ). Under these conditions, the same assay is carried out in two separate steps: first the isomerization reaction at high temperature, then dilution with cold buffer and subsequent measurement of the product formed with sorbitol dehydrogenase and NADH.

For the assay with fructose as a substrate (the “reverse reaction”), a two-step assay has been developed (Fig. 7) (68). In the first step, glucose isomerase isomerizes fructose to glucose. In the second step, glucose oxidase oxidizes the glucose formed to gluconic acid with the formation of hydrogen peroxide, while in the same step peroxidase is reducing hydrogen peroxide and oxidizing ABTS (2,2'-azino-di(3-ethylbenzthiazoline)-6-sulphonate), which can be measured and quantified spectrophotometrically at 420 nm. The activity of xylose isomerase is measured at  $35^\circ\text{C}$  (or higher temperatures) in a solution containing 0.028 M veronal-acetate buffer, pH 7.0, 0.12 M NaCl, and 10 mM MgCl<sub>2</sub>. Depending on the type of experiment, the fructose concentration is varied for  $k_{\text{cat}}$  and  $K_M$  determinations or fixed at, e.g., 50 mM for specific activity measurements. The reaction is stopped by adding 50  $\mu\text{L}$  mixture to 1 mL of a GOX-PO-ABTS solution that contains per 1 mL 0.1 M acetate buffer, pH 5, 9.5 units GOX (Sigma), 1.5 units PO (Boehringer), and 0.5 mg ABTS. After 30 min incubation at  $35^\circ\text{C}$ , the absorbance is read at 420 nm and  $25^\circ\text{C}$ , and the concentration of glucose is calculated using an extinction coefficient of  $2220 \text{ M}^{-1} \text{ cm}^{-1}$ .

## VI. PURIFICATION

Many different purification methods have been developed and published in order to obtain pure glucose isomerase for crystallization. In general, the complexity of the purification method and the number of steps involved depend on the expression level of the enzyme. This means that for the purification of xylose isomerase from non-recombinant strains, more steps are required to obtain a homogeneous preparation than from over-expressing strains. The various procedures comprise established techniques such as selective precipitation and chromatography on hydrophobic, ion exchange, or gel filtration resins. In addition, elegant procedures involving affinity chromatography have been shown to be very powerful.

A successful one-step purification procedure has been developed for glucose isomerase of *Actinoplanes missouriensis* (69) using immobilized metal affinity chromatography with copper as the affinity agent. This copper complexes strongly with the surface histidines of the enzyme. Cell-free supernatants containing the enzyme were applied to a column packed with Chelating Sepharose Fast Flow (Pharmacia) that was saturated before with copper ions using a 10 mg/mL CuSO<sub>4</sub> solution. Elution of the bound enzyme was provoked by lowering the pH of the elution buffer (MMA=20 mM MOPS + 20 mM MES + 20 mM acetate) from 7 to 5. This change in pH protonates the histidines and destroys the interaction with the copper ions. The resulting pure enzyme still contains some scavenged copper ions that are removed in a “polishing” step involving anion exchange chromatography on Mono-Q.

Assay conditions

0.025 – 2 M D-fructose  
1–10 mM metal ions (Mg, Co, Mn)

GOX-PO-ABTS-mixture contains per 1 ml 0.1 M acetate buffer pH=5: 9.5 units GOX (Sigma), 1.5 units PO (Boehringer) and 0.5 mg ABTS.  
50 µL of the GI-assay solution + 1 mL GOX-PO-ABTS-mixture  
30 minutes incubation; read absorbance at 420 nm

**Figure 7** Two-step assay for glucose isomerase using fructose as a substrate.

## ACKNOWLEDGMENT

I would like to thank my colleague Dr. Jan-Metske van der Laan for critically reading the manuscript, helpful suggestions, and preparing [Figure 5](#).
